A vibrating ship can be conceptually characterized as a one-dimensional beam, representing the basic hull girder, with attached sprung substructures, distributed stiffness and damping, and acted upon by distributed excitation. This characterization is depicted in **Figure 1** below.

A good platform for presenting the basic knowledge of ship vibration is the linear but general solution of the **Figure 1** model for periodic excitation.

The periodic vibratory displacement distribution $w(x, t)$ can be written as a modal series. First, for general periodic excitation, $f(x, t)$ is the Fourier series:

$$f(x, t) = \sum_{m=1}^{\infty} F_m(x) \cos(m\omega t - \beta_m) \quad [1]$$

where ω is the fundamental frequency of the excitation and m denotes its m th harmonic, so that $m\omega$ is the m th harmonic frequency.

The vibratory displacement, $w(x, t)$, then has the general form:

$$w(x, t) = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} W_{nm}(x) \cos(m\omega t - \alpha_{nm} - \beta_m) \quad [2]$$

with the amplitudes and phase angles:

$$W_{nm}(x) = \frac{F_{nm}/K_n}{\sqrt{\left[1 - (m\omega/\omega_n)^2\right]^2 + \left[2\zeta_n(m\omega/\omega_n)^2\right]}} \psi_n(x) \quad [3]$$

$$\alpha_{nm} = \tan^{-1} \left[\frac{2\zeta_n}{1 - (m\omega/\omega_n)^2} \right] \quad [4]$$

In eqns [3] and [4], ω_n and $\psi_n(x)$ are the n th-mode natural frequency and mode shape representing the solution to the eigenvalue problem corresponding to the undamped, unexcited system.

F_{nm} is the n th-mode, m th-harmonic modal force:

$$F_{nm} = \int_{x=0}^L F_m(x) \psi_n(x) dx \quad [5]$$

with $F_m(x)$ from eqn [2].

The formulas [1]–[4] apply generally for any arbitrary mathematical model. The form of eqn [5], however, applies strictly to the beam model, **Figure 1**, by the integral over the beam length. More generally, the modal force is the dot-product of the excitation force vector and the mode shape vector, both of which can be multidimensional and either continuous or discrete functions of position. Any of the possible forms serve the illustrative purposes of interest here.

Likewise, in terms of the one-dimensional beam characteristics, the modal mass is:

$$M_n \equiv \int_{x=0}^L \mu(x) \psi_n^2(x) dx \quad [6]$$

where the extension to arbitrary model dimension is considered obvious. The modal stiffness appearing directly in eqn [3] is then by:

$$K_n = \omega_n^2 M_n \quad [7]$$

The additional requirement for the form of eqns [3] and [4] is that the damping distribution $v(x)$ indicated on **Figure 1** be proportional to either the distributions of model mass, $\mu(x)$, or stiffness, $EI(x)$; this assures that the implied orthogonality holds with the damping as well as with the mass and stiffness distributions. Then in eqns [3] and [4]:

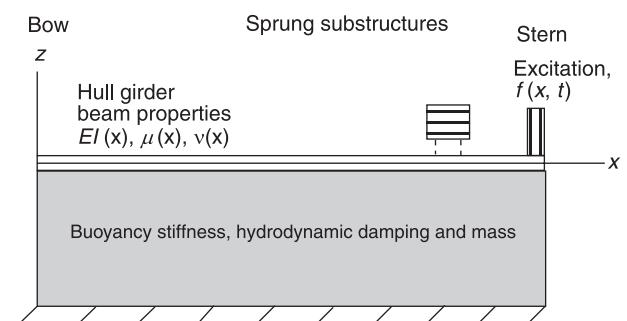

Figure 1 Ship vibration conceptual model: $EI(x)$, $\mu(x)$, $v(x)$, $f(x, t)$ distributed stiffness, mass, damping, and excitation in $x = 0 - L$.

$$\zeta_n \equiv \frac{v_n}{2M_n\omega_n} \text{ with } v_n = C_{1n}K_n + C_{2n}M_n \quad [8]$$

with C_{1n} and C_{2n} being the required constants of proportionality, which can vary with modal order.

The form of eqns [3]–[8] is very useful for discussing, sorting out, and understanding the peculiarities of any periodic vibration, but specifically ship vibration here. The vibration displacement distribution, no matter how complex, if linear, is theoretically expressible in terms of the responses of an infinite set of single mass oscillators, by eqns [2]–[4]. The amplitudes of the oscillators are just the amplitudes of the natural mode shapes, which superimpose to produce the complete displacement distribution. Thus, the key to understanding and treating almost any vibration is the one-degree-of-freedom oscillator. All possibilities for solving or preventing a vibration problem are readily discerned from the above simple formulation. These possibilities are, in the usual order of effectiveness in dealing with ships:

1. Reduce modal excitation force amplitudes, F_{nm} , in modes where the excitation harmonic frequency is in the vicinity of the modal natural frequency. This reduces $w(x, t)$ by reducing the numerator of [3]. F_{nm} can be reduced by either reducing F_m in eqn [1] directly, or by mismatching with the modes shape distributions to result in cancellation in the integral [5]. The degree of excitability of a mode is judged by the degree to which the mode shape mismatches the force distribution in this way. Direct reduction of F_m is usually the more fruitful approach to reducing excitation, which is addressed further along.
2. Avoid resonant vibration, $\omega_n = m\omega$, in modes where F_{nm} is significant. With $\omega_n/m\omega$ in eqn [3] near unity, large amplitude in a mode with nonzero F_{nm} is opposed only by damping, which is typically quite light in structural systems. The usual approach to avoiding resonance in a mode is by changing K_n , by eqn [7]. Change in the fundamental frequency, ω , usually by change of an RPM, is also sometimes possible. If resonance is to be avoided by altering stiffness, K_n should be increased, vs decreased, because of the associated reduction to be achieved in the numerator of eqn [3].
3. Increase damping. ζ_n in eqn [3] is typically small for metal structural systems, and can be influential only very near resonances where the first term in the denominator of eqn [3] is even smaller. But if resonances can be correctly avoided, damping is a relatively noninfluential factor in the equation (which contradicts the anecdotal knowledge of most laymen on the subject). The damping con-

tribution is also one that is hard to change much in design or postdesign corrective efforts.

4. Exploit modal cancellations. The considerations cited to this point have addressed the components of eqn [3] from a term-by-term perspective. In the lower region of the natural frequency spectrum of a complex structure such as a ship, the ω_n s are well spread apart. In this region, with small damping, the modal series, eqn [2], will be dominated by the mode with natural frequency closest to the exciting frequency. In this case, judgments can often be made on the basis of simple one-degree-of-freedom considerations by eqns [3] and [4]. On the other hand, in the higher modal spectrum of complex structures, tightly clustered modes, with small differences in natural frequency, can be encountered. Here, multiple terms participate to the same order in the modal expansion, at the harmonic exciting frequency $m\omega$ in their midst. But in view of the phase (eqn [4]) of the series terms in eqn [2], those significant modes above the exciting frequency will be out-of-phase with those below. This results in cancellation of the terms and a net vibration potentially less than that of any of the single contributing modal components. This is particularly true at locations in the system removed from the immediate region of application of the system excitation. Mode cancellation always occurs to some degree in all but very simple multi-degree-of-freedom systems, but is difficult to exploit in structural design or vibration problem rectification.

The background is now complete to review some of the more important facts and characteristics that distinguish the technology of ship vibration as a unique discipline.

Ship Vibration Excitation

Ship vibration excitation can and does occur via a myriad of sources. This includes sea waves. Sea waves excite the ship primarily at relatively low frequency, well below its flexural natural frequencies, but often in the vicinity of its rigid-body modes; these lowest natural modes correspond to the mode shapes of heave and pitch in the vertical plane. Ship vibration excitation by sea waves, which would also include transient slamming vibration involving the lower flexural modes, is probably the naval architects' most important problem, as it establishes the structural integrity of a vessel design. However, as addressed under General Background, this aspect is normally categorized as 'seakeeping', which falls outside of the traditional definition of 'ship vibration'. In the traditional view, ship vibration is flexural vibration

occurring at frequencies well above normal sea-wave encounter frequencies.

Ship vibration, in the more traditional sense, is excited, for example, by internal rotating machinery, such as pumps, compressors, engines, etc. But generally, little exists that distinguishes those shipboard applications from their land-based equivalents. In these cases the vibration is typically caused by rotating mass unbalance, for which diagnosis, treatment, and control is well established. The installation of large rotating units, such as main propulsion diesel engines, is, however, made more problematic by the fact that the shipboard mounting base is inherently less stiff than available with land-based power plants. The typical 6-cylinder low-speed marine diesel engine produces a vertical moment at twice engine RPM which can lie in the vicinity of the lower hull girder flexural natural frequencies. This potential vibration problem is usually avoided or treated by harmonic balancers installed by the engine manufacturer on the engine crank to reduce the exciting moments.

The primary distinguishing feature of ship vibration, and the aspect that makes it indeed unique, is propeller excitation. It is fact that in the majority of serious ship vibration problems, (over 80 percent), the vibration has been propeller excited. This is indeed a case of the ‘tail wagging the dog’.

The fundamental exciting frequency, ω , of a propeller with N identical, symmetrically spaced blades, rotating with specified RPM, is:

$$\omega = N \times \text{RPM} \left(\frac{2\pi}{60} \right) \quad [9]$$

This fundamental is called ‘blade rate’ frequency. The assumption is that the propeller and shafting system are dynamically mass-balanced. Otherwise, the fundamental frequency will be ‘shaft rate’. In that case the full spectrum will be composed of all multiples of the shaft RPM fundamental. But only those higher multiples corresponding to blade rate and its harmonics will be significant.

Shaft-rate vibration problems are not the usual, and are more straightforward to understand and resolve than those of propeller blade rate origin. Propeller blade rate excitation is hydrodynamically-based and involves complexities that are strictly unique to ships. For these reasons the focus here will be on the blade rate excitation components and consequences. The propeller excitation frequency spectrum of the Fourier series [1] is then established as $m\omega; m = 1, 2, 3, \dots$, with ω by [9].

The form of [1] is specifically for a one-dimensional, one component force distribution acting at the

stern-end of the ship hull beam, where the propeller is located. This is of course again an idealization to support conceptual understanding. The excitation is in reality a fully distributed unsteady vector composed of point force components acting in the propeller hub and a pressure distribution over hull surfaces in close proximity. The modal force, [5], would, in general, be the integral of the dot-product of the force and mode shape vectors over the affected stern regions of the hull, as might be conceived in a comprehensive numerical ship vibration model.

Ship Hull Wake Considerations

The forward moving hull of the ship leaves a rotational wake behind it. This wake manifests to the propeller as a ‘circumferentially non-uniform’ velocity distribution at radii within the propeller blade tip circle (‘propeller disc’). It is safe to say that if this wake inflow to the propeller was not circumferentially non-uniform, then propeller blade rate vibration of ships would not be, or would never have been, a problem.

It would appear to be physically clear that, if ships had perfectly uniform wakes, there would be no unsteady forces developed on the rotating propeller blades, and therefore no vibration excitation transmitted to the shafting system and hull directly from the propeller. This direct force, actually composed of both three-component force and moment vectors in the hub of the propeller, is called the ‘propeller bearing’ force.

The other component of the propeller excitation force system is called the ‘hull surface’ force, as produced by the rotating propeller blades sweeping by the hull surfaces bounding the ‘stern aperture’. It is intuitively obvious that the bearing force set would be zero for a perfectly uniform wake inflow. It is not so intuitively obvious, yet true, that the hull surface force would be negligibly small and inconsequential as an exciter of ship vibration for circumferentially uniform propeller inflow. Simple fanning action of the hull by the propeller blades is not of consequence.

Locating the ship propeller in the nonuniform flow behind the ship, rather than in uniform flow in front, is superior in all respects but one. The efficiency of the propeller in the reduced average wake velocity is higher than in the higher inflow corresponding to vessel speed; the propeller can be tucked into the aperture under the stern-counter for protection; the propeller is not as subject to cyclic immersion due to vessel pitch in a seaway, as the point of rotation in pitch is near the stern, etc. Vibration does not get highest priority on the list of critical performance criteria, particularly for commercial ships, so propellers

are placed at the ship stern in the non-uniform wake of the hull.

The entire propeller blade-rate ship vibration problem is due to the circumferentially nonuniform wake in producing periodically fluctuating pressure on the propeller blades as they rotate. At set angular velocity, the velocity of the rotating blades is highest in the blade tips. Consequently, by Bernoulli's equation, the pressure is lowest there. The pressure on the blade back (forward side) is lower than on the blade face (after side). This pressure difference across the cambered blade is by design and its mean is necessary for the production of propulsive thrust. But as the blades rotate through the nonuniform wake, fluctuations in blade pressure occur with blade position. With the steadily rotating propeller, the blade back pressure is lowest as the blades traverse the high wake (low velocity) regions of the wake field, and fluctuates periodically on each blade with each propeller revolution. For typical commercial ships, the high wake regions are at the top and bottom of the propeller disc. The fluctuating blade pressure distributions integrate and sum to produce the six propeller bearing force components, all at blade rate frequency and its harmonics [1]. The blade rate (fundamental) component of 'alternating thrust' was responsible, along with resonant conditions, for a number of serious main propulsion machinery longitudinal vibration problems as the power of steam turbine plants began to increase in the 1950s and 1960s. However, it was in the 1970s that the upward evolution of ship size, speed, and power exploded propeller-induced vibration with new ships to critical levels. This was initially not very well understood technically by the international naval architecture community.

Propeller Blade Cavitation

In the mid-1970s the European model basins, in Holland and Scandinavia primarily, achieved the revelation that unsteady propeller blade, intermittent cavitation, triggered by wake nonuniformity, was the main culprit in all ship vibration trouble.

Cavitation is essentially the vaporization of water on the propeller blades due to low pressure; it is equivalent to boiling, but from low pressure rather than high temperature. As the blade backpressure drops into the vicinity of water vapor pressure (less than 1 psia), the water locally in contact with the blade backflushes to steam. Some cavitation in the blade tip regions is usually unavoidable with ship propellers and is not particularly deleterious to propulsive performance. However, its intermittency of growth and unstable collapse on the blade backs as the blades rotate through the high wake gradients can

radiate very large pressure into the field (Figure 2). There is no dramatic effect on the propeller bearing forces, as the blades still lift effectively with the low pressure vapor on their backs, but the hull surface forces can be amplified by an order of magnitude over the noncavitating level.

The excitation series, (eqn [1]), also converges much more slowly with the involvement of intermittent cavitation. Twice and three-times blade rate frequency is clearly seen in vibration records. As a result, cavitation-induced vibration can be accompanied by extreme noise in the afterspaces of a ship.

Great strides were made in the 1970s in solving the problem of high-powered ship vibration. There was a concerted effort worldwide by laboratories, universities, shipbuilders, classification societies, owners, and others in developing the technology for controlling propeller-induced ship vibration, largely by control of propeller unsteady cavitation.

It should be stated here that the above pertains to commercial ships and perhaps some naval auxiliaries. With combatants, the problem is different. The propulsion system design is driven by quietness. Propeller cavitation is still the driver, but the measures taken to

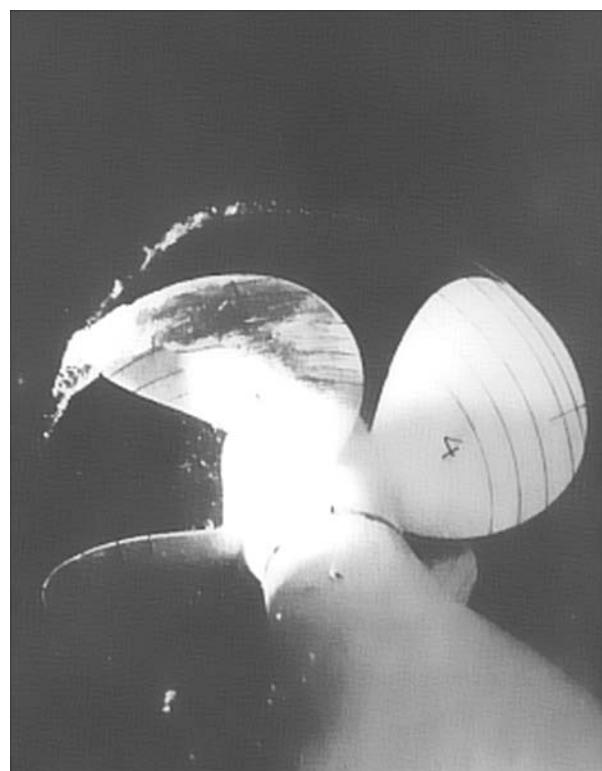

Figure 2 Propeller blade unsteady cavitation. Reprinted from *Principles of Naval Architecture* (1988), vol. 3, with the permission of the Society of Naval Architects and Marine Engineers, 601 Pavonia Ave, Jersey City, NJ 07306, USA.

achieve low noise signature, still mainly wake-smoothing, results in vessels that do not have vibration problems in the sense addressed here. For smaller, high-speed vessels, propeller-induced vibration is also not problematic as a rule. Here, wakes are naturally more uniform both because of the relative thinness of the hull viscous boundary layer, and the fact that this wake defect is swept laterally away from the propeller by the sloping sides of the typical V-shaped planing hull. Furthermore, high-speed propeller blades cavitate, or ‘ventilate’, more continuously around the full revolution cycle and therefore do not tend to exhibit the violent intermittency of cavity growth and collapse with in the revolution.

Propeller Blade Tip Clearance

As a final consideration with regard to propeller excitation, a great deal has been made over the years of maintaining minimum clearance between the propeller blade tips and the hull surfaces in proximity; vertical clearance of 20% of the propeller diameter is the general rule. This is also a wake-uniformity issue. The closer the blade tips to the hull surface overhead, the higher the wake gradient that the blade tips traverse. Again, unsteady blade pressure variations are the principal issue. Hull surface pressure due to diffraction of the propeller flow is a very weakly varying function of the separation distance, and not sensitive to tip clearance. Diffraction is a near-field hydrodynamics process and does not vary as the inverse of clearance, as is the case with far-field distances.

The fact that the hull wake in-flow to the propeller is the most important aspect of the problem and not the propeller itself has exacerbated the difficulty in dealing satisfactorily with propeller-induced ship vibration. The wake character is dictated by the hull lines, and the hull lines are probably the most difficult feature of the ship to alter significantly when, all too often, vibration problems have been discovered post-construction.

Resonance Effects

The attention to this point has been on the numerator of eqn [3]. We now turn to the denominator.

The full power shaft RPM of ships varies between about 80 and 150, depending on size, speed, and installed power. Propeller blade number N is almost universally either 4 or 5. This places the fundamental exciting frequency between approximately 5⁺ and 12⁺Hz. Even the lower of these two limits generally lies above the frequency at which the ship hull responds as a beam; beam response, vertically, is

considered to occur up to about the fifth flexural mode, which will typically lie in the range just below 5 Hz. Even in the lower flexural modes below about the fifth mode, where the ship may behave more or less one-dimensionally as a beam, the buoyancy spring implied on the Figure 1 conceptual model is irrelevant; the beam vibrates in any of the flexural modes as free-free, statically unsupported, effectively. At the frequency level of any of the flexural beam modes, the water-added mass is significant, but is simplified physically by the fact that the flexural natural frequencies are all above the level of gravity wave generation and their outward radiation at the water surface. The water surface acts as a simple relief surface of zero transverse velocity.

As the modal order goes up, the mode shapes become increasingly more complex; one additional node is, in fact, added somewhere in the vibrating system for each successively higher mode. Above the fourth or fifth system mode, substructures have broken away from the hull girder, and are vibrating in a coupled response to the hull girder base excitation. It is at this point that modal clusters begin to develop, accompanied by mode cancellation, as discussed in the general background section, above. For a high-order mode with many nodes, adding an additional node is associated with smaller and smaller changes in the corresponding added natural frequency as the modal order advances. Because of this, resonance, where $m\omega/\omega_n = 1$ and the denominator of the n th modal component amplitude in eqn [3] is minimum, loses some significance. All the modes in the cluster are contributing at $m\omega$, leading to the canceling contributions described above. Although the formulas [1]–[8] should still hold, the hull structural system vibration response has become exceedingly complex in the range of full-power blade rate frequency and its multiples.

Damping

Damping of ship vibration, represented by ζ_n in eqn [3], is the least physically understood of the principal system parameters of mass, stiffness, damping, and excitation. In eqn [8], v_n is a small quantity composed of a myriad of even smaller components that are not rationally quantifiable. Furthermore, the modal mass for ships is very large relative to the scale of v_n . So, in eqn [8], ζ_n is viewed to be generally on the order of 1–2%. But v_n is still a large number, involving small dissipative effects integrating over large regions. Useful percentage changes in v_n would therefore be very difficult to achieve with a mind toward incorporating increased damping to prevent or eliminate ship vibration trouble.

There is some evidence that damping increases with modal order, via C_{1n} and C_{2n} in eqn [8]. This being the case, the size of the cluster-set participating in the sum at eqn [2] is then expanded because of the reduction in the amplitudes of the modes closest to the resonance, by eqn [3]. The result is even stronger mode cancellation.

Summary

The main consequence of the damping uncertainty and the mode cancellation effects that prevail in blade rate frequency excitation of ships is in the unreliable predictability of ship vibration response. Mode cancellation prediction is particularly prone to inaccuracy. It is the often encountered problem that maintaining accuracy in the net sums of large distributions of different signs (eqn [2]) requires much higher accuracy in predicting the distributions themselves.

A serious vibration problem is a 0.2–0.3 mm displacement amplitude at a blade rate frequency of, say, 10 Hz. The experience of the 1970s showed that, even with the most detailed structural dynamic math-models, this amplitude could not be predicted reliably within order of magnitude accuracy, and predictions of its distribution throughout the vessel were typically even worse. It could not be predicted to a useful level of accuracy for support of engineering/design judgments of either design adequacy or resolution alternatives.

The technology that proved effective with the prevailing problem settled as one that focused on minimizing the numerator of eqn [3], and not trying to maximize the denominator. The minimization was purely hydrodynamic, in assessing, through both experimental and analytical/numerical analysis, the technology necessary to minimize the propeller blade rate excitation force harmonic spectrum, F_m , in eqn [1].

The technology that emerged was measurement of pressure on modeled overhead surfaces in the large cavitation tunnels of the world, supported by hydrodynamic computations. Criteria was established for judging when the pressure levels predicted likely implied a ship vibration problem, or not.

With the lull in new ship design and construction worldwide, the ship vibration front was relatively quiet in 1990s. But with the need for new, more advanced ships approaching, the problem will be back. The ship design/shipbuilding community will be much better-equipped with understanding and technology for dealing with the problem the next time around than they were the last.

Nomenclature

C_{1n}, C_{2n}	constants of proportionality
$EI(x)$	stiffness
F	force
$w(x, t)$	vibratory displacement
$v(x)$	damping distribution
$\mu(x)$	model mass
ζ	damping
ω	frequency

doi:10.1006/rwvb.2001.0171

This article covers mechanical shocks as they apply in product protection within a packaging system. Please refer to **Vibration Transmission** for more details on

packaging design and testing. All products in distribution receive impacts, and most products are not designed to sustain the rigors of the distribution environment. Packaging is used to mitigate these impact forces and avoid damage. In Figure 1, notice that the use environment has a lower stress level than the transport environment. In other words, it is much more likely that a product, e.g., a television set, will

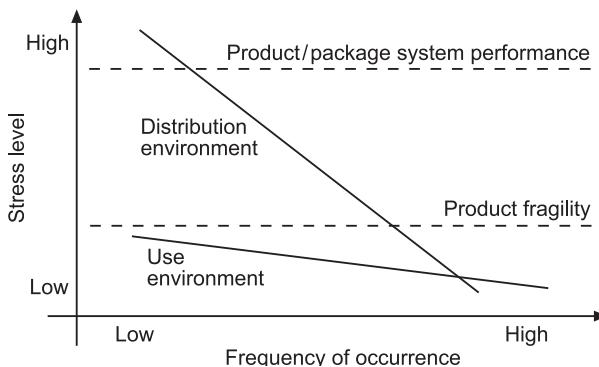

Figure 1 Distribution environment and use environment vs product and package.

be dropped from 0.5 m during distribution (now inside a package) than it will when in use (outside the package, at a user's home). Therefore, products are designed to sustain only those impacts that will most likely occur during use rather than during transport. For transport, the package can add the required ruggedness to the system to avoid damage.

Measuring Shock in the Distribution Environment

Acceleration vs time measurements are easily obtained with the use of portable, self-contained recording devices, composed of a triaxial accelerometer and memory and powered by a battery. Impact data are converted into 'equivalent free fall'. This is done to simplify the design and the testing procedure to assess package performance. Almost all impacts may be converted into an equivalent free-fall drop height. Figure 2 shows the types of shock data typically recorded in distribution environments. These are called 'impact signatures'. Type (i), 'free fall drops', are identified by the typical intensity of 1g (acceleration of gravity) just before impact. Note that the other types of impacts do not have this characteristic. Type (ii), 'horizontal impact', shows some acceleration activity just before impact, but at a level hard to distinguish – that is because the package is sliding to the floor or ground and hits something like a wall or another stationary package. Type (iii), 'kicks', are characterized by a zero, flat line before impact – nothing is happening to the package and suddenly there is an impact – in this case, the package was stationary and something hit it. The last type, (iv) 'throw-hit-fall', is characterized by three shocks with 1g in between – this first shock is the impulse caused by a throw, usually of long duration and low intensity; the second impact is a hit on a wall, for example, and the third is the impact with the ground. These

four types are not the only possible cases, but they are the most common ones. Any combination happens all the time.

These measurements may be done with a dummy package, as shown in Figure 3. This is a typical configuration for impact monitoring. The foam shown in the picture is used to protect the recorder and of course has an important role in the shape of the shock pulse recorded and the intensity of the impact. However, the essential information required for calculating drop height does not depend on the type of package. What accelerometers measure is the impact received by the unit in a drop, which is then converted into velocity or time of fall – neither depends on the type of package or the thickness of the foam that protects the recording unit.

Typical Results of Shock Measurements

Some results of measurements taken inside packages, like the one shown in Figure 3, sent by express couriers a number of times along a certain route, were used to construct the graph shown in Figure 4. In this figure, note that high drop heights have a low probability of occurrence, however, impacts from up to 140 cm high are normal occurrences in parcel shipments in the USA.

Calculating equivalent drop height using velocity change The equivalent drop height is obtained by measuring the impact acceleration vs time history of an impact. Two parameters may be used independently to determine the height from which the package fell, or its equivalent (drop height):

1. Velocity change of the shock pulse generated by the impact; the velocity change is the sum, in absolute values, of the impact velocity and the rebound velocity;
2. Length of time the package was under gravitational acceleration (1g)

The conversion is quite simple. The velocity change of the shock pulse (acceleration vs time) is calculated by numerically integrating the acceleration history given by:

$$\Delta v = \int a(t) dt \quad [1]$$

The resultant velocity change of a triaxial measurement is:

$$\Delta v_R = (\Delta v_x + \Delta v_y + \Delta v_z)^{0.5} \quad [2]$$

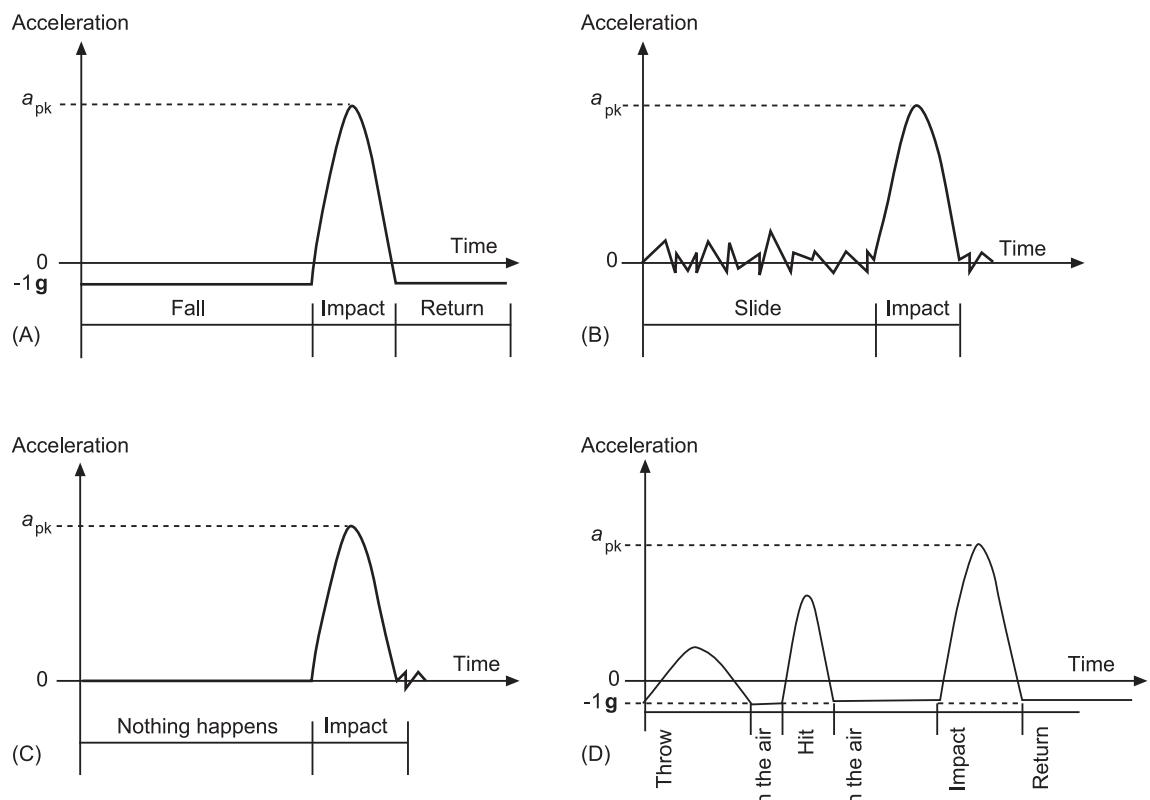

Figure 2 Typical impact signatures. (A) Free fall; (B) horizontal impact; (C) kick; (D) throw-hit-fall.

Figure 3 Monitoring the distribution environment with self-contained data acquisition instrumentation: (A) recording unit; (B) typical package configuration; (C) dummy package with the recording unit installed.

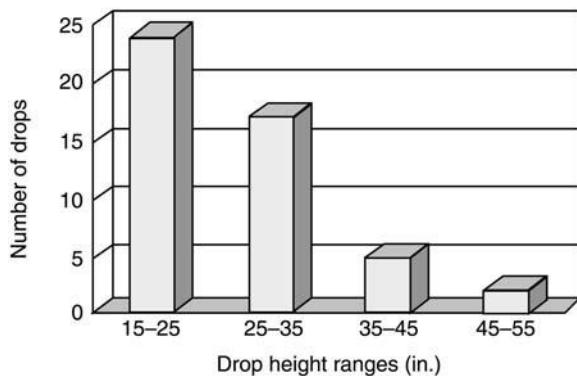

Figure 4 Drop height (equivalent), UPS + FedEx, 2nd day air, 20lb package, San Diego–Chicago route.

where x , y , and z are the orthogonal directions of the triaxial measurements. The equivalent drop height is then given by:

$$h_{\text{eq}} = [\Delta v_R / (1 + e)]^2 / (2g) \quad [3]$$

where the values for the coefficient of restitution e are obtained by calibrating the packaging system prior to shipment. In most conditions, it varies between 0.25 and 0.75. The coefficient of restitution e is defined as the ratio between rebound velocity and impact velocity, in absolute values. The diagram in Figure 5 shows the individual axes and a typical result of an impact, in three axes. The orientation of the axes is also used to determine the direction of the impact. A positive intensity in the x -axis indicates that the impact occurred in that direction whereas a negative intensity indicates the opposite direction. Most results show components in all three directions, which

indicates that most impacts are not exactly flat on the package surfaces but on the edges or corners.

Calculating equivalent drop height using duration of fall The equivalent free-fall drop height may be estimated by measuring the time the package takes in free fall. In Figure 2, observe that the free-fall type (i) shows the acceleration at 1g level during the entire duration of the fall. The free-fall drop height may be calculated by:

$$h_{\text{eq}} = gt^2 / 2 \quad [4]$$

where t is the time taken for the package to fall to the ground (friction with air is insignificant). Most recording units use these two techniques to estimate the equivalent free-fall drop. When the impact is a free fall it is easier to apply eqn [4]; however, as most drops are not free-fall, eqn [3] is used more frequently.

The impacts produced in the distribution environment need to be known by the packaging designer. The information will be essential in designing protective packages and in designing performance-testing protocol. When measurement is not possible, the designer may use commonly accepted values, or standards, which usually depend on the weight of the package.

Assessing Product Shock Fragility

A procedure recommended by ASTM D-3332 may be used to determine the shock fragility of the product. This procedure requires that an item of the product be tested on its six faces, using two series of tests, using a tester capable of producing shock pulses of controllable duration and intensity (programmable shock

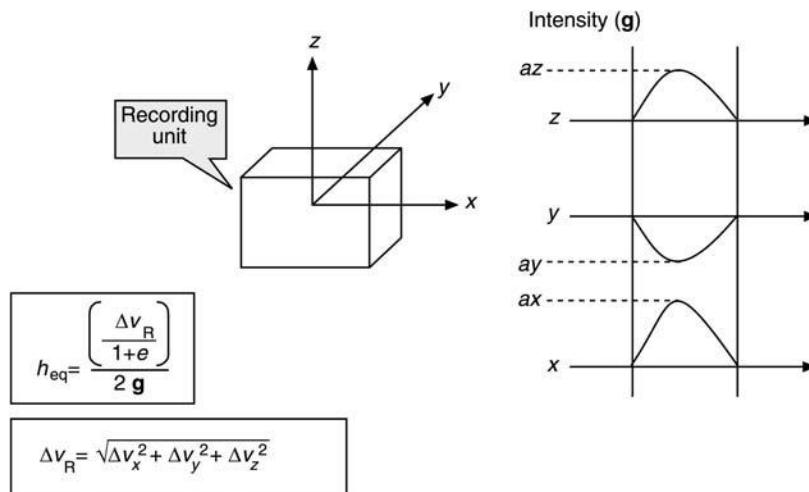

Figure 5 Impact measurement in the distribution environment.

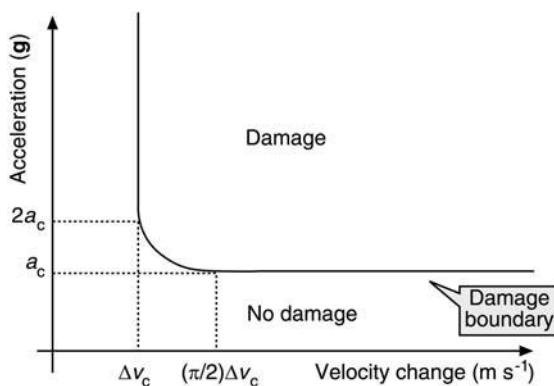

Figure 6 Product shock fragility.

machine). The first series is to determine the critical velocity change of the product, Δv_c , and the second series is used to determine the critical acceleration of the product, a_c . These two parameters are then used to plot a damage boundary curve for the product, one for each product face. Figure 6 shows a damage boundary curve for a product.

Damage Boundary Curve for a Product

The damage boundary curve indicates the level and duration of impacts, which can cause product damage. These are impacts applied to the exterior of the product, in the same fashion a package cushion would do. It may not be the same impact intensity that is received by components of the product. The method utilized to determine the critical acceleration (a_c) employs the application of a trapezoidal shock pulse. When a spring-mass system receives an impact of long duration and almost constant intensity (trapezoidal shock), the shock transmission (intensity) to the various product components is modified by the factor A_m , which is plotted in Figure 7. Note that the value of A_m depends on the ratio ω_{Rc}/ω_{Rp} , which is the ratio between the natural frequencies of the

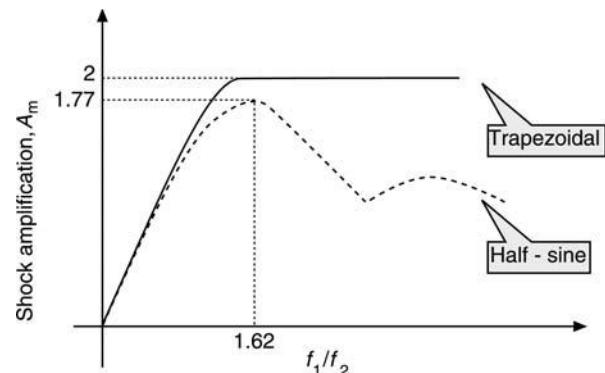

Figure 7 Shock transmission with no damping.

component being considered and the frequency of the shock applied to the product.

In Figure 8, a model of a spring-mass system is shown to identify product and package components used to define ω_1 (m_1 and k_1) and ω_2 (m_2 and k_2).

Most package cushions impose a half-sine shock on a product during an impact. Notice in Figure 7 that the half-sine shock usually transmits to the components of the product an impact of less intensity than the trapezoidal shock. In many instances, this procedure for testing product fragility is conservative, and this may be taken into account by designers as a safety factor.

Shock Absorption Properties of Materials

The shock absorption characteristics of packaging materials are obtained by subjecting samples of the material to a batch of impact tests. The ASTM D-1596 or D-4168 protocols may be used to obtain this information. The results of this test are often presented in the form of cushion curves. Figure 9 shows typical shapes of the shock pulses as the weight of a product increases, all else being equal. Figure 10

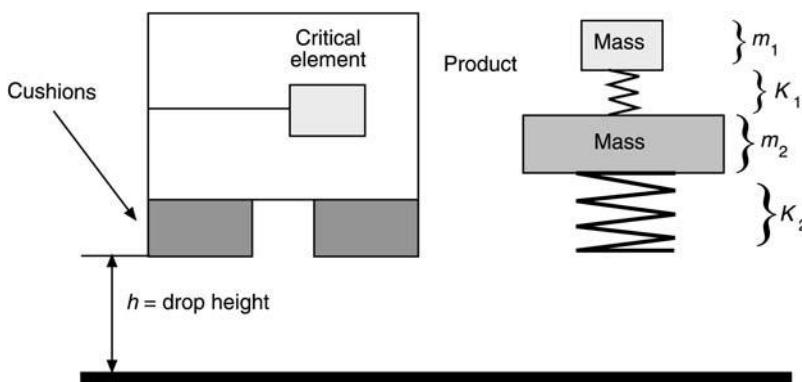

Figure 8 Physical model product package.

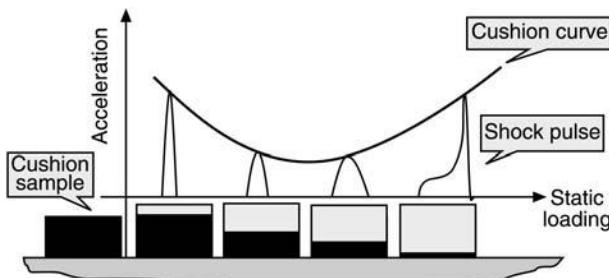

Figure 9 Plotting a cushion curve.

shows cushion curves obtained by testing double wall corrugated fiberboard (BC flute) at different conditions.

During impact, the most important property of a material is its ability to deflect. Note in Figure 11 the relationship between cushion deflection and acceleration during a product free fall. The dynamic deflection, d_m , varies according to the material being utilized. The goal in package design is to allow d_m to be as large as possible, as long as the material does not bottom out or, depending on requirements, does not crush beyond ability to recover reasonably. Most packages receive multiple impacts and the condition of the protective cushion is important; also, from the product presentation point of view, it is not a good idea to present a customer with a package that has crushed components; although the crushing occurred to protect the product, consumers do not always know that.

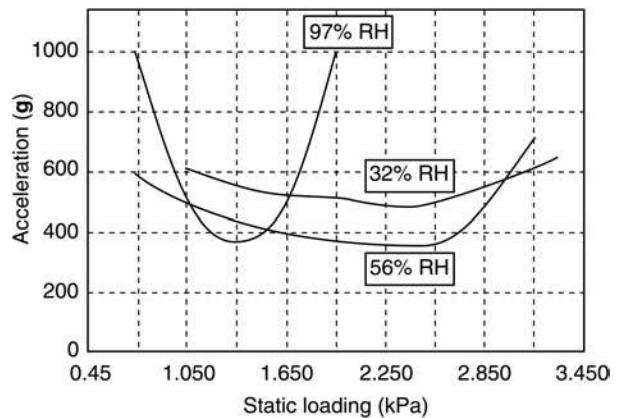

Figure 10 Cushion curves – effect of humidity, BC-flute corrugated, DH = 120 cm, first impact, 30°C. RH, relative humidity.

Interpretation of a Shock Cushion Curve

A shock cushion curve is a tool used by designers to choose a proper cushion. The curve shows peak acceleration, a_{pk} vs static loading, SL. The peak acceleration is the maximum level of shock during the impact. The static loading is the ratio between the weight of the product, $m_p g$, and the bearing area of the cushioning material, as long as the block of cushion is a rectangular block. Trapezoidal blocks and other forms that are different from rectangular blocks, often used in design, are adjusted to their equivalent rectangular block dimensions. Figure 12 shows a cushion curve broken down into three

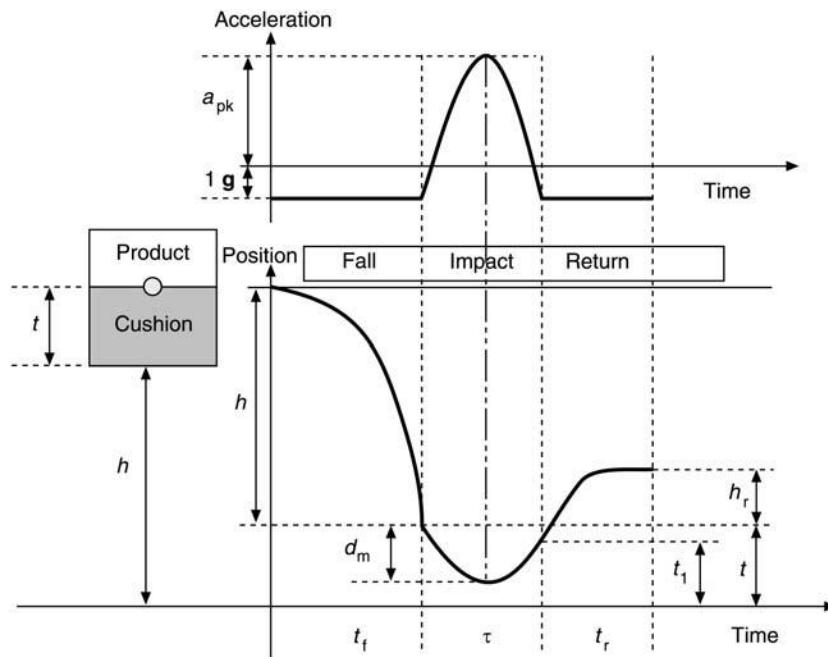

Figure 11 Impact free fall and acceleration.

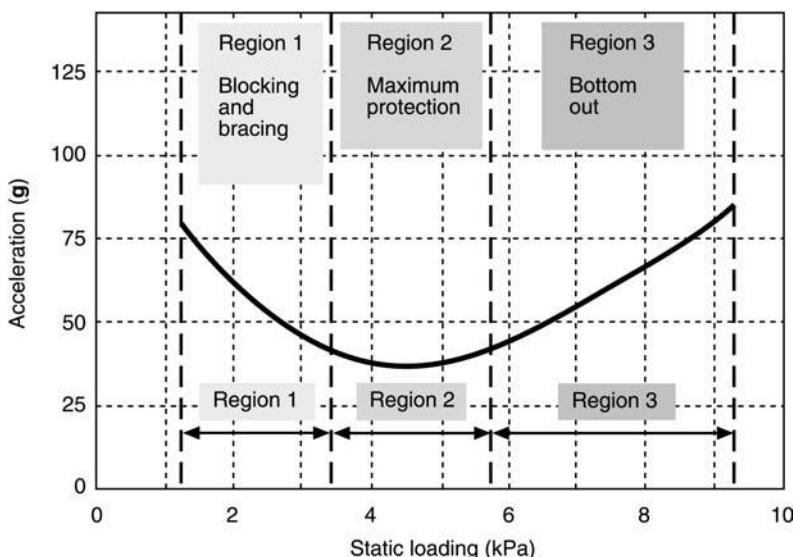

Figure 12 Typical cushion curve.

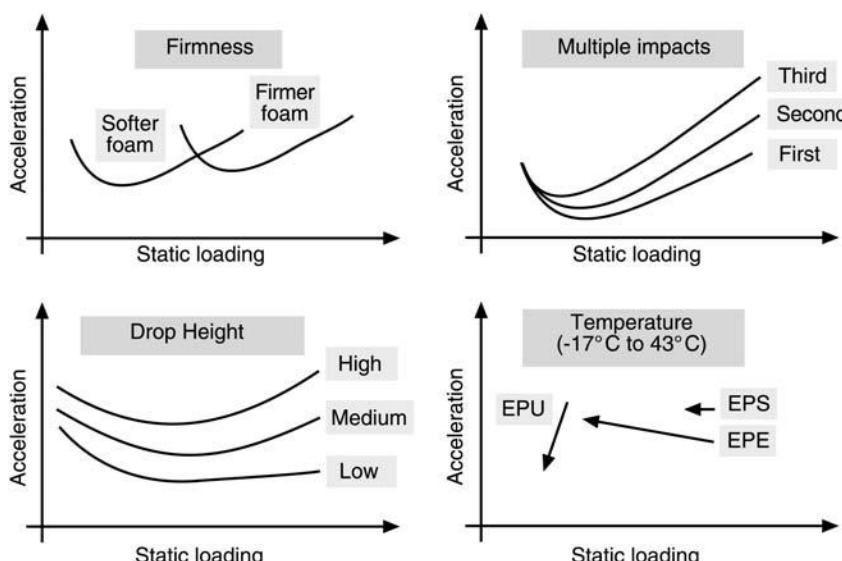

Figure 13 Effects of various parameters on cushion curves. EPE, expanded polyethylene; EPS, expanded polystyrene; EPU, expanded polyurethane.

regions. The goal is to pick a static loading that provides the best cushioning – region 2 in Figure 12. Factors that influence peak acceleration are shown in generic cushion curves presented in Figure 13. In this figure, temperature comparisons were made between expanded polyurethane, polystyrene, and polyethylene. The arrows indicate the direction that the lowest point on the curve moves in when the temperature is increased.

For applications of cushion curves in packaging design, see **Packaging**.

Nomenclature

a_c	product critical acceleration or shock fragility
a_{pk}	peak acceleration
a_x	acceleration in the x orientation

a_y	acceleration in the y orientation
a_z	acceleration in the z orientation
Am	shock amplification
d_m	dynamic deflection of a cushion
e	coefficient of restitution
g	acceleration of gravity
H_d	free fall drop height
h_{eq}	equivalent drop height
H_r	rebound height
RH	relative humidity
SL	static loading
t_f	time of fall
t_r	time of rebound
T_c	cushion thickness
T_1	thickness after impact
τ	impact duration
ω_{Rc}	resonant frequency of a product's component
ω_{Rpc}	resonant frequency of a product/cushion combination
Δv	velocity change
Δv_c	critical velocity change of a product

Δv_R	resultant velocity change
Δv_x	velocity change in the x direction
Δv_y	velocity change in the y direction
Δv_z	velocity change in the z direction

doi:10.1006/rwvb.2001.0177

Shock isolation systems are designed for protection against high-rate input loadings from machinery excitation, transportation environments, or weapon effects. This section describes several high-performance shock isolation elements. Their design is usually based on shock disturbances expressed as motion or force-time histories. Design specifications are expressed in terms of equipment fragility levels given as acceleration response time histories or peak acceleration-frequency curves. An effective shock isolator must possess: first, a long stroke capability; second, a facility to attenuate high-frequency disturbances; and, third, a design able to control the generation and propagation of internal stress waves. These properties are not encountered in commercially

available vibration isolators that have short strokes and low flexibility.

Stranded Wire Spring

A robust shock isolator is the stranded wire spring shown in Figure 1. The helix of the spring is wound in the opposite direction to the helix of the strands. When the spring is compressed, the strands bind together, giving rise to Coulomb friction forces between wire strands.

Ring Spring

In the ring spring, shown in Figure 2A, the energy is absorbed by the Coulomb friction forces between the adjoining rings. The axial spring deflection is obtained from stretching of the outer rings and compression of the inner rings. The damping force acting on the conical surfaces of the adjacent rings is proportional to the axial displacement. A typical load deflection curve is shown in Figure 2B. For increasing

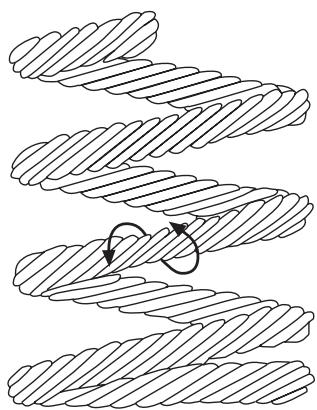

Figure 1 Stranded wire spring. From Eshleman (1970) with permission.

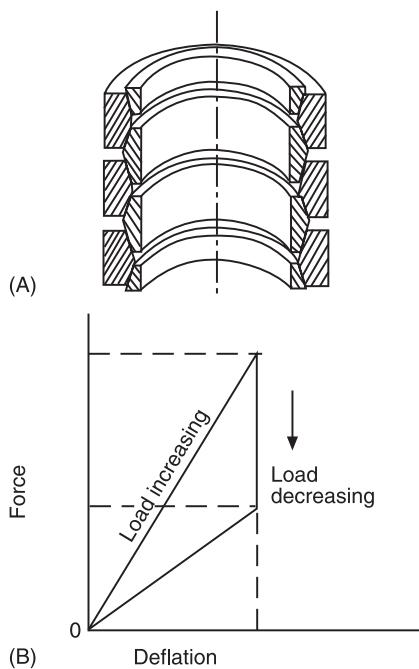

Figure 2 Ring spring. (A) Diametral section; (B) load deflection curve. From Eshleman (1972) with permission.

loads, the elastic and the friction forces act in the same direction, absorbing a large amount of energy. For decreasing loads, the friction force reverses. Part of the stored elastic energy is used to oppose the friction force. The result is a load release curve of smaller slope. The area inside these lines is a measure of the energy dissipated by the ring spring in a loading cycle. Ring springs have inherent small displacements. This drawback is alleviated by stacking rings.

Belleville Spring

The Belleville spring shown in **Figure 3** is made from washers stressed circumferentially and radially. Its

nonlinear hard-to-soft spring characteristic is best suited for shock isolation. Local damping can be introduced by parallel elements or contained fluids.

Volute Spring

The volute spring (**Figure 4**) has flat steel coils wound helically to form a conical spring. The reverse-wound coils are subject to bending. The nested coils press against each other and generate friction forces to dissipate energy.

Friction Snubber

An effective shock isolation element can be made combining a helical spring in parallel with a friction snubber (**Figure 5**). The friction is produced between a liner material and the snubber wall. Preadjusting the helical spring compression, the liner material is wedged against the wall.

Solid Elastomeric Elements

Elastomeric or rubber elements work in either compression or shear. The load deflection curve is nonlinear. The nonlinearity is usually ignored for strains up to about 10%. For a compression block (**Figure 6A**), the stiffness is corrected for the effect of bulk compression. For an element in compression, provided the thickness is less than one-fourth of the least plane dimension, there should be no instability. Long strokes can be obtained by special geometrical design (**Figure 6B**).

Foam Blocks

Polyurethane foam isolation elements have large energy dissipation capacity, high stroke-to-overall-length ratio and high shock-attenuation-to-weight

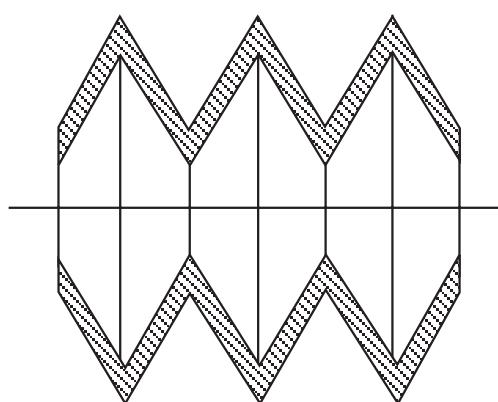

Figure 3 Belleville spring. From Eshleman (1970) with permission.

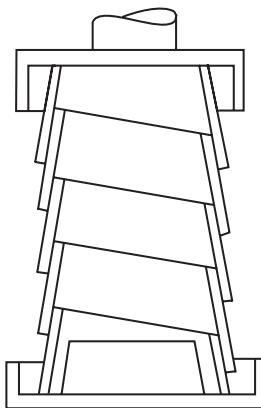

Figure 4 Volute spring. From Eshleman (1973) with permission.

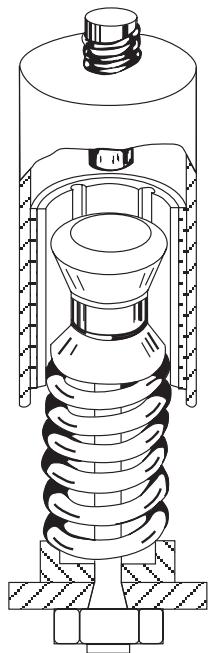

Figure 5 Friction snubber. From Eshleman (1973) with permission.

ratio. The resisting force generated by the foam isolator has two components: one is due to the nonlinear deformation of the porous structure, the other is due to the air pressure generated by the air flow produced by the distortion of the foam cell structure. The foam does not exhibit surging under high rate loading.

Liquid Spring

The liquid spring shown in **Figure 7** works on fluid compressibility. It has high damping and high wave propagation velocity. To increase the stroke, that is proportional to the volume of the constrained fluid, a fluid reservoir is added to the basic isolator.

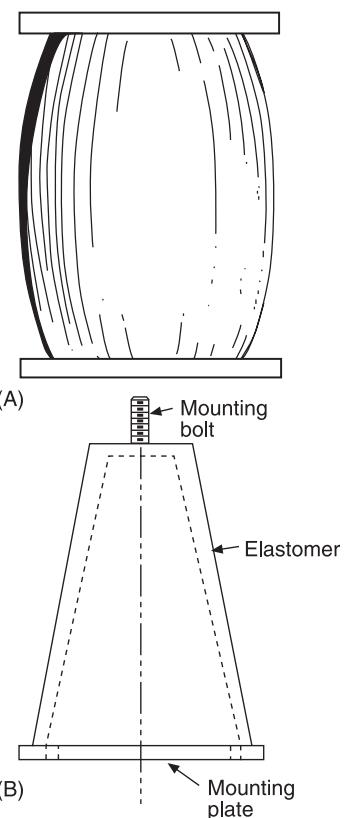

Figure 6 Solid elastomer. (A) Rubber block, from Eshleman (1973); (B) long stroke isolator, from Eshleman (1970) with permission.

Pneumatic Spring

The pneumatic spring (**Figure 8**) has similar characteristics to those of the liquid spring. Its flexibility can be adjusted by varying the air pressure. A passive

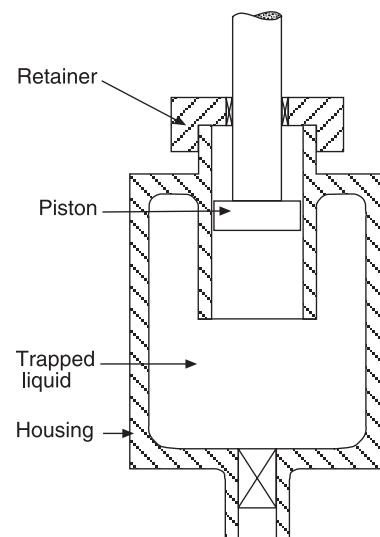

Figure 7 Liquid spring. From Eshleman (1970) with permission.

pneumatic shock isolator is shown in Figure 9. The transient response of the system reaches a minimum for a certain ratio of orifice area to load area. Similar shock absorbers have been applied to the carriage return mechanism of a printer. Variable-area orifice designs have also been studied.

Active Pneumatic Isolator

A schematic diagram of an active mechanopneumatic shock isolator is shown in Figure 10. The use of integral displacement control reduces the steady-state relative displacement of the mass to zero.

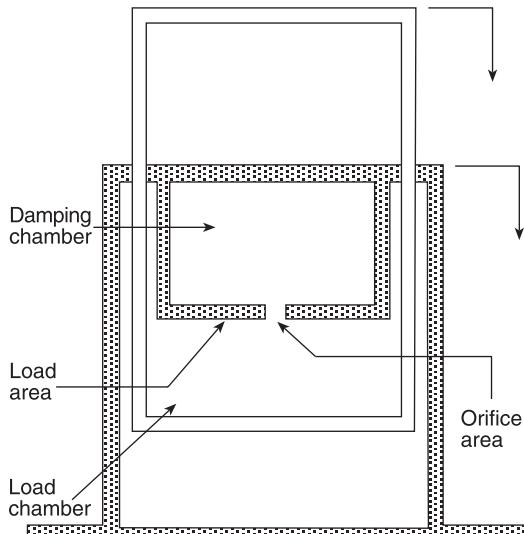

Figure 9 Passive pneumatic shock isolator. From Hundal (1980) with permission.

Semiaactive Fluid Device

A fluid shock absorber with servo-controlled valving is shown in Figure 11. It contains a dissipative element in which the dissipation law can be modulated actively. By means of a small amount of power

SIGNAL GENERATION MODELS FOR DIAGNOSTICS

Introduction

Vibrations in rotating machines are due to various dynamic forces, including those due to abnormal running conditions or faults. Vibration signal generation models have been developed and make possible the identification, from measured signals, of the generating phenomena and as a consequence the faulty condition of the machine. These models allow the determination of specific characteristics or features, which can be extracted by signal processing, in order to deliver a ‘diagnosis’ of the machine state. These features are often termed symptoms.

Vibrations in rotating machines are due to various excitation phenomena. We use them to distinguish between mechanical, electrical, aerodynamic, and hydraulic phenomena.

Characteristics of Vibration Signals

On the Models

Most of the vibration generators are considered as the sources or excitations for which one wishes to develop a signal generation model. The existence of various models ‘explaining’ various phenomena in rotating machines makes vibration analysis a very powerful tool for condition monitoring and diagnosis. In fact, the models allow us to ‘identify’ the state of the machine from vibration measurements done with sensors which are usually fixed on the bearing casings. However, it is assumed that the transmission from the source to the measured signal is linear and not time varying. This allows us to trace any modification of the vibrations to the sources, i.e., the faults. This hypothesis implies that for any harmonic source the measured vibration will be harmonic with the same frequency content (Figure 1).

Models may be analytical, ‘symptom’-based or statistical. Analytical models come from the kinematics and dynamic modeling and require various physical parameters which are difficult to evaluate, such as stiffness and damping. However, such models have developed in the context of modal analysis and

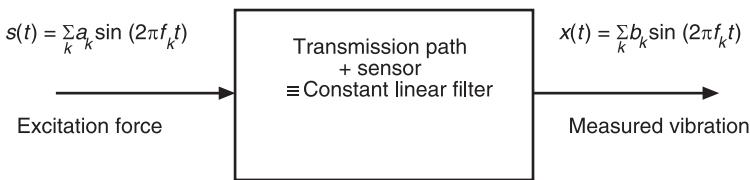

Figure 1 Linear system hypothesis.

design. Their use for vibration analysis is still under investigation. ‘Symptom’-based models are more often used for condition monitoring and diagnosis. In the main they make use of the rotating machine kinematics. This allows them to determine specific frequencies that may be identified using simple frequency domain analysis. Statistical models are those that consider the signals to be random. We are generally interested in the statistical characterization (random impulse, random noise, etc.).

Vibrations of Rotating Machines

The vibrations generated by rotating machines are cyclic in nature. The frequencies of the phenomena are defined by the kinematics. A simple example, is shown in **Figure 2**: a constant speed rotating punctual mass will create a centrifugal force, and at the bearing case it creates a sinusoidal vibration with frequency equal to the rotating mass speed (linear transfer is supposed).

We will express the vibration signal measured on a rotating machine as the sum of three terms:

$$x(t) = x_r(t) + x_n(t) + b(t) \quad [1]$$

where $x_r(t)$ is the part of the signal with cyclic frequencies which are synchronous to the fundamental shaft rotation f_r . It may have ‘sinusoidal’ components at frequency $f_r, 2f_r, 3f_r, \dots$, or a more complex signal

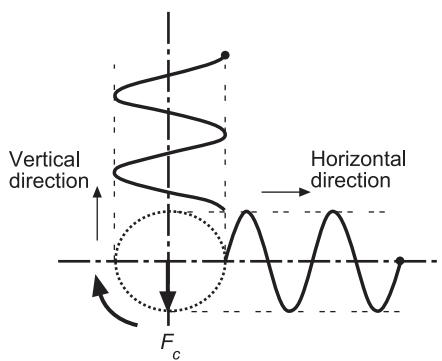

Figure 2 Sinusoidal variations in vertical and horizontal axis for a constant speed rotating force.

such as a repetitive impact at the same frequency rate. $x_n(t)$ is similar to $x_r(t)$, in this case the cyclic frequencies are not synchronous to the fundamental f_r , and $b(t)$ is an additive noise with random characteristics.

Most of the signal generation models will ‘explain’ the signal in that form. This is very useful when we have to decide which signal processing technique to use for the vibration signals analysis.

Vibrations of Mechanical Origin

Unbalance

Unbalance is the most common vibration generator in a rotating machine. It is due to nonsymmetrical mass distribution around the rotation axis. We consider here, only rigid rotors (rotation speed lower than the first critical speed). A rotor is well balanced if its mass center belongs to the rotation axis and if this axis is the principal axis of inertia. We distinguish between static, couple, and dynamic unbalances.

Static unbalance (**Figure 3A**) The mass center of the rotor is not on the rotation axis, this leads to the inertia force:

$$F_c = m.e.\omega_r^2 \quad [2]$$

where ω_r is the constant rotation speed in rad s⁻¹, m is the mass of the disc in kg, and e is the distance from the mass center to the rotation axis in m.

Couple unbalance (**Figure 3B**) When the mass center does not coincide with a principal rotation axis, a couple is generated. The resulting inertia moment may be written as:

$$M = I.\omega_r^2 \quad [3]$$

where I is the inertia product.

Dynamic unbalance (**Figure 3C**) This is considered for a rotor with both static and couple unbalances. We then have both an inertia force, eqn [2], and a couple moment, eqn [3]. The angle between the

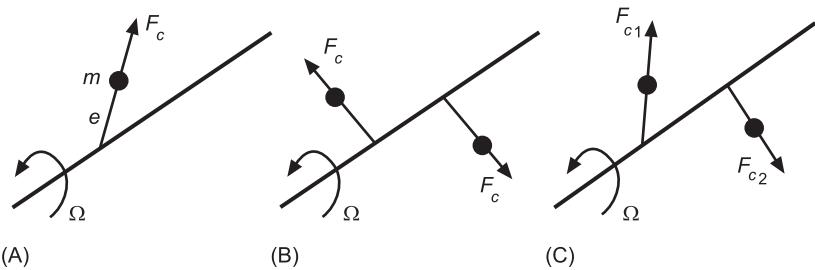

Figure 3 Forces for different kinds of unbalance. (A) Static unbalance; (B) couple unbalance; (C) dynamic unbalance.

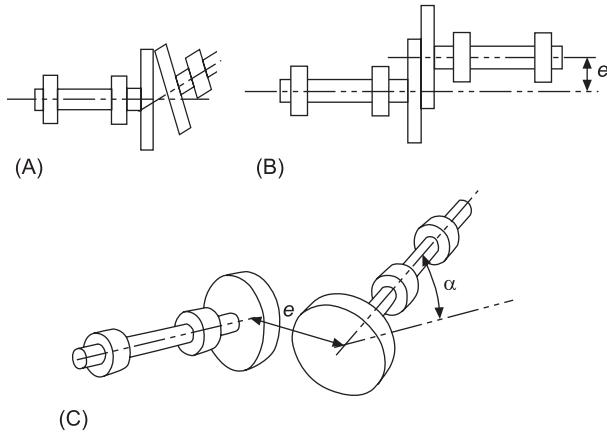

Figure 4 Types of misalignments. (A) Angular; (B) parallel; (C) both.

inertia force and the inertia moment is between $-\pi$ and $+\pi$.

Symptoms of unbalance According to eqns [2] and [3], when unbalance occurs, the measured vibrations are characterized, in the frequency domain, by a component at the rotation frequency $f_r = \omega_r/(2\pi)$. The amplitude is proportional to the amount of unbalance and to the square of the rotation speed. The phase between the vibrations on the two supporting bearings is in phase in the case of static unbalance, with π out of phase for a couple unbalance and

arbitrary for a dynamic unbalance. The orbit of the rotor in the bearings, measured with two radial and orthogonal displacement sensors, exhibits a single-loop elliptical shape. Due to the transmission path, higher harmonics ($(2f_r), \dots$) may occur especially when the unbalance is severe.

Misalignment

Mechanical power is transmitted by coupled shafts which have to be aligned. Otherwise, significant vibrations may occur. Misalignment is a very common fault in rotating machines. The generated vibrations act on the bearings and are related to the type of misalignment (Figure 4), or to the type of couplings used to connect the shafts (Figure 5). Detailed models of the generation signals have been developed in the literature, we give only a qualitative analysis for gear couplings. Figure 6 shows the gear coupling forces that occur when misalignment occurs. Periodic forces are caused by the friction in gear meshing and exhibit a periodicity of half of the shaft rotation period. This results in a fundamental frequency of $2f_r$.

Symptoms of misalignment The vibrations are harmonic and mainly characterized by the first harmonics of the rotation frequency f_r , i.e., $1f_r, 2f_r, 3f_r, 4f_r, \dots$. The axial direction is, in general, more sensitive. In this direction, the measurements at each side of the coupling are in opposite phases (180°). In sleeve bearings, misalignment may also be

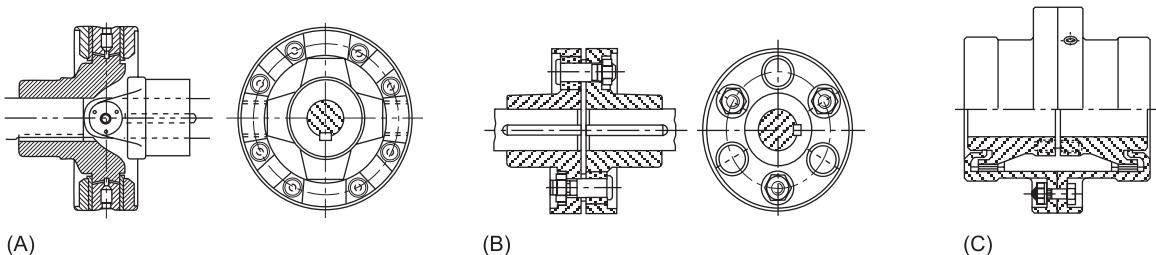

Figure 5 Types of couplings. (A) Hooke's joint; (B) elastomer coupling; (C) gear coupling.

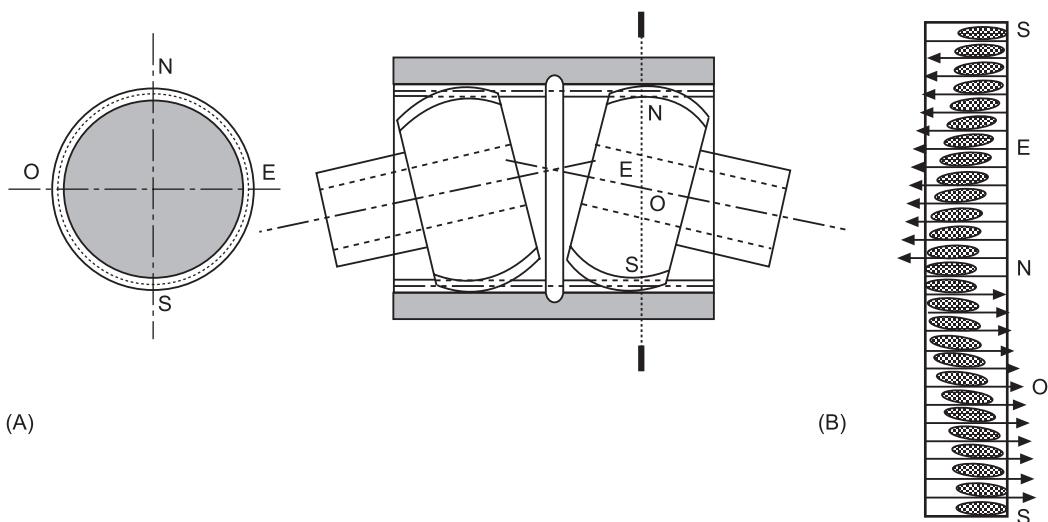

Figure 6 Friction forces acting on the teeth in misaligned gear coupling.

detected by orbit analysis, which exhibits a double loop when the $2f_r$ component is dominant. General features of the vibration due to misalignment are summarized in **Table 1** for various coupling types.

Rolling Bearing Faults

Rolling bearings are comprised of various components: the inner and outer races, the cage and the rolling elements (Figure 7). Vibrations are generated when the rolling bearing conditions are not perfect, i.e., surface damage, forces acting on the bearings (unbalance, misalignment, etc.). The surface damage is due to fatigue in the presence of high stresses at the contact points. More specifically, the vibrations are generated by the impacts which occur when the surface of one component strikes another surface. As the bearing rotates, the generated impulses will occur periodically. The frequencies of these impulses are uniquely determined by the location of the defect, on the inner race, outer race, or on the rolling elements (Figure 8). The geometry of the rolling bearing is required (Figure 9). The characteristic frequencies for inner race, outer race, cage and ball bearing faults are given in Tables 2 and 3 for ball bearings with fixed and rotating outer race, respectively.

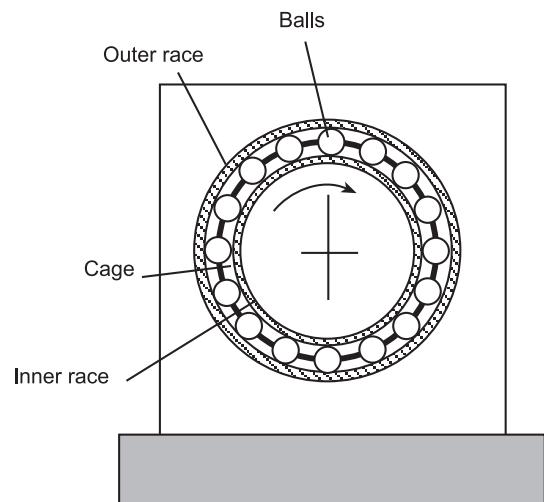

Figure 7 Rolling bearing components.

This model stating that the rolling bearing generates periodical impulses with specific frequencies is not complete. It is important to take into account first, the distribution of the load around the circumference of the bearing, which under radial load, is defined by the Stribeck equation:

Table 1 Vibration characteristics of misalignment

Coupling types	Hooke's joint	Gear coupling	Elastomer/metallic	Elastomer/metallic
Misalignment	Angular	Angular	Angular	Parallel
Direction	Radial, axial	Axial, radial	Axial	Radial
Frequency components	$2f_r, 4f_r, 6f_r, \dots Nf_r$ (N = number of teeth)		$1f_r, 2f_r, 3f_r$	$2f_r, 4f_r, 6f_r, \dots$
Out of phase	180°	180°	180°	180°
Orbit	Double or more loops	Double or more loops	Double or more loops	Double or more loops

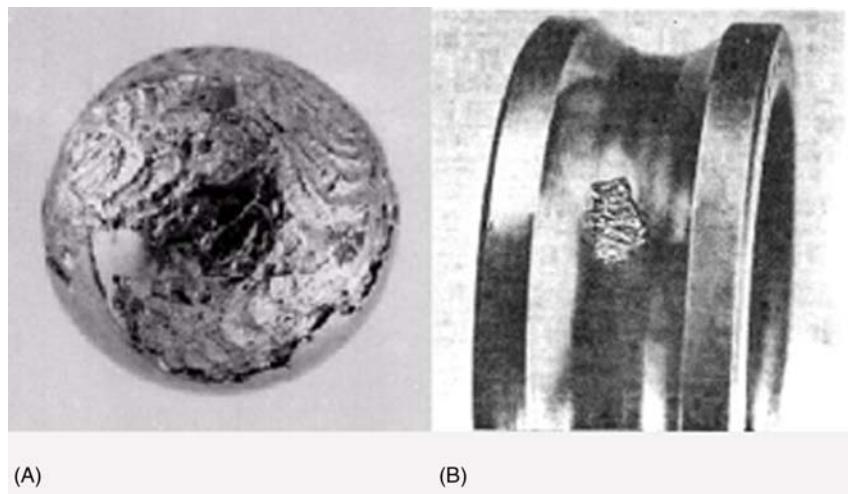

Figure 8 Rolling bearing faults. (A) Spalling on a ball; (B) spalling on inner race.

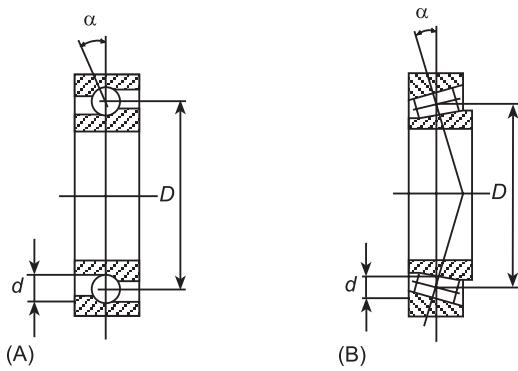

Figure 9 Rolling bearing geometry. (A) Cross-section of a ball bearing; (B) cross-section of a tapered roller bearing. D = mean diameter to the center of the ball; d = ball diameter; α = contact angle.

Table 2 Characteristic frequencies for a radial ball bearing with fixed outer race

Bearing component	Frequency expression
Cage frequency (fundamental train frequency)	$FTF = f_c = \frac{f_r}{120} \left(\left(1 - \frac{d}{D} \right) \cos \alpha \right)$
Inner race frequency (Ball pass frequency of inner race)	$BPI = f_i = \frac{f_r Z}{120} \left(\left(1 + \frac{d}{D} \right) \cos \alpha \right)$
Outer race frequency (Ball pass frequency of outer race)	$BPFO = f_o = \frac{f_r Z}{120} \left(\left(1 - \frac{d}{D} \right) \cos \alpha \right)$
Rolling element frequency (Ball spin frequency)	$BSF = f_s = \frac{f_r D}{120 d} \left[1 - \left(\left(\frac{d}{D} \right) \cos \alpha \right)^2 \right]$

f_r = shaft rotation frequency (Hz), D = mean diameter (to the ball center), d = diameter of balls, Z = number of balls, α = contact angle (**Figure 10**).

Table 3 Characteristic frequencies for a radial ball bearing with rotating outer race

Bearing component	Characteristic frequencies, Hz
Cage	$f_c = \frac{f_R}{2} \left(1 - \frac{d}{D} \cos \alpha \right) + \frac{f_{Rout}}{2} \left(1 + \frac{d}{D} \cos \alpha \right)$
Inner race	$f_i = \frac{Z}{2} \left[(f_R - f_{Rout}) \left(1 + \frac{d}{D} \cos \alpha \right) \right]$
Outer race	$f_o = \frac{Z}{2} \left[(f_R - f_{Rout}) \left(1 - \frac{d}{D} \cos \alpha \right) \right]$
Rolling	$f_b = \frac{1}{2} \frac{D}{d} (f_R - f_{Rout}) \left[1 - \left(\frac{d}{D} \cos \alpha \right)^2 \right]$

f_R = shaft rotation frequency, f_{Rout} = outer race rotation frequencies, D = mean diameter (to the ball center), d = ball diameter; Z = number of rolling elements, α = contact angle.

$$q(\theta) = q_0 [1 - \varepsilon (1 - \cos (\theta))]^n \quad [4]$$

where ε controls the load distribution and θ is the angular load zone ($n = 3/2$ for ball bearings, $n = 10/9$ for roller bearings, q_0 is the maximum load value).

This results in a modulation effect for a rotating defect, i.e., ball or inner race defect. This effect is illustrated in **Figure 10**. When dynamic load is present, due to centrifugal forces, modulations are also generated for a fixed outer race defect. Secondly, the transmission from the impact to the measured vibration (bearing casing and sensor transfer function) which acts as a filter. The impacts are high-frequency dominated, they excite the system resonance localized in a high frequency band. This property is used to ‘amplify’ the rolling bearing impulses and is at the

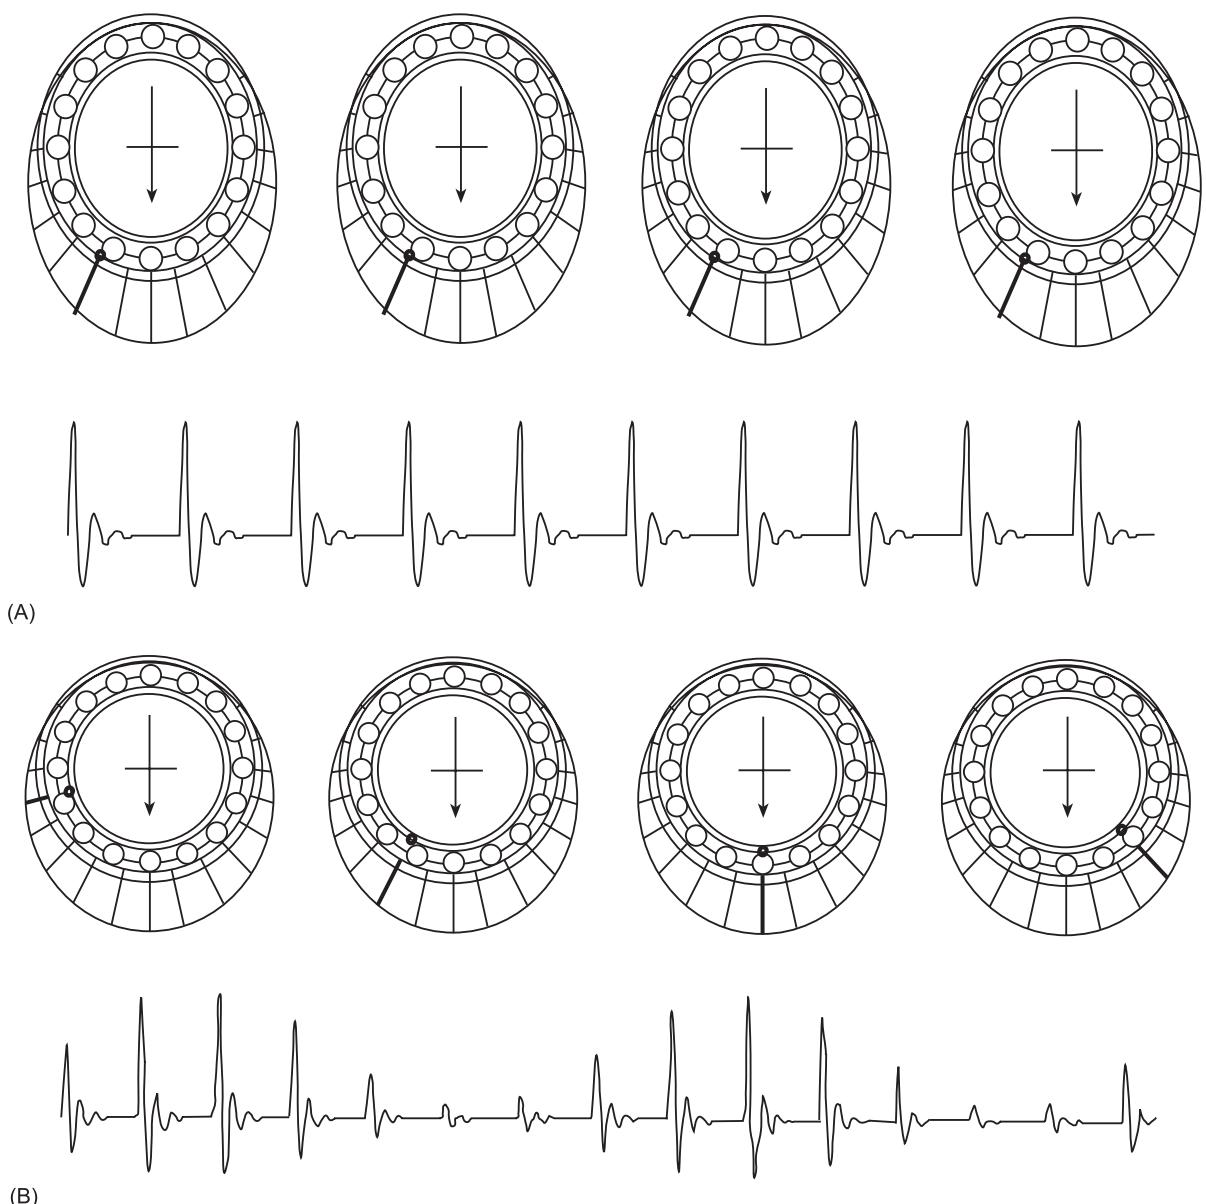

Figure 10 Rolling bearing with fixed outer race, rotating inner race and fixed load. (A) Damage in the fixed race, without modulation; (B) damage in the rotating race with load modulation.

basis of several detection techniques high-resonance frequency technique (HFRT) or the envelop demodulation technique, because of the response of a system to repetitive impulses.

Gear vibrations signal generation

Gears are important and complex mechanical elements. Different types of gears may be distinguished, some are shown in Figure 11. They transmit significant torques, and are subject to considerable deterioration, often with dramatic consequences. Faults may concern the teeth surface (wear, spalling, cracks) (Figure 12) or the wheels (eccentricity, misalignment, etc.).

The essence of the vibration generation models is, however, similar for all the gear types: the gear vibrations are produced by the impact between the teeth of the two wheels. The meshing signal is given by the deviation of the meshing point position relative to the ideal motion of a perfect gear with no load. This deviation is called the transmission error, and its components come from the deflection of the teeth due to the load and from deviations of the teeth shape from their ideal profile. Relatively simple models can be based on elementary systems composed of two gears, such as pinion/gear, planetary, etc. Taking as an example the system depicted in Figure 13, the model predicts, in perfect conditions

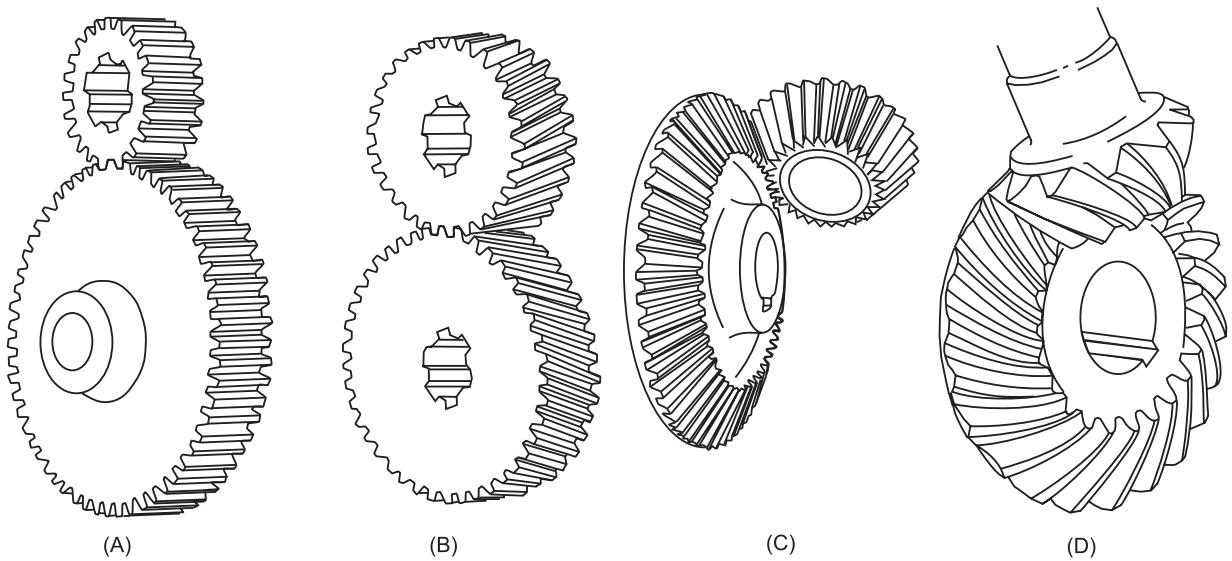

Figure 11 Various gears. (A) Spur gear; (B) helical gear; (C) bevel gear; (D) spiral bevel gear.

(perfect profile, no faults), a periodic vibration $x(t)$ given by:

$$x(t) = \sum_k x_k \sin (2\pi k f_m t + \phi_k) \quad [5]$$

with a fundamental meshing frequency of:

$$f_m = f_{r1} n_1 = f_{r2} n_2 \quad [6]$$

Faults occurring in a gear system will introduce time-varying torques. This will induce a multiplicative effect and obviously modulation effects. In brief, distributed effects, affecting all the teeth, (imperfect tooth profile, wear, etc.) will generate modulation at the meshing frequency, f_m . Localized defects like spalling, cracks, and obvious breakage generate repetitive impulses at the shaft's rotation frequencies f_{r1} and f_{r2} . This gives rise to amplitude or phase modulation effects at these frequencies. The simplest case would be the effect of wheel eccentricity, generating a once-per-revolution torque variation.

The amplitude, phase or combined modulation mechanisms have been noted, resulting in:

$$y(t) = \sum_k x_k [1 + a_k(t)] \sin [2\pi k f_m t + \phi_k + b_k(t)] \quad [7]$$

where $a_k(t)$ and $b_k(t)$ are, respectively, the amplitude and phase modulating functions. The modulations are basically of periodic character, and can be described by:

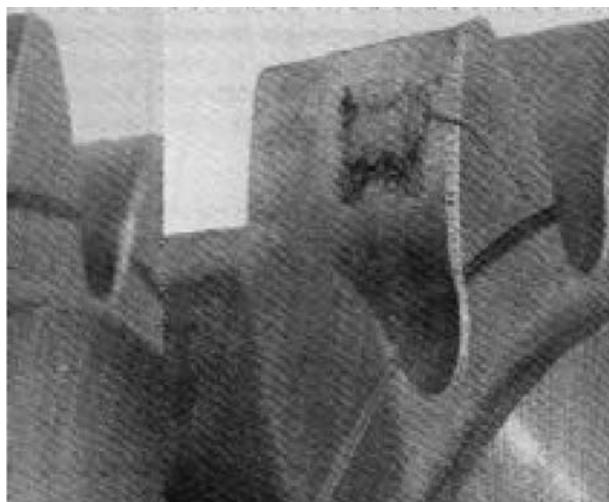

$$\begin{aligned} a_k(t) &= \sum_p a_{kp} \sin (2\pi p f_{r1} t + \alpha_{kp}) \\ &\quad + \sum_q a'_{kq} \sin (2\pi q f_{r2} t + \alpha'_{kq}) \\ b_k(t) &= \sum_p b_{kp} \sin (2\pi p f_{r1} t + \beta_{kp}) \\ &\quad + \sum_q b'_{kq} \sin (2\pi q f_{r2} t + \beta'_{kq}) \end{aligned} \quad [8]$$

However, it should be noted that, specially for distributed faults such as spalling or cracks, the parameters a_{ij} , b_{ij} , α_{ij} and β_{ij} in eqns [7] and [8] are random. In the frequency domain, the models thus predict the following frequencies:

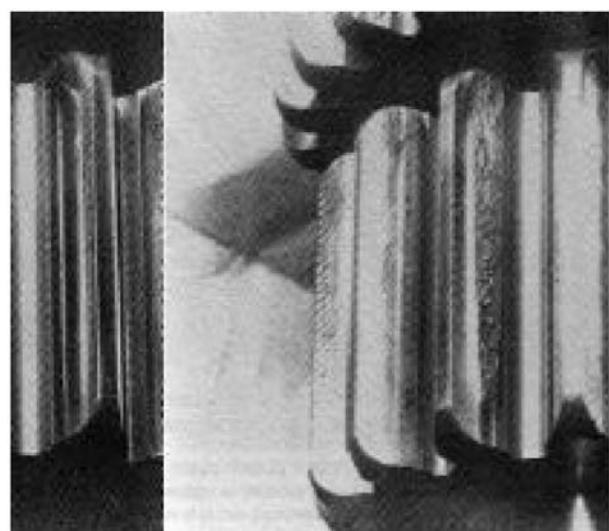

$$\begin{aligned} kf_m &\pm pf_{r1} \pm qf_{r2} \\ k &= 1, 2, \dots, K \\ p, q &= 0, 1, 2, K \end{aligned} \quad [9]$$

This shows that the gear vibrations spectrum is rich with numerous harmonics even with a new gear set. This is due to the complexity in manufacturing these mechanical components (profile under load, teeth surface quality, etc.). Imperfect profile (specially under load) and surface quality generate these modulation effects.

The existence of complex phase and amplitude modulation may also be interpreted as a nonlinear or cyclostationary phenomenon. These models justify, for the diagnostic process, the use of more advanced signal processing techniques.

(A)

(B)

Figure 12 Teeth gear faults. (A) crack, (B) spalling.

Table 4 summarizes the time and frequency characteristics for the various type of faults that may happen in a gear system.

Other Mechanical Faults

Oil film excitation (whirl) will appear in (high speed) turbomachinery, with journal bearings. It can be described as a travelling wave in the oil film, with a speed just less than half of the shaft rotation speed ($0.43 - 0.45f_r$).

Shaft cracks are of importance in high-power turbomachinery. This nonlinear phenomena is difficult to detect. Run-up and run-down are often used to detect these phenomena by examining the relative amplitude and phase of the first harmonics of the rotation.

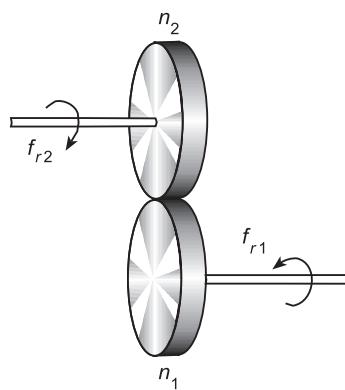

Figure 13 Pair of spur gears ($f_{r1}n_1 = f_{r2}n_2$).

Vibrations of Electric Origin

In electric machines, the electromagnetic forces give rise to vibrations. For synchronous machines, the fundamental frequency is the line frequency which is the rotation speed, and the harmonics are defined by the number of pair poles.

In asynchronous machines (induction machines), the rotation speed is just under the sector frequency (i.e., the synchronous speed), the difference being the ‘slip’ frequency multiplied by the number of poles. A localized fault on the rotor, say a broken bar, will produce an ‘electrical unbalance’ rotating at speed shaft f_r . This will generate amplitude modulation of the vibrations:

$$f_r \pm 2sf_l \quad [10]$$

where s is the per unit slip and f_l the line frequency.

Signal generation models have been developed for the motor current. Physical models have been developed in the context of control but are also used for diagnosis.

Aerodynamic and Hydraulic Origin

Turbomachines (turbines, centrifugal pumps, fans, etc.) generate vibrations due to the excitations of the driven fluid. Clearly, for such machines harmonics forces are generated by the rotating blades (N), i.e., components at passing blade frequency (Nf_r) and harmonics are relevant. Wide-band vibrations also exist and are due to fluid turbulence and cavitation. These wide-band vibrations are high-frequency dominated. Several studies are being conducted to adapt ‘specific signal processing tools’ to analyze these phenomena. Wavelets are the expected candidate because of their ‘fractal’ nature.

Table 4 Time and frequency characteristics of faulty gear vibrations, (f_{ri} shaft rotation, f_m meshing frequency).

Types of faults	Frequency domain	Time domain	Comments
Eccentricity	Side bands $f_m \pm kf_{ri}$	Modulation at shaft rotation speed	New gears often exhibit these modulations
Misalignment Machining effects	Increase of f_m and harmonics 'Ghost' component		Frequency related to the gear manufacturing machine
Backlash Wear	Higher gear mesh harmonics Increase f_m , harmonics and RMS value	RMS, crest value, etc.	Noisy gear Low evolution faults
Spalling (individual teeth)	$af_m \pm kf_{ri}$	Repetitive impacts at f_{ri} , small impacts when incipient fault	Amplitude modulation
Cracks (individual teeth)	$af_m \pm kf_{ri}$	Repetitive impacts at f_{ri} , small impacts when incipient fault	High rate evolution fault Concerns hard case hardened gears
Rupture	$af_m \pm kf_{ri}$	Wide-band spectra	Phase and amplitude modulation High rate evolution fault
			Repetitive high-level impacts

Synthesis

We have showed that most of the faults occurring in rotating machines may have more or less complex underlying models. This knowledge is of importance to achieve detection and diagnosis of faults in rotating machines in order to take maintenance actions or to achieve quality control. The type of expected signal helps in the definition of the more suitable signal processing technique.

It is useful to summarize the results with tables giving the symptoms of the main faults occurring in rotating machines, classified into three categories:

- faults generating signals (that may be harmonic or impulse repetitive) with fundamental frequency synchronized to the main shaft rotation speed (**Table 5**)
- generating signals not synchronized to the rotation speed (**Table 6**)
- generating random signals (**Table 7**).

These tables clearly show that different faults may have similar symptoms. Signal processing is one way to identify the faults without any ambiguities. Knowledge-based techniques (artificial intelligence, neural networks, etc.) may be the second way.

Table 5 Excitations generating signals synchronous with the shaft rotation (f_r)

Excitations	Main frequencies	Other characteristics	Comments	Direction
Unbalance	$1f_r$	Elliptic orbit		Radial
Misalignment	$1f_r, 2f_r, 4f_r, 6f_r$	Double orbit		Axial, radial

SIGNAL INTEGRATION AND DIFFERENTIATION

S Dyne, University of Southampton, Southampton, UK

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0053

The need to differentiate and integrate measured signals arises frequently in the analysis of vibration signals. For example, an accelerometer measures surface acceleration but we may be interested in surface velocity or even displacement requiring a single or double integration of the measured signal. Conversely a linear voltage differential transform (LVDT) gauge attached to a cam measures displacement directly but this would need to be differentiated once to obtain velocity and twice to obtain acceleration. This article describes the integration and differentiation of vibration signals and demonstrates the performance of algorithms for the integration and differentiation of sampled signals. Although the algorithms have been previously published widely as difference equations, Lynn and Fuerst was the inspiration for their representation as sampled signal filters and for the expressions and graphs of their performance.

Continuous vibration signals

The processes of differentiation and integration are covered by elementary calculus courses. A key result for vibration arises from the differentiation of a harmonic signal amplitude A and radian frequency ω :

$$\frac{d}{dt} A \cos \omega t = -A\omega \sin \omega t$$

That is, differentiation increases the amplitude of the signal by a factor ω and introduces a 90° phase shift. Figure 1 shows a displacement signal with radian frequency $\omega = 2 \text{ rad s}^{-1}$ together with the corresponding velocity signal. We see both the amplification factor of ω and the 90° phase shift. Similarly, for integration:

$$\int A \cos \omega t dt = (A/\omega) \sin \omega t$$

and this reduces the amplitude by a factor ω and introduces a 90° phase shift in the opposite direction to differentiation. Note that if the frequency is given as f in Hz then the amplitude factor is $2\pi f$.

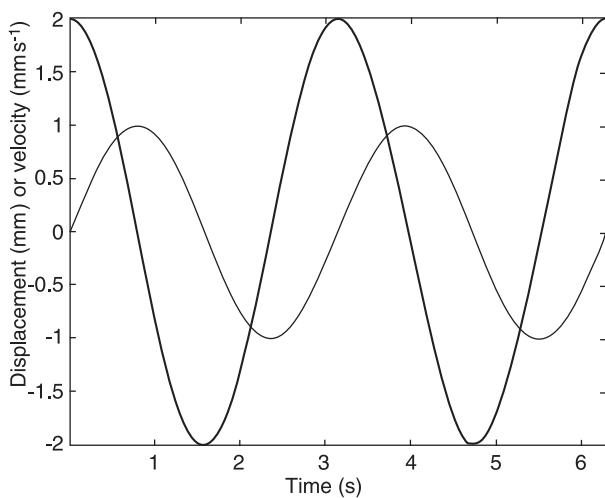

Figure 1 Harmonic displacement and corresponding velocity signal for $\omega = 2 \text{ rad s}^{-1}$. (—) Displacement; (---) velocity.

The analytical results are sometimes used directly: suppose, for example, that we wish to determine the peak velocity of a component on a machine operating at 3000 rpm and we have an accelerometer signal which reveals that the vibration is dominated by a harmonic component RMS amplitude 10 g. In this case:

$$A = 9.81 \times 10\sqrt{2} = 139 \text{ m s}^{-2}$$

$$\omega = 2\pi f = \frac{2\pi \times 3000}{60} = 314 \text{ rad s}^{-1}$$

so the peak vibration velocity level is:

$$\frac{A}{\omega} = \frac{139}{314} = 0.44 \text{ m s}^{-1}$$

The analytical expressions have some fairly important implications for the integration and differentiation of all vibration signals. First, since differentiation increases amplitude by a factor ω we may think of this as a process which amplifies high-frequency components (where ω is large) while attenuating low-frequency components (where ω is small) – in effect a differentiator behaves like a high-pass filter. Conversely, integration has the opposite effect. Here the amplification is greatest at low frequencies and attenuation is produced at high frequencies, so integrators act as low-pass filters. Finally, we can use the analytical results to test the performance of algorithms to compute the differentiation and integration of sampled signals which we shall explore later in this article.

At very low frequencies the integration amplification factor $1/\omega$ can become very large. Thus, any DC drift or spurious low-frequency noise in a signal will become amplified by the integration process and this may dominate the integrated signal. Consider, for example, an acceleration signal comprising a harmonic component amplitude, A but with a steady DC offset, A_0 . The integrated signal is:

$$\int (A \cos \omega t + A_0) dt = (A/\omega) \sin \omega t + A_0 t$$

The term due to the offset $A_0 t$ superimposes a ramp upon the harmonic component and for large values of t this ramp may dominate the signal. If the signal were to be integrated a second time to produce a displacement, this integrated signal would be:

$$\int \left(\frac{A}{\omega} \sin \omega t + A_0 t \right) dt = (A/\omega^2) \cos \omega t + A_0 t^2$$

and the offset term has now produced a superimposed parabola $A_0 t^2$ and this can dominate the signal for even very small values for t .

For these reasons it is customary to high-pass-filter a signal to remove any low-frequency or DC offset or drift components prior to integration. Analog filters are often used for this, and the ‘AC-coupled’ input to signal conditioning is particularly appropriate for this application. A high-pass filter with a cut-off of 0.1–10 Hz is also suitable. It should be noted that, as the vibration signals generated by piezoelectric sensors are inherently ‘AC-coupled’, removal of any low-frequency components in the signal should present no particular difficulties.

An illustration of integration as a filtering operation is provided by Figure 2 which shows the acceleration and corresponding velocity of a transient vibration. We observe that the velocity time history appears to be smoother than the acceleration time history. This is because of the low-pass filtering characteristic of the integration process between acceleration and velocity.

Sampled Signals

Differentiation

Modern signal analysis is carried out using digital computations on sampled signals. The conversion from an analog to digital signal is discussed elsewhere but a most important parameter in the conversion is the sample rate F_s and corresponding sample interval $\Delta t = 1/F_s$. We denote the sampled

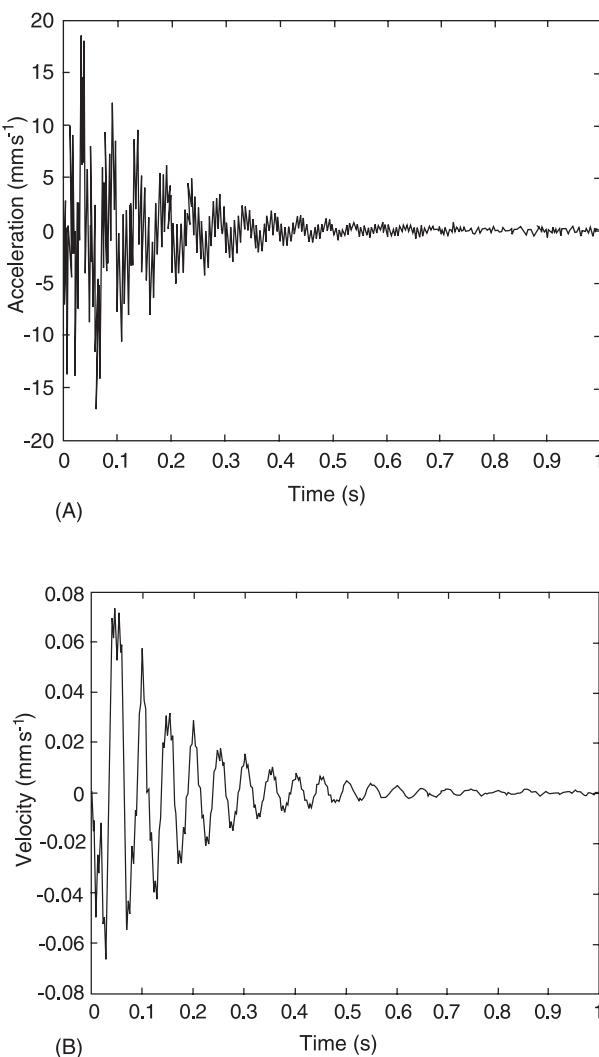

Figure 2 Comparison of transient signals. (A) Transient vibration acceleration; (B) transient vibration velocity.

values of a continuous signal $x(t)$ by the sample values $x(n)$, $n = 0, 1 \dots N - 1$.

We now consider algorithms that will differentiate and integrate a sampled input signal $x(n)$ to produce an output signal $y(n)$. Conceptually the simplest differentiator arises from the definition of differentiation as the limit of a ratio of small changes. This expresses the differential coefficient as the limit of a ratio as the small change in the independent variable (time, for vibrations) becomes infinitesimally small:

$$y = \frac{dx}{dt} = \lim_{\delta t \rightarrow 0} \frac{\delta x}{\delta t}$$

For the differentiation of a vibration signal, then, the differential coefficient would be the difference between two successive values divided by the sample interval:

$$y(n) = \frac{x(n) - x(n - 1)}{\Delta t}$$

This differentiator is called the first-order difference approximation.

Let us now investigate how good this algorithm is compared with the ideal behavior that we discussed above. Taking the z -transform of this relation (a unit sample delay corresponds to z^{-1} so the z -transform of $x(n - 1)$ is $z^{-1}X(z)$) gives:

$$Y(z) = \frac{X(z) - z^{-1}X(z)}{\Delta t} = \frac{1 - z^{-1}}{\Delta t} X(z) = H(z)X(z)$$

where: $H(z) = (1 - z^{-1}) / \Delta t$. Thus, differentiation (using this method) amounts to a filtering operation using a filter with transfer function $H(z)$. We can use tools developed for digital filters to analyze the performance of this differentiator. In particular, we obtain the frequency response function $H(j\omega)$ (note that many textbooks on signal processing use a normalized frequency Ω when dealing with the frequency response characteristics of filters where $0 < \Omega < \pi$ and where the upper frequency limit of π corresponds to half the sample rate of the process $F_S/2$. The relationship between actual frequency ω and the normalized frequency Ω is $\omega = \Omega F_S = \Omega / \Delta t$) by replacing z^{-1} by $e^{-j\omega\Delta t}$:

$$H(j\omega) = \frac{1 - e^{-j\omega\Delta t}}{\Delta t} = \frac{1 - \cos \omega\Delta t + j \sin \omega\Delta t}{\Delta t}$$

The modulus of this is:

$$\begin{aligned} |H(j\omega)| &= \left[\frac{(1 - \cos \omega\Delta t)^2 + \sin^2 \omega\Delta t}{\Delta t} \right]^{1/2} \\ &= \frac{2 \sin(\omega\Delta t/2)}{\Delta t} \end{aligned}$$

How does this compare with the ideal differentiator modulus which simply multiplies by ω ? Figure 3 shows that, for small values of ω , the filter behaves like an ideal differentiator but as ω approaches the folding frequency of πF_S the filter gain is restricted to a value of $2F_S$, so the differentiator produces lower amplitude output than is required at higher frequencies. An implication of this is that, in addition to the normal aliasing considerations, use of the integration/differentiation algorithms presented here may impose even more stringent requirements upon the sample rate F_S to achieve a given level of amplitude accuracy.

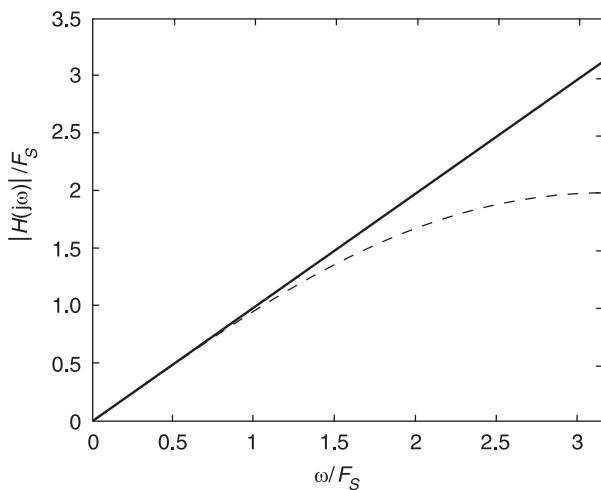

Figure 3 Comparison of the frequency response of an ideal differentiator and an algorithm based on the first-order difference approximation. (—) Ideal; (---) first-order difference.

It can be shown in Lynn and Fuerst that a digital filter can be designed which takes the ideal differentiator modulus and phase into account. The coefficients of such a filter are:

$$h(n) = \frac{-1}{n}, \quad n = \pm 1, 3, 5 \dots$$

$$h(n) = \frac{1}{n}, \quad n = \pm 2, 4, 6 \dots$$

and:

$$h(0) = 0$$

This is an acausal filter, i.e., the filter responds before an input has arrived (which is obviously impractical for real-time analysis), which is antisymmetric about $n = 0$ with infinitely long ‘tails’. In practice, we would restrict the filter to use finite number of points and put a delay into the filter to make it causal. So, for example, a seven-point filter would have the transfer function:

$$H(z) = \frac{2 - 3z^{-1} + 6z^{-2} - 6z^{-4} + 3z^{-5} - 2z^{-5}}{6\Delta t}$$

which corresponds to the difference equation:

$$\begin{aligned} y(n) = & [2x(n) - 3x(n-1) + 6x(n-2) - 6x(n-4) \\ & + 3x(n-5) - 2x(n-6)]/6 \end{aligned}$$

The frequency response of this filter is shown in Figure 4. Note the ripples due to the truncation of

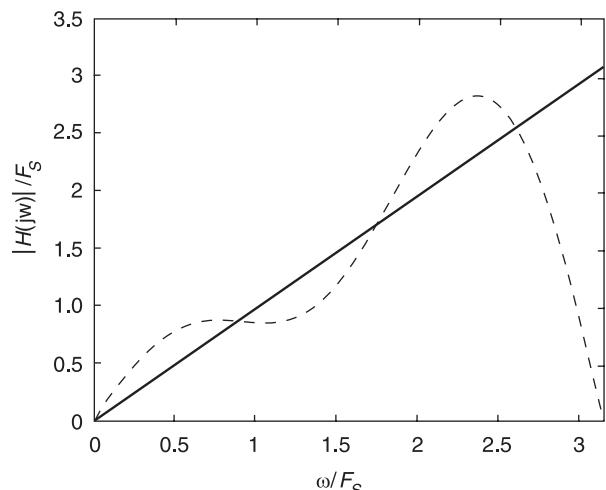

Figure 4 Comparison of an ideal differentiator and a filter designed using an improved digital algorithm. (—) Ideal; (---) improved differentiator.

the infinite series (this could be reduced by use of a window on the filter coefficients).

Many systems which implement differentiation use only the simplest first-order approximation, above, as the more refined algorithms produce only a small benefit but at the expense of considerable complexity.

Integration

We now consider the integration of sampled signals. We use as a starting point three algorithms that are often taught in a foundation course on numerical analysis for numerical integration: the running sum, the trapezium rule, and Simpson’s rule.

Running Sum

The running sum amounts to finding the area under a sampled signal, assuming all sample values are held constant over the sample interval (Figure 5A). It is sometimes called the zero-order hold approximation.

The difference equation for a running sum is straightforward: the value of the integrated signal is the sum of the previous value and the area under the rectangle at the current point:

$$y(n) = y(n-1) + x(n) \times \Delta t$$

where signal $x(n)$ is integrated to produce $y(n)$. It can be seen that this recursive equation is actually identical to the equation for the first-order difference approximation to the differentiation with variables x and y reversed.

We can again use digital filter theory to investigate the performance of this algorithm and to compare

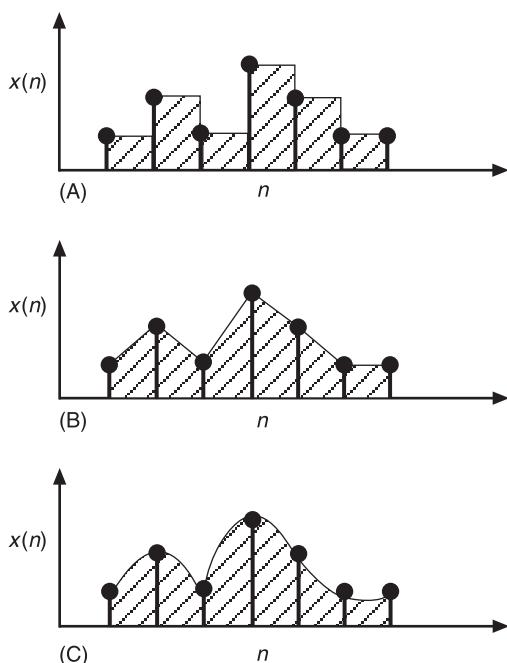

Figure 5 Integration algorithms using various interpolation methods. (A) Zero-order hold; (B) trapezium rule; (C) Simpson's rule.

this with an ideal integrator. The z -transform of the difference equation can be used to define a filter for the integration process:

$$Y(z) = z^{-1}Y(z) + \Delta X(z)$$

hence:

$$Y(z) = \frac{\Delta t}{1 - z^{-1}} X(z) = H(z)X(z)$$

where $H(z) = \Delta t / (1 - z^{-1})$ defines the filter for the running sum approximation for integration.

Trapezium Rule

For the trapezium rule we replace the zero-order hold interpolation with a straight line (or linear) interpolation between sample values (Figure 5B). It can be seen that the additional area to be added to the accumulated integration sum is the average of the two sample values multiplied by the sample interval so the difference equation becomes:

$$y(n) = y(n-1) + \frac{\Delta t}{2} [x(n) + x(n-1)]$$

This gives a trapezium rule filter transfer function:

$$H(z) = \frac{\Delta t(1 + z^{-1})}{2(1 - z^{-1})}$$

Simpson's Rule

For Simpson's rule, the interpolation between sample points is extended to quadratic segments between three sample values (Figure 5C) producing the difference equation:

$$y(n) = y(n-2) + \frac{\Delta t}{3} [x(n) + 4x(n-1) + x(n-2)]$$

and the corresponding filter:

$$H(z) = \frac{\Delta t(1 + 4z^{-1} + z^{-2})}{3(1 - z^{-2})}$$

Now the integrated signal is only updated for every other sample so that the integrated signal is effectively sampled at half the sample rate of the original signal. It should be noted that this can be most inconvenient for vibration signal analysis where we would generally wish to maintain the same sample rate throughout.

The performance of the three approximations is shown in Figure 6. The plot shows filter gain on a decibel scale ($0 \text{ dB} = \text{unity gain}$) against frequency on a logarithmic scale up to $\omega = \pi F_S$. We have used these scales because the performance of all three algorithms is very similar for frequencies up to $\omega = F_S$. Thereafter the running sum approximation produces too much gain and the trapezium rule approximation produces too much attenuation. The Simpson's rule approximation is closer to the ideal than the other

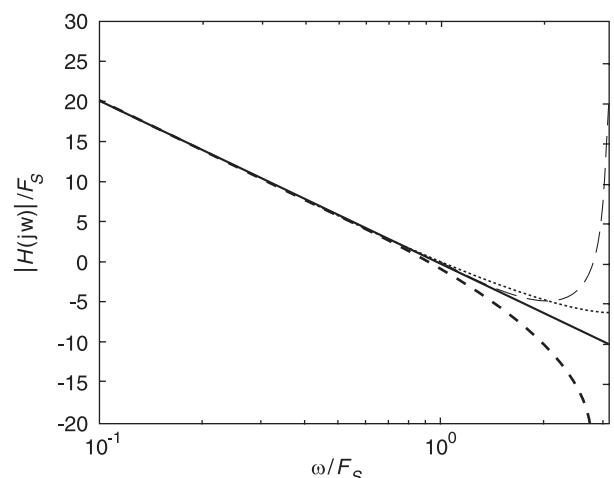

Figure 6 Comparison of the frequency response of an ideal integrator with three digital approximations. (—) Ideal; (—) Simpson's rule; (· · ·) running sum; (- - -) trapezium rule.

approximations until about $\omega = 2.1F_S$ but then produces too much gain.

The three algorithms described above have effectively interpolated between the sampled values using polynomials of order 0, 1, and 2 but the first two methods are used most commonly for the integration of vibration signals as the improved accuracy of the third is obtained at the expense of complexity and the inconvenience of the sample rate change. There is, however, an interpolation algorithm for band-limited, sampled data, which is an improvement on any possible polynomial approximation. Indeed, Shannon's sampling theorem states that a function $x(t)$ may be expressed in terms of its sample values $x(n)$ by the relation:

$$x(t) = \sum_{n=-\infty}^{\infty} x(n\Delta t) \frac{\sin(\pi(t - n\Delta t)/\Delta t)}{\pi(t - n\Delta t)/\Delta t}$$

It can be shown in Dyne and Hammond that, while integration based upon this interpolation is superior to all three polynomial approximations, this is very much at the expense of simplicity and is therefore not appropriate for the majority of vibration signals.

Differentiation and Integration in the Frequency Domain

As we have seen previously, the differentiation of a harmonic signal amounts to multiplication by an angular frequency, ω , and a change of phase of 90° . Integration is a division by ω with a phase change of 90° in the opposite direction. It follows that differentiation and integration may be carried out in the frequency domain, i.e., on the spectral representation of signals, by multiplying the spectrum by $j\omega$ or dividing the spectrum by $j\omega$, respectively. So, for example, the Fourier transform of velocity can be found by multiplying the Fourier transform of displacement by $j\omega$ or by dividing the Fourier transform of the acceleration by $j\omega$.

Care needs to be exercised in the case of spectra which represent energy, or power quantities such as the power spectral density or the autospectral density formed using the product of a Fourier transform and its conjugate. For example the autospectrum of a segment of signal $x(t)$ of duration T , is the value of the product of the Fourier transform $X(f)$ and its conjugate $X^*(f)$:

$$S_{xx}(f) = \frac{X(f)X^*(f)}{T}$$

If $x(t)$ represents a velocity signal the autospectrum of the acceleration signal $y(t)$ would be:

$$S_{yy}(f) = \frac{Y(f)Y^*(f)}{T} = \omega^2 S_{xx}(f)$$

So the spectrum of the differentiated signal is found by multiplying the spectrum by ω^2 because both the Fourier transform and the conjugate take the $j\omega$ factor.

It is also worth noting that integration in the frequency domain by dividing the Fourier transform by $j\omega$ with a view to subsequent transformation back into the time domain is not straightforward and that there are pitfalls associated with the singularity at $\omega = 0$. Similarly, division of the DFT/FFT(fast Fourier transform) of an N -point sequence:

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-j2\pi nk/N}$$

by frequency $\omega_k = (2\pi kF_S)/N$, is subject to similar difficulties when subsequent transformation back into the time domain is under consideration. A pragmatic approach is often to set the value of the Fourier transform (or FFT) to zero at 0 rad s^{-1} . However, while this amounts to only a single point error in the frequency domain, the error will have an impact on the whole signal following transformation back into the time domain. This method of integrating signals is therefore not recommended.

Summary

- Integration and differentiation of harmonic signals, with radian frequency ω , effectively multiply and divide the signals by a factor of $j\omega$, respectively. If the frequency is given as f in Hz then the factor is $j2\pi f$.
- For sampled signals, algorithms which approximate the effect of differentiation and integration can be implemented using difference equations and/or the equivalent digital filters.
- The frequency domain performance of differentiators/integrators can be investigated using tools developed for the interpretation of digital filters.
- The performance of the algorithms presented in this article is generally better at lower frequencies than at frequencies approaching the folding frequency $\omega = \pi F_S$ and this may have implications for the choice of F_S .
- The frequency domain characteristics can be improved by increasing the complexity of the filters but this is generally not necessary for measured vibration signals.
- Starting from the spectrum of displacement, velocity or acceleration, it is very straightforward to

derive the spectrum of any of the other quantities by multiplying by $j\omega$ to differentiate and by dividing by $j\omega$ to integrate. However, subsequent transformation back into the time domain is not recommended because of the effects of the singularity at $\omega = 0$.

General

Many signal-processing techniques, which are relatively modern, extract models from measured data. In the context of vibration engineering, two major application areas utilize such techniques: signal modeling, and system identification. This article deals with signal modeling, and some applications.

Signal Modeling

Consider a signal $x(i\Delta t)$, where $i = 0, 1 \dots n$. It may be possible to model the signal with a number of parameters p , where $p < n$. Signal modeling is thus concerned with the representation of signals in an efficient manner.

Applications of such signal models include data compression, signal prediction, classification, diagnostics and spectral analysis techniques.

It will be convenient to classify methods according to types of signal, whether random or deterministic.

Signal Models

Stochastic Models

The signal models used in vibration analysis include random process models and time series models that approximate discrete time processes encountered in

practice, specifically sampled signals acquired from vibrating systems. Three major types, all of rational polynomial form in the Z -domain (see **Transform methods**), are used:

1. AR: autoregressive models
2. MA: moving average models
3. ARMA: autoregressive moving average models

One convenient point of view is to model these processes as being generated by filtering white noise by linear shift invariant filters. The following is a brief description of these three processes.

MA (moving average) process This is described as:

$$\begin{aligned} x_i &= w_i + b_1 w_{i-1} + b_2 w_{i-2} + \dots + b_q w_{i-q} \\ &= \sum_{k=0}^q b_k w_{i-k} x_i = \mathbf{w}^T \mathbf{b} \end{aligned} \quad [1]$$

with:

$$\mathbf{w} = [w_i \ w_{i-1} \ \dots \ \dots \ w_{i-q}] \quad \mathbf{b} = [1 \ b_1 \dots b_q]$$

In the context of linear systems, w is the system's input (white noise) and x the output. Applying a Z transform results in a transfer function:

$$X(z) = \sum_{k=0}^q b_k z^{-k} W(z) = B(z) W(z) \quad [2]$$

where $B(z)$ is a rational system with q zeros – an all-zero system

AR (autoregressive) process This is described by:

$$\begin{aligned} x_i &= -a_1 x_{i-2} - a_2 x_{i-1} - \cdots - a_{i-p} + w_i \\ &= -\sum_{k=1}^p a_k x_{i-k} + w_i \end{aligned} \quad [3]$$

This can be considered as a linear regression of x on itself, with w the residual, hence the name autoregressive.

In the Z domain:

$$X(z) = \frac{1}{1 + \sum_{k=1}^p a_k z^{-k}} W(z) = \frac{1}{A(z)} W(z) \quad [4]$$

where $1/A(z)$ is a rational system with p poles, i.e., an all-pole system.

ARMA (autoregressive moving average) process

This is a combination of the above two processes:

$$x_i = -\sum_{k=1}^p a_k x_{i-k} + \sum_{k=0}^q b_k w_{i-k} \quad [5]$$

$$X(z) = \frac{B(z)}{A(z)} w(z) \quad [6]$$

where $B(z)/A(z)$ is a rational system with p poles and q zeroes.

Deterministic Models

These are based on equating a signal to the impulse response of a linear shift invariant filter, having a rational system function:

$$X(z) = H(z) = \frac{B(z)}{A(z)} \quad [8]$$

where $B(z)$ and $A(z)$ have q and p zeros, respectively. The matching of a given signal x_i to such an impulse response is called a Padé matching (or a Padé approximation).

This can also be stated by a time domain formulation as:

$$x_i = \sum_{k=1}^p c_k r_k^i$$

where r_k are the roots of the denominator of $A(z)$ and c_k are the complex coefficients of the expansion. This is similar to an original formulation (dating from

1795) created by Baron de Prony, and called the Prony model. The original model considered only the case of real roots r_k , whereas the interest in the context of vibration signals usually deals with complex roots:

$$x_i = \sum_{k=1}^p A_k \exp(\alpha_k + j2\pi f_k) \quad [9]$$

i.e., decaying oscillatory signals.

Modeling of Signals

The signal models are used to approximate data. Thus, the data generated by the model will approximate measured data. The sense in which the approximation is to hold has to be defined. For example, we may require that the autocorrelation (and hence the power spectral density) of the data generated by the model corresponds to that of the observed data.

The modeling task consists of two major phases. In the first one, the model's structure (or form) is defined, for example whether it is an AR or ARMA structure. This may also include the determination (or choosing) of the model's order, for example p in the AR case. In the second phase the model's parameters are found, such that the best approximation results. Obviously the criterion used must be defined, and is not necessarily unique.

The parameters themselves may have a direct physical interpretation. A synthetic model, where the parameters are purely mathematical, can still be used for the purpose of simulation and characterization. In what follows we address first the modeling of random data.

Modeling of Stochastic Signals

ARMA models From eqn [5], multiplying by x_{i-k} , we get:

$$R_x(l) = \sum_{k=1}^p a_k R_x(l-k) + \sum_{k=0}^q b_k R_{wx}(l-k) \quad [10]$$

where R are correlation functions. Let us consider x_i as the result of filtering the white noise w by a filter with impulse response b :

$$x_i = h_i \otimes w_i \quad [11]$$

Then:

$$R_x(l) + \sum_k^p a_k R_x(l-k) = \sigma_w^2 \sum_{k=0}^q b_k b_{k-l} = \sigma_w^2 c_k \quad [12]$$

where:

$$\begin{bmatrix} R_x(0) & R_x(-1) & \dots & R_x(-p) \\ R_x(1) & R_x(0) & & \\ \vdots & & & \\ R_x(p) & & \dots & R_x(0) \end{bmatrix} \begin{bmatrix} 1 \\ a_2 \\ a_2 \\ \vdots \\ a_p \end{bmatrix} = \sigma_w^2 \begin{bmatrix} 1 \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad [14b]$$

$$c_k = \sum_{k=1}^q b_k b_{k-l} \quad [13]$$

Or, in matrix notation:

$$\mathbf{Ra} = \sigma_w^2 \mathbf{I}, \quad \text{with } \mathbf{I} = [1 \ 0 \ 0 \ 0]^T$$

Thus:

$$R_x(l) + \sum_{k=1}^p a_k R_x(l-k) = \begin{cases} \sigma_w^2 c_k & 0 \leq l \leq q \\ 0 & l > q \end{cases} \quad [13a]$$

which for $k = 1, 2$:

$$\begin{bmatrix} R_x(0) & R_x(-1) & \dots & R_x(-p) \\ R_x(1) & R_x(0) & & R_x(-p+1) \\ \vdots & & & \\ R_x(q) & R_x(q-1) & & R_x(q-p) \\ \dots & \dots & \dots & \dots \\ R_x(q+1) & & & R_x(q-p+1) \\ \vdots & & & \vdots \\ R_x(q+p) & & & R_x(q) \end{bmatrix} \begin{bmatrix} 1 \\ a_1 \\ a_2 \\ \vdots \\ a_p \end{bmatrix} = \sigma_w^2 \begin{bmatrix} c_1 \\ \vdots \\ c_q \\ \dots \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad [13b]$$

This is known as the Yule Walker (YW) equation.

AR models AR models are probably the most widely used models, and we will first concentrate on them.

From eqn [10], where $q = 0$, we have:

$$R_x(l) = - \sum_{k=1}^p a_k R_x(l-k) \quad [14a]$$

Using $k = 1, 2$, we get:

The modeling consists of computing the elements a of \mathbf{a} . An estimate of \mathbf{a} can be solved by estimating $R(k)$ based on available data, i.e., by:

$$R(l) = E[x_k x_{k-l}] \quad [15]$$

The special symmetry noted for R is that of a Toeplitz matrix. A recursive solution, known as the Levinson-Durbin procedure, can solve this type of matrix equation in an efficient manner. Not only does it eliminate the need for a matrix inversion; at each iteration it increases the dimension of \mathbf{a} (i.e., the model's order), a valuable feature when the order p has to be dealt with.

Some available procedures are based on a slightly different interpretation of the AR model (eqn [5]). This can be considered as linear prediction, where x_i is a linear combination of past observations x_{i-k} , and w is the residual or prediction error. This is a forward prediction procedure. A backward prediction can also be defined, where it is desired to predict the next earlier value, as per:

$$x_{i-p} = -b_1 x_{i-p+1} - b_2 x_{i-p+2} + \dots w_b \quad [16]$$

It can be shown that the YW equation:

$$\mathbf{Rb} = \sigma_{wb}^2 \mathbf{I} \quad [17]$$

can be used to solve \mathbf{b} , which minimizes the backward error w_b (in some specific sense).

Least-square estimation methods for AR modeling These are based on casting the AR prediction equations as a set of linear equations in the parameter vector \mathbf{a} , and minimizing the mean square of the prediction error.

From eqn [3]:

$$w_i = x_i + \sum_{k=1}^p a_k x_{i-k} \quad [18]$$

A matrix equation can be cast as:

$$\begin{bmatrix} w_1 \\ \vdots \\ \vdots \\ w_p \\ \vdots \\ \vdots \\ w_n \\ w_{n+1} \\ \vdots \\ \vdots \\ w_{n+p} \end{bmatrix} = \begin{bmatrix} x_0 & \dots & 0 \\ \vdots & & \vdots \\ \vdots & & \vdots \\ x_{p-1} & \dots & x_0 \\ \vdots & & \vdots \\ \vdots & & \vdots \\ x_{n-1} & \dots & x_{n-p} \\ x_n & \dots & x_{n-p+1} \\ \vdots & & \vdots \\ \vdots & & \vdots \\ x_{n+p-1} & \dots & x_n \end{bmatrix} \begin{bmatrix} a_1 \\ \vdots \\ a_p \end{bmatrix} + \begin{bmatrix} x_1 \\ \vdots \\ \vdots \\ x_p \\ \vdots \\ \vdots \\ x_n \\ x_{n+1} \\ \vdots \\ \vdots \\ x_{n+p} \end{bmatrix} \quad [19a]$$

$$\mathbf{w} = \mathbf{X}\mathbf{a} + \mathbf{x} \quad [19b]$$

With the least-squares solution:

$$\hat{\mathbf{a}} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{x} \quad [20]$$

The expression $\mathbf{X}^T \mathbf{X}$ is a correlation matrix, based on observed data, and has already been encountered in eqn [13]. Correlation functions computed from data are used. In that sense it is similar to the solution of the YW equations, as computed estimators of correlation functions, and not the unknown theoretical correlation functions, are the only ones available for the solution.

Various computational schemes are available to the analyst, some of which depend on the range used. The method utilizing the range $0 \dots n$ is called the autocorrelation method. It computes by forcing x to be zero outside the observed interval, i.e., windowing. The Toeplitz structure is however kept, enabling the use of the Levinson recursion. The range $i = n + p$ is called the covariance method. No windowing is now implied, which typically gives more accurate results, but the Toeplitz structure no longer exists. It can be shown that the autocorrelation method is equivalent to the YW method.

A modified covariance method is based on a similar approach, but minimizes the forward and backward error terms. The names are misnomers, due to historical reasons, and have no relation to the statistical functions of autocorrelation and covariance.

Another procedure, Burg's method, also minimizes the sum of squares of the forward and backward prediction errors, but uses a recursive procedure up to the p th parameter a_p , with the advantage that the resulting $A(z)$ is always stable.

Most of the above procedures are well documented and readily available in commercial as well as public domain software packages.

MA and ARMA models The ARMA model has more degrees of freedom, with a greater latitude in generating spectral shapes with sharp maxima and minima. The computational aspects are however much more complex. This is mainly due to the fact that the equations to be solved are nonlinear in the model's parameters. There exist a multitude of possible approaches, and only a few will be briefly described here.

We first start with MA models. A relatively simple approach is Durbin's method. A high-order AR model $A_p(z)$ is first fitted. A lower-order MA model $B_q(z)$ can then be obtained as:

$$A_p(z) \approx \frac{1}{B_q(z)} = \frac{1}{b_o + \sum_{k=1}^q b_k z^{-k}} \quad [21]$$

The two-step procedure thus consists of the following (Figure 1).

Fit a p th order model to the data, with a larger p than would have been used for pure AR model fitting.

Fit a q th-order model to the $B(z)$ sequence.

We turn now to ARMA modeling.

One possibility to reduce the computational complexity is applying a two-phase suboptimal procedure. First, the AR coefficients and then the MA are computed separately. In both phases a linear set of equations is solved. One typical algorithm is the following:

Fit a model via a well-established AR modeling algorithm, resulting in an approximate $A(z)$.

Apply an AR filter to the data, resulting in:

$$w(z) \frac{B(z)}{A(z)} \tilde{A}(z) \approx w(z)B(z)$$

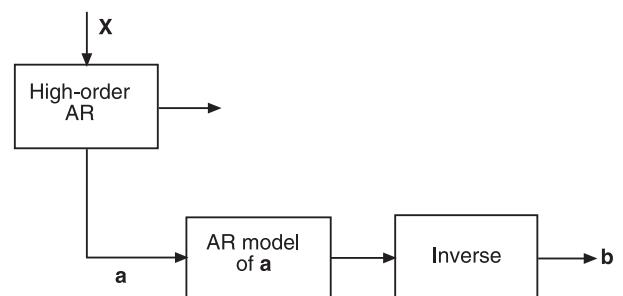

Figure 1 The Durbin moving average method. AR, autoregressive.

Fit an MA model to wB by an existing MA procedure (say, the Durbin logarithm). This is shown in **Figure 2**.

Simultaneous estimation of AR and MA parameter methods also exists, via iterative schemes. Basically an initial input excitation \tilde{w} is used. One possibility is then to identify a high-order AR model, in order to apply it as an inverse filter. Then an ARMA model is sought, such as to minimize an error between its output when driven by the assumed input w and the data x :

$$\text{Minimize } e^2 \left(x - \tilde{w} \frac{B}{A} \right)^2 \quad [22]$$

This is then linear in the coefficients a_k and b_k , and an iterative solution is readily found. Like most iterative searches for a minimum, convergence aspects need to be considered. Commercially available software for identification is often based on such iterative solutions.

Sequential methods A time-varying modeling is possible by sequential as opposed to block analysis. Techniques developed in the areas of adaptive filters can be used. As an example, let us mention the least mean square (LMS) method, where filter coefficients are updated as new data are incoming. This can be useful to track signals with relatively slow time-varying characteristics.

For the AR polynomial, the coefficients a_k will now be time-dependent. Thus, the equation will become:

$$x_i = \Phi_i^T \mathbf{a}_i + w_i = [-x_{i-1} \cdots x_{i-p}] \mathbf{a}_i + w_i \quad [23]$$

where the index 1 denotes the time dependency of \mathbf{a} . The coefficient vector is now updated as per:

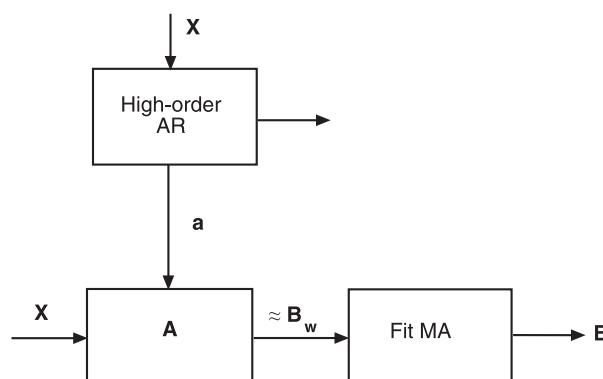

Figure 2 ARMA modeling. AR, autoregressive; MA, moving average.

$$\mathbf{a}_i = \mathbf{a}_{i-1} + \Delta \mathbf{a}_{i-1} \quad [24a]$$

and the following updating is the LMS algorithm:

$$\Delta \mathbf{a}_{i-1} = \mu \Phi_i^T (x_i - \Phi_i^T \mathbf{a}_{i-1}) \quad [24b]$$

where μ is the adaptive time constant which affects the adaptive performance, including its convergence. It is often suggested to use:

$$\mu = 0.01 / \sigma_x \quad [24c]$$

with σ_x the standard deviation of x . Other well-known adaptive schemes, like the RLS (recursive least square) and its various variations, are also options for the analysis of nonstationary signals.

Parametric Methods for Deterministic Signals

Model-based methods also exist for cases involving deterministic signals, such as decaying transients and harmonic signals.

Some modeling approaches attempt to approximate a signal x by an impulse response h of a linear shift time-invariant filter. In general, the transfer function of this filter is:

$$H(z) = \frac{B(z)}{A(z)} \quad [25]$$

The coefficients of H , a_k and b_k of A and B are found by minimizing the error term:

$$\begin{aligned} \text{Minimize } E &= \sum |e|^2 \\ e &= x - h \\ \frac{\partial E}{\partial a_k} &= 0 \quad k = 1, 2, \dots, p \\ \frac{\partial E}{\partial b_k} &= 0 \quad k = 1, 2, \dots, q \end{aligned} \quad [26]$$

This results in a set of equations which are nonlinear in a and b . Direct methods of solving are thus of iterative form, such as the method of steepest descent. One other method is the iterative prefiltering method (also known as the Steiglitz–McBride method) which is available in many commercial signal-processing packages.

Indirect methods are usually simpler to solve; among these are Padé's and Prony methods.

The basic Prony method consists of modeling the signal as a sum of exponentially decaying transients.

The fact that decaying oscillating signals are accommodated can make this modeling attractive for specific vibration signals, like those of impulse response of linear vibrating systems. The original Prony procedure thus starts with:

$$x_i = \sum_{k=1}^p c_k \exp(s_i \Delta T) + w_i = \sum_{k=1}^p c_k z_k^i + w_i \quad [27a]$$

where:

$$z_k = \exp(s_i \Delta T) \quad [27b]$$

$$\begin{aligned} x_0 &= c_1 + c_2 + \dots + c_p \\ x_1 &= c_1 z_1 + c_2 z_2 + \dots + c_p z_p \\ x_2 &= c_1 z_1^2 + c_2 z_2^2 + \\ x_{p-1} &= \\ x_p &= c_1 z_1^p + \\ x_N &= c_1 z_1^N + \dots + c_N z_p^N \end{aligned} \quad [28]$$

Let z_i be the roots of the polynomial:

$$p(z) = \sum_{k=1}^p a_k z^k = 0 \quad [29]$$

It is simple to show that:

$$\begin{aligned} a_0 x_0 + a_1 x_1 + \dots + a_{p-1} x_{p-1} &= 0 \\ a_0 x_1 + a_1 x_2 + \dots + a_p x_p &= 0 \\ \vdots &\vdots \end{aligned} \quad [30]$$

We thus solve eqn [30] for the a_i s. While the original Prony procedure was developed for p parameters using an equal number p of data points, a so-called overdetermined Prony procedure utilizes $N > p$ data points, and eqn [30] is in a least square sense.

The next step solves eqn [29] for z_k , using available root solvers. These are then used in eqn [28] (a Vandermonde matrix) to solve for the amplitudes c_k , again in least squares sense. The Prony method is a suboptimal procedure, computing in separate phases the parameters z_k and c_k , each one via a set of linear equations.

Another method which similarly solves separately for two sets of parameters via linear equations is often called the (modern) Prony method. Here an over-determined set of linear equations solves $A(z)$ and $B(z)$ of eqn [25]. While the original time domain version of the Prony model is eqn [27a], it is this

later Prony method which often prevails in many commercial software packages.

A comment comparing eqn [27] with fast Fourier transform analysis seems warranted. Whereas the DFT can only compute (and hence decomposes into) components of discrete frequencies of:

$$f_k = k \Delta f \quad \text{where} \quad \Delta f = \frac{1}{N \Delta T}$$

the Prony method has basis function of frequencies directly determined from the data.

Model order and overdetermination The accuracy of the parameters computed via the Prony method are highly affected by the existing signal-to-noise ratio and the model order chosen. Like all model-based methods, choosing too large a model order will result in poles which model noise terms. It is sometimes possible to estimate the signal model order via the rank of the covariance matrix of the signal (computable by a SVD decomposition).

An interesting phenomenon occurs with overdetermination of p , where p is the correct model order. In addition to generating noise-related poles, it is found that the signal-related poles will get closer to the true ones in the presence of noise. Thus it can be beneficial to choose too large a model order. The correct signal poles can be recognized by consecutively increasing the model order. Clustering of identified parameters will occur for the correct ones, while the location of the noise-related ones will be all over the parameter space.

Model-based spectral analysis

Procedure

Once a rational signal model is available, then the computation of the power spectral density is basically straightforward. For a linear system:

$$S_x(\omega) = S_w(\omega) |H(\omega)|^2 \quad [31]$$

where S_x is the power spectral density of the signal, and S_w that of the innovation process (or residual). H is the frequency response function of the signal model.

With:

$$\begin{aligned} S_w(\omega) &= S_w = \text{con} = P_w \Delta t \\ S_x(\omega) &= P_w \Delta t \left| \frac{B(\omega)}{A(\omega)} \right|^2 \end{aligned} \quad [32a]$$

where:

$$\begin{aligned} B(\omega) &= B(z)|_{z=\exp(i\omega\Delta t)} \\ A(\omega) &= A(z)|_{z=\exp(i\omega\Delta t)} \end{aligned} \quad [32b]$$

The power spectral density estimation thus consists of three basic steps (Figure 3):

- Step 1: selection of the signal model, including an appropriate order
- Step 2: estimation of the model parameters
- Step 3: insertion of the parameters into the theoretical power spectral density (equation).

The statistical properties of the estimated power spectral density depend heavily on the number of data points versus the number of model parameters. For the AR case, the result is asymptotically unbiased for large N . As parametric methods are often used in view of their improved frequency resolution, i.e., for time-limited records, such knowledge is of limited value. The variance of the estimators are roughly proportional to p/n , with p the model order.

Model or Selection

The smoothness of the PSDS function and the frequency-resolving power are strongly dependent on the model order chosen. One convenient point of view is that of data reduction, when $p + q$ parameters (plus the innovation process power) describe the characteristics of the data.

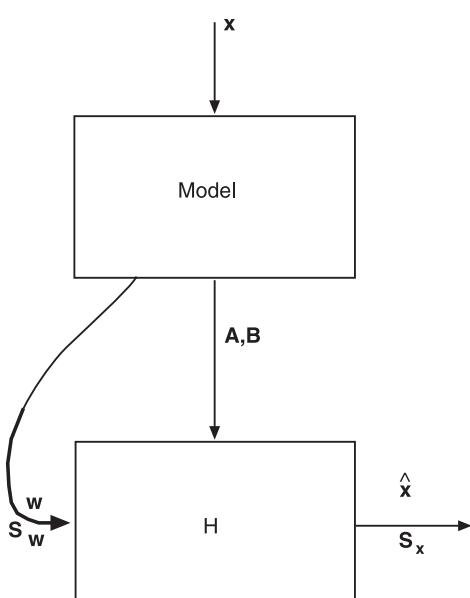

Figure 3 Model-based power spectral density.

For ARMA models, a search for reasonable orders is often an option, where the term reasonable is determined by heuristic arguments. Objective model orders, based on the minimization of specific criteria, mainly exist for AR models.

The following criteria achieve some balance between a high model order which causes a decrease in the prediction error power, and a penalty increasing with the model order.

The Final Prediction Error (FPE) Criterion

$$FPE(p) = \sigma_w^2 \frac{n + (p + 1)}{n - (p - 1)} \quad [33]$$

A smaller p/n ratio uses, on average, fewer data points per parameter a_k of the AR model. This results in less statistically accurate parameters. The order p minimizing $FPE(p)$ is then used as the optimal one.

The Akaike Information Criterion (AIC)

$$AIC(p) = n \ln (\sigma_w^2) + 2p \quad [34]$$

An information theoretic function is minimized. Actually, $AIC(p)$ and $FPE(p)$ will be asymptotically equivalent as $n \rightarrow \infty$.

The Minimum Description Length (MDL) criterion

$$MDL(p) = n \ln (\sigma_w^2) + p \ln (n) \quad [35]$$

The penalty term $p \ln (n)$ increases with both n and p . The MDL is claimed to be consistent for increasing n .

The practical choice of p is often problematic, as no clear minimum of any criterion may be evident. A local minimum may be erroneously chosen. Often the region where a criterion plateaus is the best alternative.

An example is shown in Figure 4. An AR-based power spectral density is computed for an acceleration signal measured on a beam undergoing flexural vibrations. A single record of $n = 1024$ data points is available for the analysis. Increasing the model's order decreases the power spectral density's smoothness, and spurious peaks seem to occur. Lowering the model order results in smoother power spectral densities. A fast Fourier transform power spectral density (based on analyzing the same data as a single record, i.e. without any averaging) is shown for comparison.

Computing the FPE, an order of $p = 10$ seems indicated (Figure 5). The resulting power spectral density is shown in Figure 4c. This smoothed power

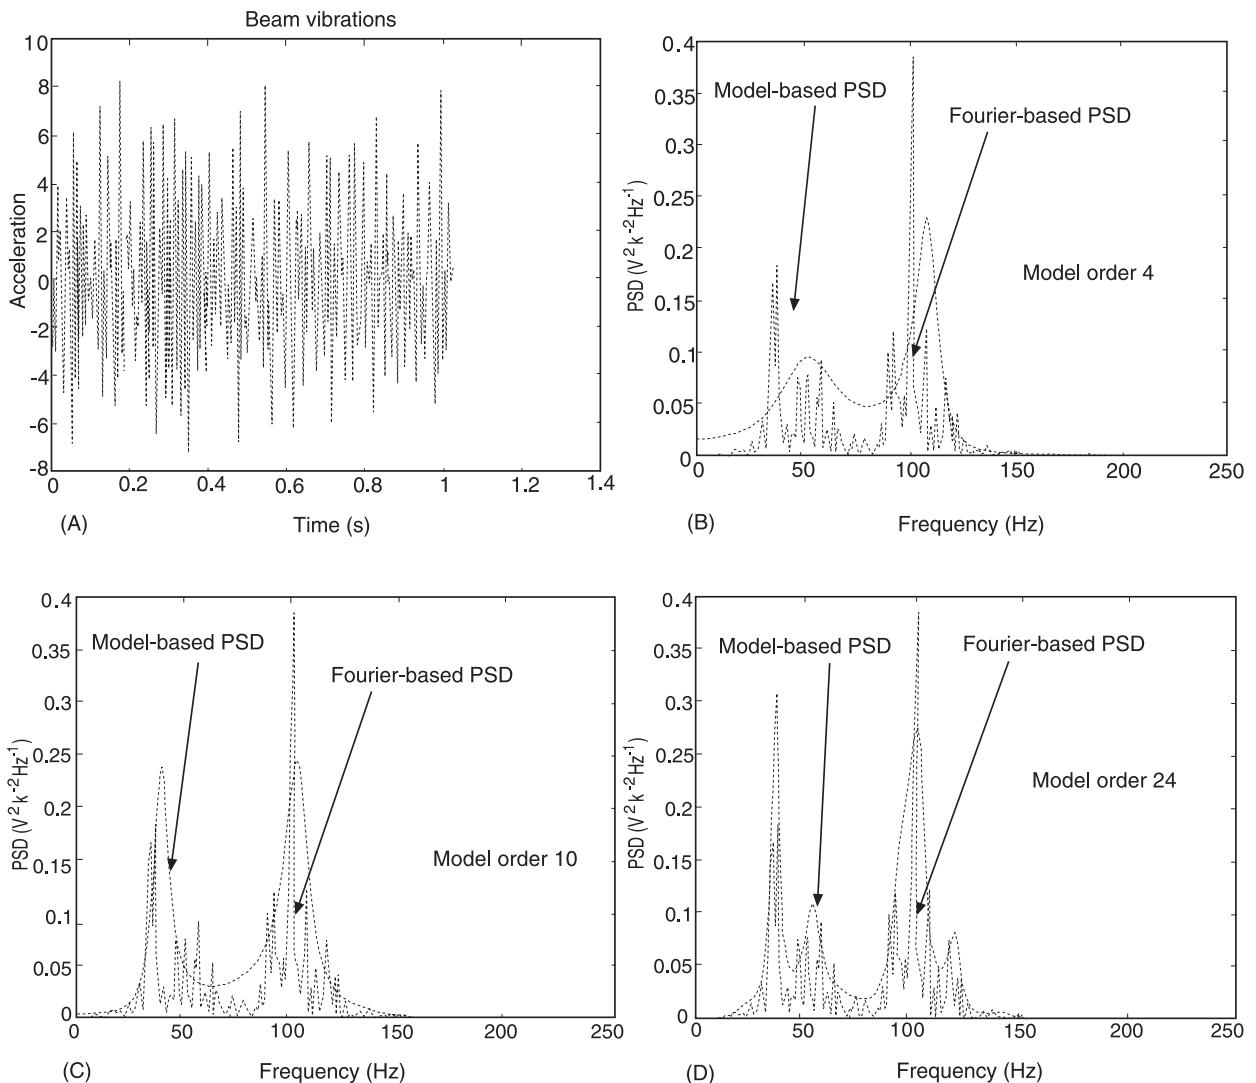

Figure 4 Fourier-based versus model-based power spectral density (PSD) of beam vibrations. (A) The time data; (B) $p = 4$; (C) $p = 10$; (D) $p = 24$.

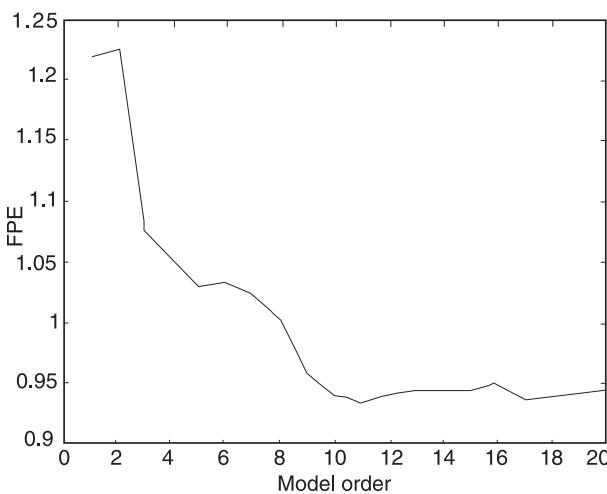

Figure 5 Akaike's criterion for beam vibration. FPE, final prediction error.

spectral density (compared to the fast Fourier transform based one) shows objective versus spurious peaks, i.e., those justified by the data (based on our model order criteria). Only additional external knowledge could indicate that additional peaks are significant.

The technique of overdetermination, already mentioned above, could also be used to identify true poles. Clustering of poles, around areas corresponding to spectral peaks, would occur while increasing the model order from 4 to 10 to 34.

Additional Analysis Methods

There exist many additional methods aimed at spectral analysis and estimation of frequencies of discrete line spectra. Only a few will be briefly mentioned, as their application to vibration signals is rare.

Subspace Methods

These are basically model-based methods aimed at estimating discrete components in the spectrum. The Pisarenko and multiple signal classification (MUSIC) are among the best known, and are aimed at estimating the frequency of line spectra. Thus they deal with signals composed of sinusoids and random components. They are based on the eigenanalysis of the correlation matrix of the observed data. For an n -point signal composed of m sinusoidal components and additive noise, the correlation space can be divided into two subspaces: a signal subspace with m eigenvectors, and a complementary subspace with $n - m$ eigenvectors. For practical situations, the largest m eigenvalues are then associated with the line spectra.

Minimum-variance Power Spectral Density

This is an adaptation of the maximum likelihood spectral analysis (hence actually a misnomer) developed for beam-forming applications. It is based on analyzing the signals by filters of unity gain, which minimize the output when a random signal is applied to them.

This is in contrast to classical spectral analysis, where the DFT filter bank (see **Transform methods**) has a constant bandwidth, independent of the signal's character. The frequency responses of the DFT filters are also less ideal, with side lobes and resulting leakage phenomenon.

Discussion

For vibration signal analysis, model-based techniques are a possible alternative to the classical, nonparametric Fourier-based ones. Some of the rationales for opting for such an approach are listed below.

1. Finite, limited data records: for the same data length, parametric methods have the potential of improved frequency resolution. If unlimited-duration signal durations are available, it is generally accepted that classical analysis performs better.
2. Again, for finite-duration data records, a smooth power spectral density is obtained. This follows from the computation of eqn [32] based on a limited number of model parameters. Using any defined criterion for model order selection, a best objective power spectral density is obtained for the given data.
3. Tracking time-dependent model parameters may be used to compute time-varying power spectral densities.

4. A model needs to be fitted to the data for the purpose of control, prediction, and diagnostics. While some models can be based on frequency domain representation, those based directly on time signals may be preferred.

In practice, the model-based spectral analysis is liable to many difficulties. The choice of model order is important. Misleading results may occur if the model chosen is not consistent with the signal generation process. For example, the best results for an ARMA process will result if an ARMA model is fitted, and the same goes for any other process. The practitioner can sometimes rely on physical insight, whenever possible. If mainly spectral peaks are anticipated (for example, for structural resonances), an all-pole (AR) model could be chosen. The AR model is also popular due to the easier computational load involved in the modeling, as a set of linear equations must be solved.

The choice of model order is perhaps the most important one in the analysis. Spurious spectral peaks occur if too large an order is chosen (i.e., overdetermination), as the contaminating noise will also be modeled.

The choice of the computational algorithm can also affect results. For example, Burg's method may result in spectral splitting, where two spectral lines occur instead of a single one. There is evidence that the modified covariance method often performs better in this respect. It also performs best when sinusoidal components exist in the data.

Where there are processes consisting of sinusoids in broad-band noise, the increased analysis resolution is a function of the signal-to-noise ratio. Thus spurious peaks have been noted. The low-frequency part of the AR spectrum can also be corrupted by DC components in the data. Like many signal-processing tasks, it may be of advantage to subtract it before any analysis is made.

Nomenclature

A, a	polynomial of denominator of transfer function
B, b	polynomial of nominator of transfer function
p, q	orders of polynomials A and B (a and b)
n	number of data points
R	correlation matrix of elements
S	power spectral density

SPECTRAL ANALYSIS, CLASSICAL METHODS

doi:10.1006/rwvb.2001.0187

Rationale of frequency domain representation

The use of spectral analysis, in many areas of applications, but almost exclusively in vibration analysis, is so predominant that the rationale for using it is often ignored. The main possible reasons for this are as follows:

1. Physical insight is often easier to obtain in the frequency domain, as opposed to the original time domain description of signals and systems. The existence of periodic vibrations occurring with rotating machines is a classical example. The recognition of constant-frequency, resonance-excited signals is another one.
2. The orthogonality properties of Fourier decompositions implies that cross-products of signal components of unequal frequencies is zero. No power is contributed by such cross-products. It is thus possible to investigate independently the contribution of certain frequency regions to the total power or energy. For example, we may try to attenuate vibrations in a certain frequency band independently of other frequency regions, and different approaches could be tried for different frequency ranges.

3. Vibration patterns of diagnostic significance are often recognized more easily. Small changes, barely affecting the time signature, are often easily detected in the frequency domain representation.
4. Finally, we mention the closed-form solution for vibrating systems, often modeled as lumped linear systems, and hence described by linear differential equations. Applying a Fourier transform (or Laplace or even Z transform for discrete cases) results in sets of algebraic equations. Closed-form solutions are readily obtained, and frequency domain descriptions of signals and systems often prevail in introductory vibration textbooks (and this advantage is sometimes cited as the rationale for Fourier method).
5. While the rationale given in the previous point is of less interest to real-life situations, the closed-form solution is of practical interest, as it is often compared to experimental results. Thus, predicted signals (or system properties) are compared to those obtained experimentally, and again the patterns are often easier to interpret in the frequency domain. Examples are vibration spectra of rotating elements, and structural responses, which will be compared to those predicted analytically.

Engineering Units

Different types of frequency domain analysis can be performed, depending on the type of signals at hand, and also on the intended application, i.e., the use of the analysis results.

Some applications, mainly in the area of diagnostics, often mainly need changes to be detected. In such cases, the type of presentation and engineering units (EU) are less critical. Almost any of the prevalent spectral presentations can be used, as long as consistency is retained for comparison purposes.

For applications which require quantitative results, however, EU are of utmost importance.

Below, we address the most prevalent EU and their suitability for specific signal classes.

We thus assume that for a signal:

$$x(n) \quad n = 0, 1, \dots, N - 1$$

we have computed the fast Fourier transform (FFT) (see **Transform methods**):

$$X(k) = \sum_{n=0}^{N-1} x(n) \exp \left(-j \frac{2\pi}{N} nk \right) \quad [1]$$

All signals are considered to have dimensions of voltage (V). Mechanical vibration units are readily obtained in appropriate EU when the measurement conversion units are applied.

Addressing the frequency scale, this will consist of equally spaced frequencies, with a spacing of:

$$\Delta f = 1/(N\Delta t)$$

where Δt is the sampling interval.

The time scale is thus $t = n\Delta t$, and the corresponding frequencies:

$$f(k) = k\Delta f$$

We will sometimes refer to $f(k)$ as computational (or analysis) frequencies, as opposed to actual physical ones, the reciprocal of the period of a signal. It is important to realize that the analyst has some control over the analysis frequencies (via the choice of N , or equally the signal duration), whereas the physical frequencies are independent of the analysis parameters chosen.

We now address the EU according to the type of signal analyzed.

Transients

The obvious choice is the DFT, which approximates samples of the continuous FT, given by eqn [1], which is readily computed via the FT. For EU we compute:

$$X_{\text{EU}}(k\Delta f) = \Delta t X(k\Delta f) [\text{V-s}] \quad [2]$$

Periodic Signals

A Fourier series decomposition is indicated, at least in principle. As an example we might be interested in estimating the amplitude of the fundamental (or any specific harmonic frequency) component.

From the entry on **Transform methods** note that:

$$\begin{aligned} X &= N X_{\text{DFS}} \\ X_{\text{FS}}(f_k) &= \frac{1}{N} X(k) \quad [\text{V}] \end{aligned} \quad [3]$$

The computation equals that of the DFT, except for the factor N . The results are expressed directly in volts. A two-sided presentation (see later) is given by eqn [3].

Some aspects of the frequency scale warrant discussion. In the DFS, one period of the assumedly periodic signal is analyzed. The frequency scale:

$$f(k) = k\Delta f$$

thus shows the fundamental (at $k = 1$), second harmonic (at $k = 2$), and so forth, of a periodic signal which consists of the periodic extension of the signal section used in the FFT.

The length of the signal spanned by the analyzing window may be such that a multiple of physical periods are spanned. Let us assume that p integer periods are spanned by the signal length $N\Delta t$ being analyzed.

Denoting the number of samples in the period by M , we have:

$$T_p = M\Delta t$$

with T_p the actual period of the physical signal. Hence the total signal length:

$$N\Delta t = pM\Delta t$$

and the location of f_p on the frequency scale is:

$$\begin{aligned} k\Delta f &= f_p = 1/(M/\Delta t) \\ k &= 1/(M\Delta t\Delta f) = N/M = p \end{aligned}$$

Thus, the location index of the fundamental (physical) frequency equals M , the number of periods spanned by the signal analyzed (Figure 1).

It also follows that, only when an integral number of periods is spanned will the physical frequency coincide with one of the frequencies at which the DFS is computed, i.e., an integer multiple of Δf . For signals spanning a noninteger number of cycles in the analysis window, the true physical frequency will be at some intermediate location between two computed

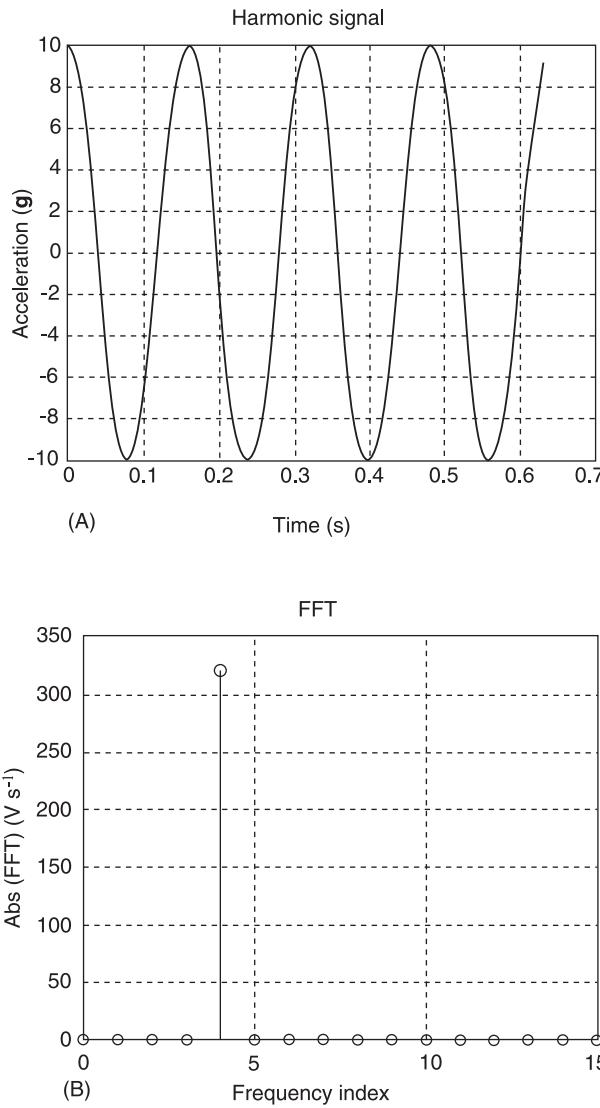

Figure 1 Harmonic signal: number of periods and frequency index. (A) Signal; (B) line spectrum.

frequencies. The magnitude, at the true frequency, is not computed.

Random Continuous Signals

Second-order statistics are used, based on the definition of the power spectral density (PSD) as the Fourier transform of the autocorrelation function (see **Correlation functions**).

We note the interpretation of the PSD (this is sometimes used as a definition) as:

$$P = \int_{-\infty}^{\infty} S(f) df \quad [4]$$

which is the distribution of the power in the frequency domain. The PSD is a distribution function,

and the portion of the total power contributed by the specific frequency range is given by an integration (or summation) of $S\Delta f$.

$$P_{f_1-f_2} = \int_{f_1}^{f_2} S(f) df \quad [5]$$

and the units of S are $V^2 \text{Hz}^{-1}$ (Figure 2). For digital computations, we note that for a finite N point signal, the correlation is estimated as:

$$\begin{aligned} R(m) &= \frac{1}{N} \sum x(n+m)x(n) \\ &= \frac{1}{N} x_N(m) \otimes x_N(-m) \end{aligned} \quad [6]$$

where x_N denotes the N point signal (zero outside the interval) and \otimes convolution. Applying a DFT to the convolution results in:

$$S(k) = \frac{1}{N} |X(k)|^2 \quad [7]$$

For EU we note that a factor of Δt is needed for discrete computations of $S(\Delta f)$.

Thus, we compute the PSD via the DFT as:

$$S(k\Delta f) = \frac{\Delta t}{N} |X(k\Delta f)|^2 \quad [8]$$

Additional Representations

As with PSD, we may define an energy spectral density for energy signals:

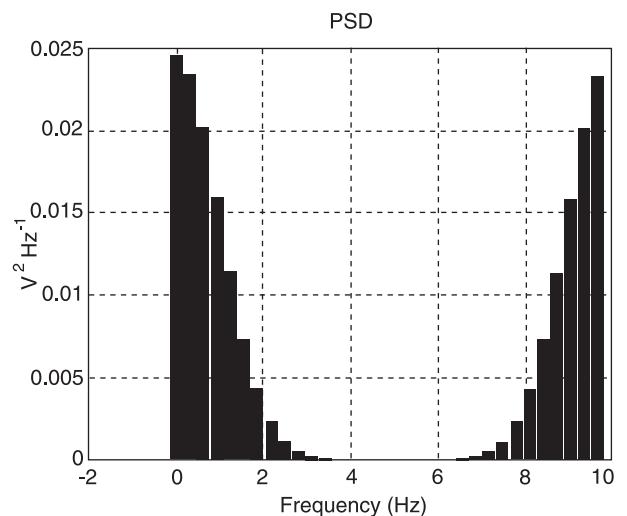

Figure 2 Power distribution in the frequency domain.

$$E = \int_{-\infty}^{\infty} S_E(f) df \quad [9a]$$

with:

$$E_{f_1-f_2} = \int_{f_1}^{f_2} S_E(f) df \quad [9b]$$

showing the contribution to the total energy in the band $f_1 - f_2$. These are computed as:

$$S_E(k\Delta f) = T_t S(k\Delta f) = \Delta t^2 |X(k\Delta f)|^2 \quad [V^2 - s^2] \quad [9c]$$

We may also wish to see the power distribution as opposed to the power density distribution. This would be computed as:

$$S\Delta f = \frac{\Delta T}{N} |X(k\Delta f)|^2 \frac{1}{N\Delta t} = \frac{1}{N^2} |X(k\Delta f)|^2 \quad [V^2] \quad [10]$$

Linear (sometime called voltage)-based units are sometimes preferred over squared (power or energy)-based ones. Taking the square root of all expressions discussed so far.

It is important to realize that the original data cannot be reconstructed from power (or energy) functions in the frequency domain. This should be evident from the actual procedure, which only utilizes the magnitude of the DFT, while the phase information is ignored.

Frequency Scales, One-and Two-sided Presentations

The (computational) resolution being $\Delta f = 1/(N/\Delta t)$, the frequency scale is:

$$f(k) = k\Delta f$$

This is a two-sided presentation, involving both positive and negative frequencies. For the basic FFT algorithm, the locations:

$$k = N - 1, N - 2 \dots N/2$$

correspond to negative frequencies according to:

$$X(-k) = X(N - k)$$

while $X(0)$ is the DC component (multiplied by N), and $X(N/2)$ the value at the Nyquist frequency.

A more classical presentation is often used by simple shifting (Figure 3).

A one-sided presentation is often preferred for engineering applications. Thus, for $X(k)$, the two-sided transform, a one-sided transform $X_1(k)$ is computed as:

$$X_1(k) = \begin{cases} X(k) & k = 0, \quad k = N/2 \\ 2X(k) & k = 1, 2 \dots N/2 - 1 \end{cases} \quad [11]$$

One-sided presentations for power energies are also used, for example (Figure 4):

$$G(k) = \begin{cases} S(k) & k = 0, \quad k = N/2 \\ 2S(k) & k = 1, 2 \dots (N/2) - 1 \end{cases} \quad [12]$$

For quantitative results, the EU used must be stated. This will depend on whether the signals are deterministic transients, deterministic periodic, stationary, etc. The application may also be a factor. Power units would be used for random or mixtures of deterministic and random signals. Straight DFT or alternatively EU could be used for transients. For periodic signals, the PSD, DFT or even a Fourier series decomposition X_{DFS} could be used.

The fact that all different EU are computed via the DFT (by means of the FFT algorithm) means that similarities (and sometimes equivalences) can sometimes cause confusion. The type of presentation, whether one-or two-sided, is obviously important. Table 1 shows the different EU used, according to the type of signals.

The computational formulae contain Δt , the sampling interval. General-purpose software often includes signal-processing functions where a normalized sampling interval of $\Delta t = 1$ is assumed. Caution is thus needed when such software is used for real-case sampled signals. On the other hand, most dedicated vibration-processing software (especially operating in conjunction with data acquisition systems) will usually offer the choice of many EU and compute them automatically. Their presentation will usually be one-sided.

Performance, Errors, and Controls

Like many signal-processing tasks, the ease of employing available procedures is not enough to warrant meaningful results. The analyst must be aware of mechanisms generating uncertainties in the analysis results. Next the analyst must be acquainted with the possibilities of controlling those uncertainties. As will

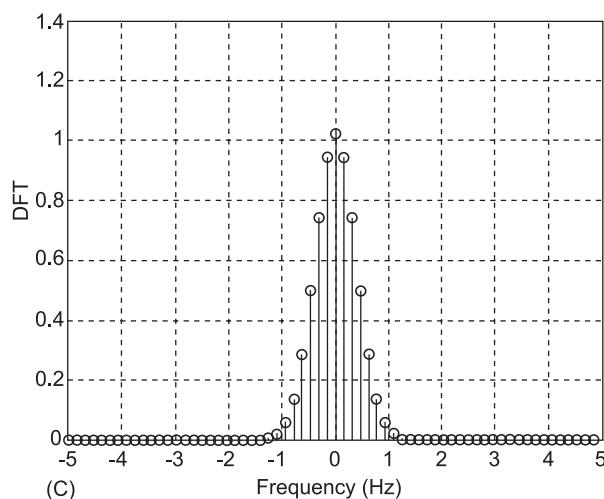

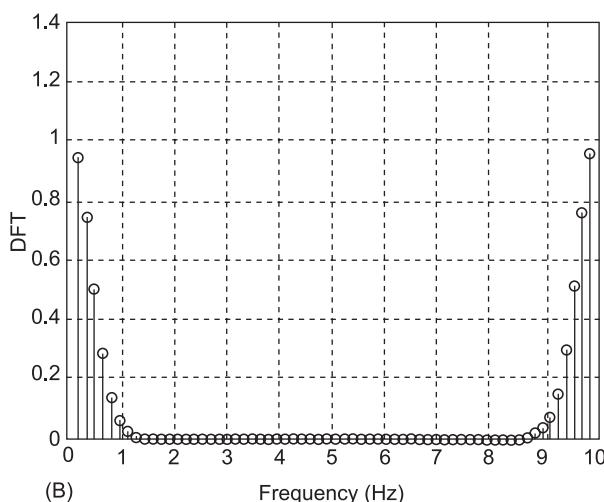

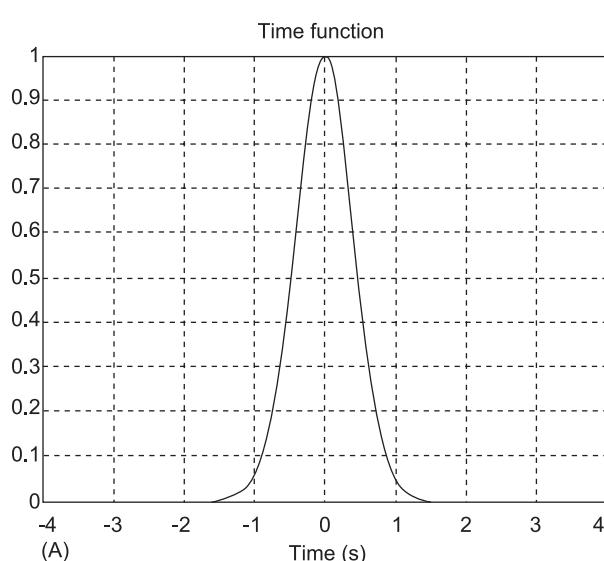

Figure 3 Frequency scale for the DFT. (A) The signal; (B) frequency index 0 to $N - 1$; (C) frequency index $-N/2 + 1$ to $N/2$.

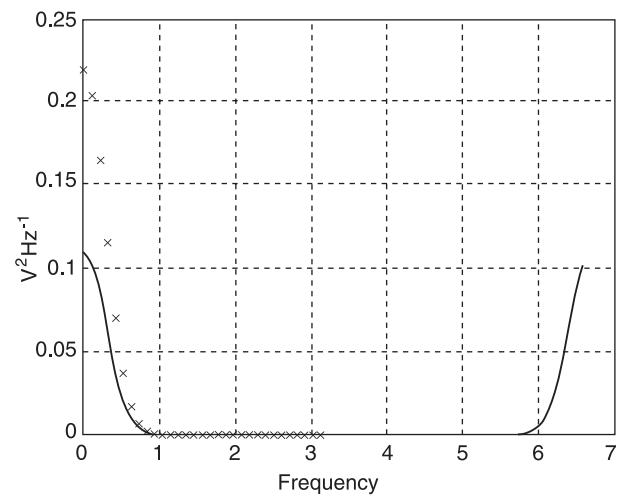

Figure 4 One and two-sided PSD. Continuous line, one-sided PSD; crosses, two-sided PSD.

become clear, these problems are of utmost importance as far as spectral analysis is concerned.

The main error mechanisms in spectral analysis can be categorized as follows:

- alias errors
- bias errors
- leakage errors
- random errors

Aliasing is related to the correct sampling of continuous signals, and hence is not addressed in the following paragraphs.

In what follows, performance aspects are tackled according to the signal's character.

Some of the errors to be controlled depend on the type of signal at hand. There is however a basic limitation to the decomposition of signals in the frequency domain, which is traceable to an uncertainty principle. This will be described first. Then errors/performances will be addressed as follows:

- transient signals
- periodic signals
- random signals

The Uncertainty Principle

The uncertainty principle describes the relationship between time duration and the frequency bandwidth of signals. The quantitative formulation depends somewhat on how the 'duration' and 'bandwidth' are defined, and more than one possibility exists for such definitions. For any reasonable definition: $(\text{time duration}) \times (\text{frequency bandwidth}) > C$ where C is in the range of 1.5–3, depending on the definition. Resolving within $f_2 - f_1$ thus necessitates a duration of:

Table 1 Engineering units. Units based on $X(k) \leftrightarrow x(n) - 1$

	<i>Computation</i>	<i>EU</i>	<i>Voltage units</i>
FT	$\Delta t X$	$V \cdot s$	
FS	X/N	V	
S(PSD)	$(\Delta t/N) X ^2$	$V^2 \text{Hz}^{-1} = V^2 \cdot s$	$V/\sqrt{\text{Hz}}$
$S_E(\text{ESD})$	$\Delta T^2 X ^2$	$V^2 \cdot s^2$	$V \cdot s$
Power in bin	$S \Delta f = (1/N^2) X ^2$	V^2	
Energy in bin	$S_E \Delta f = (\Delta t/N) X ^2$	$V^2 \cdot s$	
Total power (frequency)	$P_f = (1/N^2) \sum X ^2$	V^2	
Total power (time)	$P_t = (1/N) \sum x^2$		
Total power (time)	Parseval : $\sum x^2 = (1/N) \sum X ^2$	V^2	
Total energy (frequency)	$E_f = \Delta t \sum X^2$	$V^2 \cdot s$	
Total energy (time)	$E_t = \Delta t \sum x^2$	$V^2 \cdot s$	

$$T_t \geq \frac{2}{f_2 - f_1} \quad [13]$$

The uncertainty principle is so basic that its practical implications are sometimes overlooked. Thus, given a signal length T_t , two components separated by $f_2 - f_1 = 1/T_t$ will not be separated by any signal-processing techniques (unless additional information is at hand). Another immediate conclusion is that changes in the frequency domain separated by $f_2 - f_1 < C/T_t$ are meaningless, notwithstanding the possibility of computing at sometimes closer arbitrary frequencies (see below).

For digital FFT-based computations, the frequency scale is in steps of:

$$\Delta f = 1/(N\Delta t) = 1/T_t$$

and the uncertainty principle is ‘automatically’ satisfied. Dedicated instrumentation sometimes have a ‘zoom mode’ for spectral analysis, whereby only a partial frequency range is zoomed in for analysis. High resolution is achieved if N frequency points are computed in this range. It should be clear that this can only be achieved using an appropriate data duration, and very large T_t may be needed with such a mode of operation. Specifically, if in zoom mode N frequencies are resolved in the range $f_2 - f_1$, then:

$$T_t = 1/(\Delta f) = N/(f_2 - f_1)$$

Transient Analysis and Zero Padding

We now turn to transient signals. The performance hinges on the resolving power of the analysis. As obvious from the prior section, this is limited by the signal’s duration. Let us assume a signal with finite duration $x/n, i = 0, 1, 2, \dots, N_1$.

The basic frequency resolution is, assuming for the moment that a transform is computed for N_1 points:

$$\Delta f_{\text{transient}} = \frac{1}{N_1 \Delta t} \quad [14a]$$

If $N - N_1$ zeros are now appended to the signal, resulting in a total span of N points, a computational resolution of:

$$\Delta f = \frac{1}{N \Delta t} < \Delta f_{\text{transient}} \quad [14b]$$

will be achieved. This operation, called ‘zero padding’ has no effect on the computed DFT, as can be noted from:

$$X(k) = \sum_{n=0}^{N_1-1} x(n) \left(\exp - j \frac{2\pi}{N} \right)^{nk} + \sum_{i=N_1}^N 0 \left(\exp - j \frac{2\pi}{N} \right)^{nk} \quad [14c]$$

and nothing is contributed to $X(k)$ by the second term.

It should be clear from the uncertainty principle that no improvement in the resolving power of the frequency function has been achieved. The fact that $X(k)$ is now computed at more closely spaced intervals is equivalent to a specific interpolation scheme in the frequency domain. (The actual-type of interpolation is outside the scope of this text.) **Figure 5** demonstrates an example of zero padding and equivalent interpolation.

Zero padding is used to comply with requirements of a specific N , often dictated by the maximum length of other signals in multichannel acquisition tasks (or compatibility with the requirements of the FFT used).

Another aspect concerns the possibility of controlling the deterioration of the signal-to-noise ratio due to additive noise. An improvement in the signal-to-noise ratio can be achieved for specific cases where *a priori* information on the signal’s characteristics is at

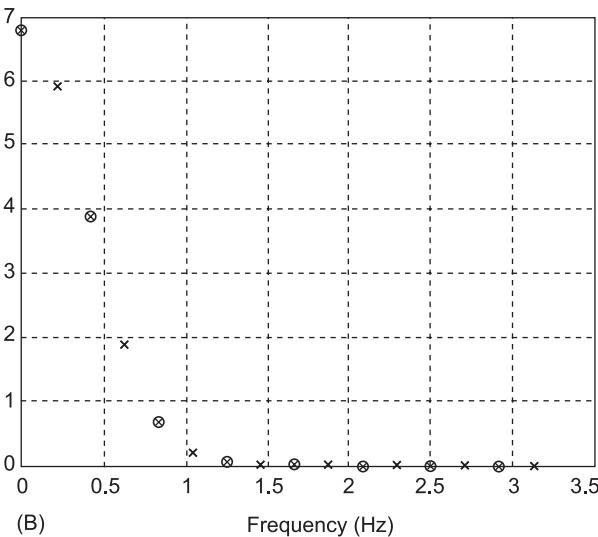

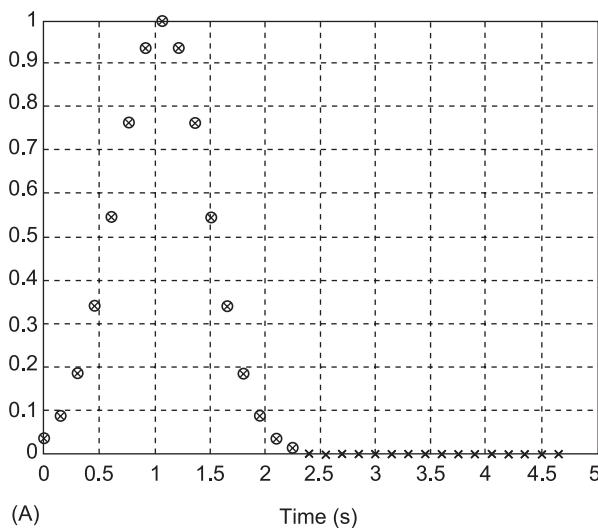

Figure 5 Zero padding. (A) Signal, time domain; (B) frequency domain. Circles, with zero padding; crosses, without zero padding.

hand. We may give less weight to signal samples with lower signal-to-noise ratio. The weighing is done by a time window function applied to the signal (see Table 2). Two examples are briefly described (Figure 6):

1. A transient limited to a small part of the analyzed time interval. A rectangular window, giving zero weight outside the signal's duration can be applied, see Figure 6A. The transition between 100% to zero weight should preferably be somewhat gradual.
2. A decaying oscillating signal, typical of transient response of low damped vibrating structure. An exponentially decaying window is then applied (Figure 6B).

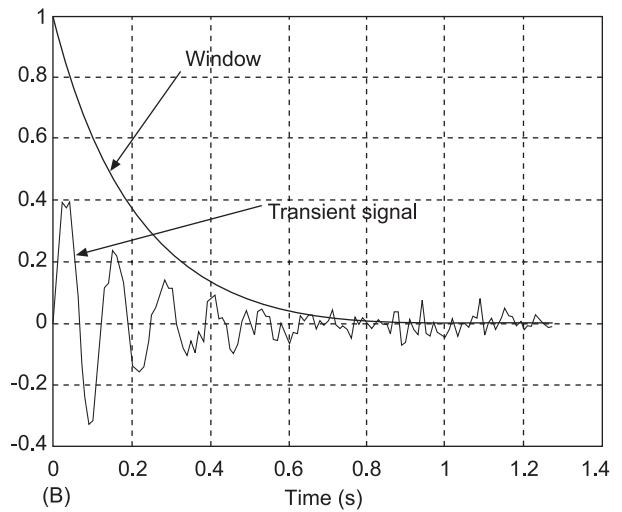

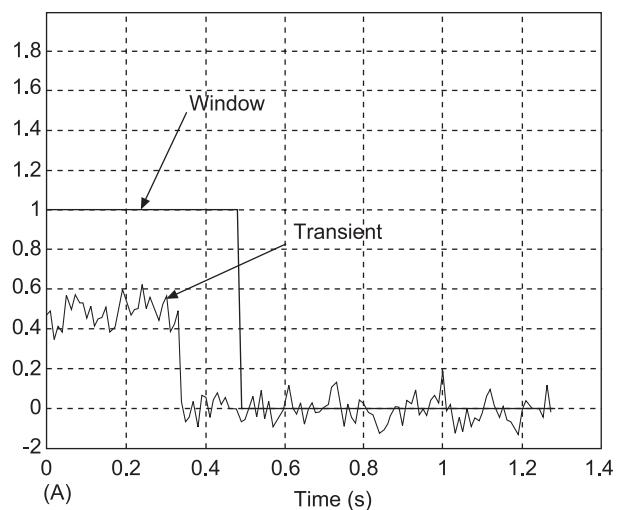

Figure 6 Specific windows for transients. (A) Time-limited signal and window; (B) decaying oscillations and exponential window.

Periodic Signals

In this paragraph we will often differentiate between ‘physical’ and computed frequencies. Only the last one can be controlled to some extent by the analyst. An error designated as leakage then occurs whenever they differ. As far as periodic signals are concerned, the analysis resolution and control of leakage are of major importance.

For periodic signals, with period T_p , the physical frequencies are:

$$k/T_p$$

whereas computed frequencies will be located at:

Table 2 Window characteristics

Window	3 dB bandwidth	Secondary lobe (dB)	Sidelobe fall-off (dB/decade)	Ripple (scallop loss) (dB)
Rectangular	$0.88\Delta f$	-13.2	20	3.92
Hanning	$1.44\Delta f$	-31.5	60	1.42
Flat top	$3.72\Delta f$	-93	0	0.01

$$k\Delta f = k/(N\Delta t)$$

As discussed before, physical and computed frequencies will only coincide when an integral number of periods are spanned by the signal analyzed.

Figure 7 shows a DFT applied to two cases: a section of a harmonic signal spanning an integral number of

periods, and a nonintegral one. We note that, in the second case the computed $X(k)$ is spread over a large frequency range, in contrast to the physical signal of an actual single frequency. The effect is called leakage, as it severely affect spectral analysis. While it is often noticeable when analyzing periodic signals, it is a general effect, which exists with all types of signal.

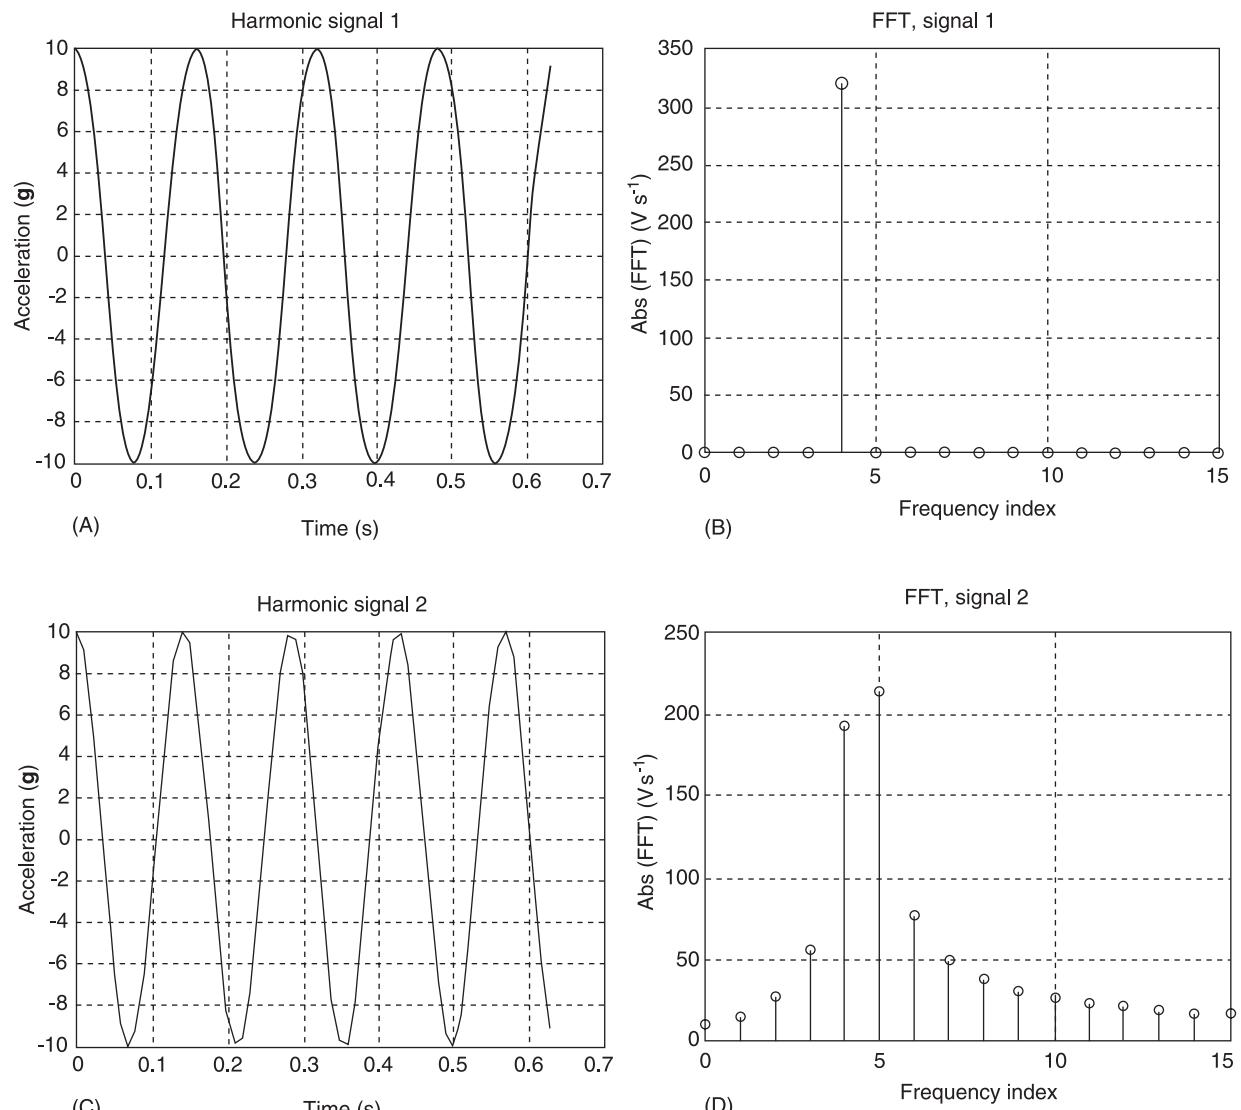

Figure 7 Example of leakage. (A) Signal 1, time domain; (B) signal 1, DFT, no leakage; (C) signal 2, time domain; (D) signal 2, DFT, leakage.

Windows One approach used to describe leakage and windows is based on imposed periodicities in DFT computations (see **Windows**). Another approach describing leakage is based on digital filtering.

Here the DFT is considered as a linear system operating on the signal. Not surprisingly, this system has characteristics of a filter bank, centered around computational frequencies. Such an approach is sometimes more intuitively appealing to the analyst (Figure 8). To see the DFT filtering characteristic, we note that the DFT equation can be rewritten in a matrix form as:

$$\mathbf{X} = \mathbf{W}\mathbf{x} \quad [15a]$$

where $\mathbf{x}(N \times 1)$ and $\mathbf{X}(N \times 1)$ are the signal and DFT vectors, and $\mathbf{W}(N \times N)$ is a matrix with elements:

$$w_{nk} = \exp\left(-j\frac{2\pi}{N}\right)^{nk} \quad [15b]$$

$$\begin{aligned} X(k) &= x(0) + x(1) \exp\left(-j\frac{2\pi}{N}\right)^n \\ &\quad + \dots + x(n-1) \exp\left(-j\frac{2\pi}{N}\right)^{(N-1)n} \end{aligned} \quad [16]$$

$X(k)$ can thus be identified as the output of a linear filter, whose unit impulse response is:

$$h_k(n) = \begin{cases} \exp\left(-j\frac{2\pi}{N}\right)^{(N-1-n)k} & n = 0, 1 \dots N-1 \\ 0 & n < 0, \quad n > N \end{cases} \quad [17a]$$

The frequency response of this filter is now found in a straightforward manner by applying a Z transform to eqn [17a] and substituting: $Z = \exp(j2\pi f \Delta t)$. This results in:

$$H_k(f) = \frac{\sin(\pi N f \Delta t)}{\sin(\pi f \Delta T - \pi k / N)} \quad [17b]$$

The frequency response function consists of a main lobe, centered around

$$f(k) = k / (N \Delta t)$$

and side lobes of gradually decreasing magnitudes. For large N the amplitude of the first lobe is down by 13.6 dB relative to that of the main lobe (Figure 9).

We may thus look at the DFT as a filtering by N parallel filters H_k , centered around frequencies $f = k \Delta f$, where Δf is the frequency spacing of the DFT. (The power trough of any filter is the PSD, equal to $|X(k)|^2 / N^2$.)

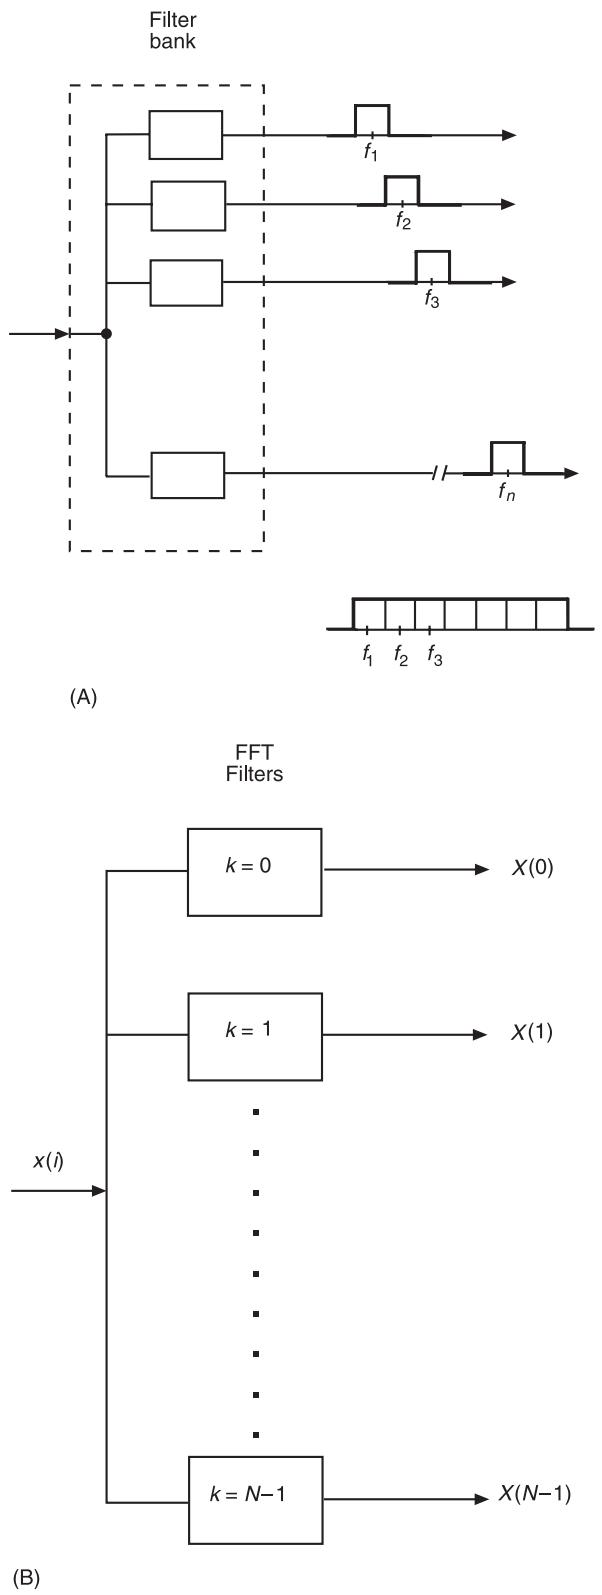

Figure 8 Filtering approach for PSD via the DFT. (A) PSD via an ideal filter bank (B) the DFT as a filter bank.

As noted above, a harmonic signal of frequency $k\Delta f$ has a period of $T_p = 1/(\Delta f)$, and the number of periods spanned by N points is:

$$N\Delta t/T_p = p = k$$

Thus, for a signal spanning exactly k periods, its physical frequency coincides computationally with the center of the main lobe of the k th filter H_k , and with zeros of all other filters, hence no leakage occurs (Figure 9A)

For all other cases when a noninteger number of periods are spanned, the physical frequency does not coincide with any of the computational frequencies where H_k is zero, the response of all filters will be nonzero, and leakage occurs over all frequency ranges (Figure 9B). The leakage, however, decreases with larger distances from the physical frequency; the attenuation is dictated by the decreasing magnitudes of the secondary lobes. We also note that increasing N will narrow the width of all lobes. This decreases the leakage; the physical frequency is now pushed to higher-order lobes for all filters except the one where it still falls in the main lobe.

To control leakage, windowing is undertaken by multiplying the time signal by the appropriate window function (see **Windows**).

$$x'(n) = w(n)x(n) \quad [18]$$

The most frequently used window, at least for vibration signals, is the Hanning window, given by eqn [19] and shown in Figure 10. Other windows are used only when specific information concerning the signal's characteristics are known, and a specific window may then be of advantage.

$$w_b(n) = 0.5 \left[1 - \cos \left(2\pi \frac{n}{N} \right) \right] \quad [19]$$

Using the original signal without any weighting is equivalent to multiplying it by a rectangular window of magnitude 1. The rectangular window is thus included in any list of possible windows. Applying it implies using the original unmodified data.

A normalization is necessary, as the total energy is reduced by the windowing:

$$S'(k) = \frac{1}{\sum_k w^2(k)} S(k) \quad [20]$$

Modifying the signal by multiplying it by a window function (eqn [18]) modifies the filtering properties of the equivalent filter (Figure 10). In the frequency domain, eqn [18] transforms into the convolution between the transform of the time window (called

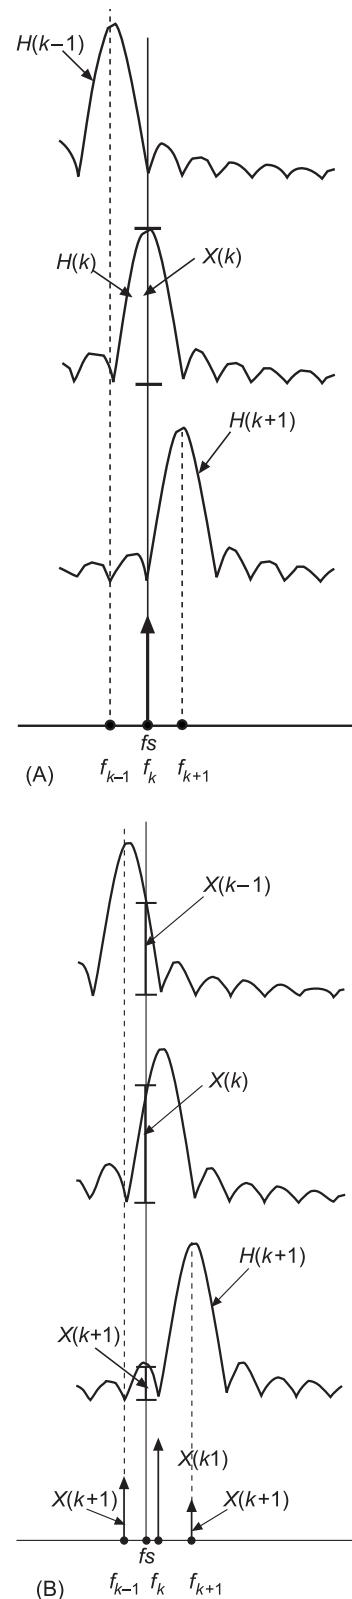

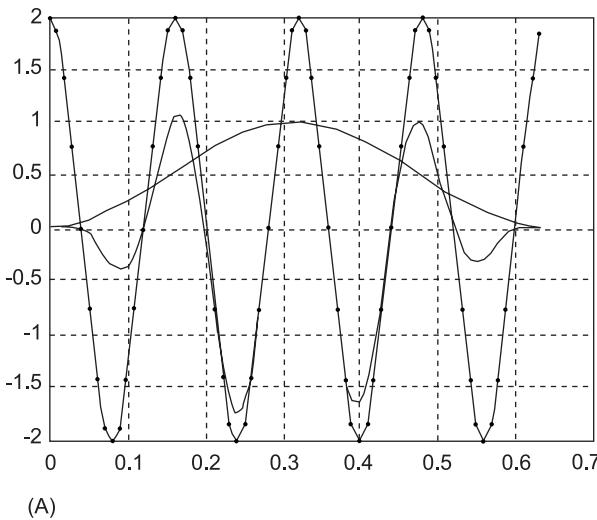

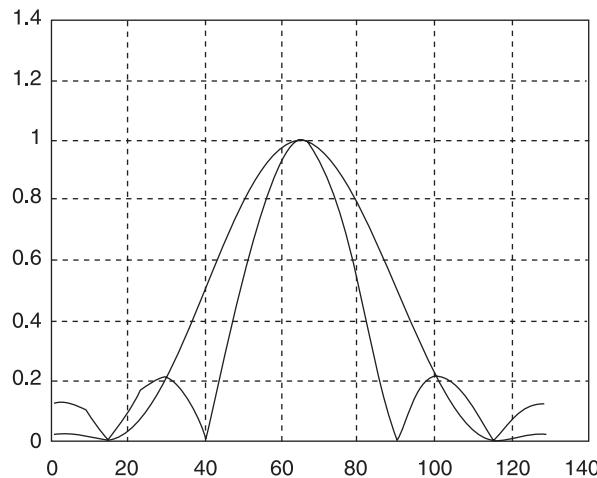

Figure 9 DFT filter bank and leakage. (A) Harmonic signal, integer number of periods; (B) harmonic signal, noninteger number of periods.

(A)

(B)

Figure 10 The use of windows and windowed signals. (A) Harmonic signal, rectangular and Hanning window; (B) filtering properties: rectangular and Hanning window.

the frequency domain window) and the transform of the signal. An equivalent filtering operation to the DFT of the windowed signal can be developed.

The effect of using a window is to modify the equivalent N filters, tuned around $k\Delta f$. The detailed derivation is beyond the scope of this text. While the main lobe is broadened, the attenuation of the secondary lobes is much sharper, and the leakage will accordingly decrease. Table 2 summarizes the main properties of some windows.

The effect of leakage depends on the type of signal analyzed. A few examples are now addressed.

Periodic signal Leakage occurs whenever the physical frequency does not coincide with a computed

version (or when a noninteger number of periods is spanned). In addition, with the signal's frequency not coinciding with the center on the main lobe of the FFT filter, the magnitude of $X(k)$ the nearest to the physical one will be attenuated. This is sometimes referred to as the scalloping loss. The maximum attenuation, occurring when the physical frequency is at $(k + 0.5)\Delta f$, at a midpoint, is 40% (corresponding to 60% attenuation in power). The use of a Hanning window will reduce the leakage as well as the scalloping loss.

For vibrations measured from rotating machinery, this can be very troublesome, as fluctuation in speeds of a few percent can cause erratic changes in peaks of $X(k)$ around rotating frequencies.

With a rectangular window, increasing N will not affect the possible scallop loss.

While the Hanning window decreases it, a special flat-top window is available which gives a very small scallop loss. It is sometimes used for rotating machinery when the effect of speed fluctuations is important. It is defined by:

$$w_{ft}(n) = a_0 + 2 \left[a_1 \cos 2\pi \frac{n}{N} + a_2 \cos \left(4\pi \frac{n}{N} \right) + a_3 \cos \left(6\pi \frac{n}{N} \right) \right]$$

$$a_0 = 0.9945 \quad a_1 = 0.95573$$

$$a_2 = 0.53929 \quad a_3 = 0.09158$$

Multiple components signals For a rectangular window, the minimum separable frequency increment is $2\Delta f$. When leakage exists, the leakage from a large component may mask the existence of smaller ones. We thus note one of the main effects of leakage: it is the reduction in the dynamic range. By the term dynamic range we refer to the minimum amplitude (referred to the maximum one, see par instrumentation).

Windows with much steeper secondary lobe attenuation thus improve the dynamic range significantly. They are thus often used automatically when closely spaced components exist, as for example with gear-generated signals. On the other hand we should note the increased bandwidth of the main lobe (for example, for the Hanning window it is $1.44\Delta f$). Thus, for very close components (of the order of $3\Delta f$), windowing would decrease the resolving power.

Random Signals

Any parameter or function describing such signals, if based on finite signals, can only be estimated. Thus, the PSD computed via eqn [8] is an estimator of the true PSD, and will be denoted by \hat{S} . The quality of this estimate is of great practical importance. The analyst

is concerned with the variance and bias of the estimate, as well as the question of consistency.

Variance Using a finite signal sequence, it is only possible to compute estimators of parameters or functions describing random data. To derive the properties of the PSD estimator, we investigate the sampling distribution of \hat{S} , the PSD of one random sample record (sometimes called a raw PSD):

$$E(\hat{S}) = S \quad [20a]$$

$$\text{Var}(\hat{S}) = S^2 \quad [20b]$$

The relative random error is thus:

$$\frac{[\text{Var}(\hat{S})]^{1/2}}{S} = 1 \quad [20c]$$

While eqn [20a] shows that the estimate is unbiased, eqn [20b] indicates a very high variability. The standard deviation of the raw PSD is 100%, making it almost meaningless. This is demonstrated by **Figure 11** showing overlays of PSDs, computed repeatedly for N points of different sections of a stationary random signal.

It should be noted that this great variability is independent of N , the data length. (The estimator is thus not consistent.)

The expected value and variance of a random variable with a probability distribution given by eqn [20] depends on v , the number of degree of freedoms of this distribution. For the raw PSD $v = 2$, except for the endpoints. In the following section, we describe how to control variability. This will be equivalent to increasing the number of degrees of freedom of the estimator's distribution.

The above results, derived for white-noise Gaussian signals, is typical for the raw spectra of most random signals.

Segment averaging To reduce the variance we attempt to use averages of estimators of the raw PSD. In the method of segment averaging, estimates to be averaged are obtained from different sections of the signal.

The method is based on sectioning the signal into M non-overlapping segments:

$$x_j(n) = x(n) + (j - 1)N_1 \quad [21]$$

where $N_1 = N/M$ is the length of each segment (**Figure 12A**).

We now compute estimates \hat{S}_j for each segment as:

$$\hat{S}_j(k) = \frac{\Delta t}{N_1} |X_j(k)|^2 \quad [22]$$

with:

$$x_j(i) \leftrightarrow X_j(k)$$

The number of degree of freedoms of the PSD will be increased by a factor of M , assuming the raw estimates to be independent (but see below), and equal $2M$ (**Table 3**). We may consider the spectral functions $\hat{S}(k)$ as members of an ensemble of random functions whose ensemble mean is then $S(k)$. The variance of this mean decreases with M , the normalized random error now being:

$$e_r = \frac{1}{[M]^{1/2}} \quad [23]$$

Figure 12B and **12C** shows the result of segmentation/averaging for the ensemble analysed in **Figure 11A** and **B**. Also shown is the theoretical PSD of this simulated example.

An improvement named after its developer, Welch, is based on averaging overlapping sections. This is depicted in **Figure 12D**, where $N_1 - D$ data points are overlapped, i.e., are used twice (for two segments) in the analysis. For $D = 0$, we have zero overlapping. The ratio:

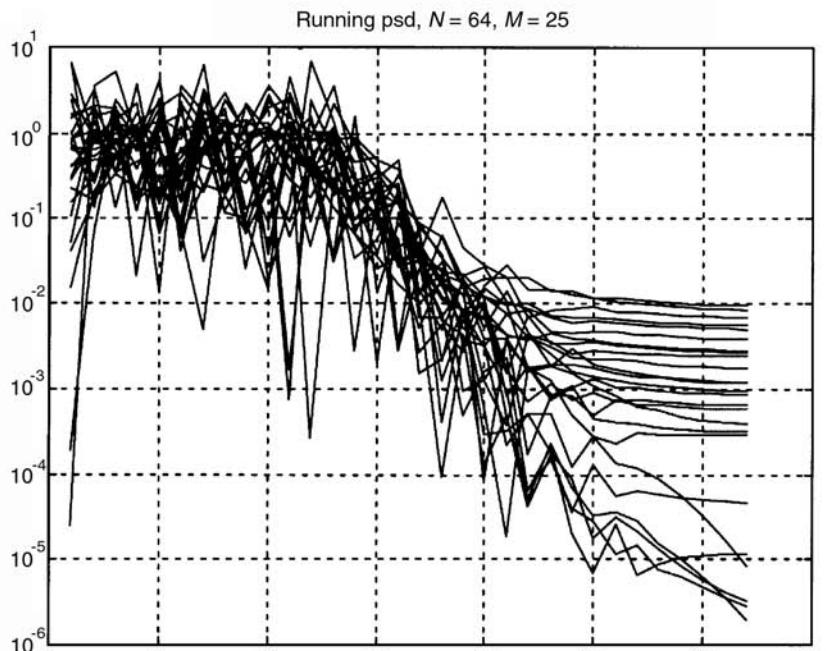

$$(N_1 - D)/N_1 \cdot 100$$

is sometimes called the overlap factor (in %). M_1 , the number of raw PSDs which can be averaged, are now increased. To retain the statistical independence of the raw PSDs, the segments are windowed, so as to give less weights to the overlapped points (see **Windows**). The analysis of Welch suggests an overlap of 50% in conjunction with a Hanning window, and the PSD of each section is thus modified to:

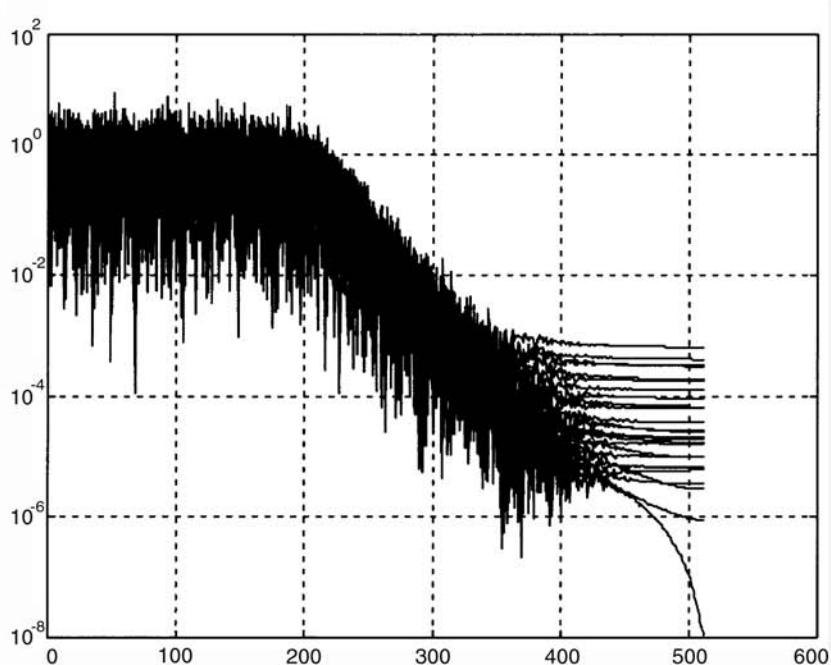

$$\hat{S}_{j(k)} = \frac{\Delta t}{N_1} |X_j(k)W(k)|^2 \quad [24]$$

Table 3 summarizes the random errors for the different procedures.

Instead of a regular averaging, we may use exponential averaging to cope with time-varying situations. The PSD is then computed with a built-in fading exponentially decreasing memory.

(A)

(B)

Figure 11 Running PSD. (A) 25 overlays, $N = 64; M = 25$; (B) 25 overlays, $N = 1024; M = 25$.

Table 3 PSD variance and overlap

Overlap	W_{rec}	W_{han}
0%	1	1
50%	0.75	0.5278
90%	0.6576	0.9307

Bias error This will occur whenever the FFT spacing is too large compared to narrow-band regions of the ‘true’ PSD. Our spacing Δf is the scale resolution at which we try to resolve the PSD, and some averaging within this spacing occurs for peaks much narrower than this spacing.

An approximation for the relative bias error is:

$$e_b = \frac{(\Delta f)^2}{24} S''(f) \quad [25]$$

The second derivative appearing in eqn [25] indicates that the bias error, if not negligible, will result in underestimation of peaks (and overestimation of minima).

To avoid large bias errors, an analysis bandwidth which is much smaller than this 3 dB bandwidth is necessary. A ratio of 1:4 between those two will result in a bias error of 2%.

$$\Delta f \leq 0.25 \text{ BW}_{3\text{dB}}$$

An example of bias error is shown in Figure 13. The PSD was computed for $M = 100$ nonoverlapping sections for both cases, i.e., with the same random error. For $N = 512$, a significant drop in the low-frequency peak of 20 Hz can be noticed, compared to the analysis results with $N = 2048$. On the other hand, the broader peak around 21 Hz is approximately unaffected by the reduced resolution. While this cannot be seen with the linear scale of Figure 13, an increase in the minima between the two peaks occurs when N is reduced to 512.

The difficulty is the need to estimate the true, narrowest, physical bandwidth of the PSD. Unless some bound can be based on *a priori* knowledge, a strategy is needed. One possibility is to do some testing, whereby N (and hence Δf) is gradually increased, and check when peaks become strongly underestimated. But, as will be seen from the following discussion, this could increase the variance, making the judgment more difficult.

Control of errors The random error can be controlled by the number of sections averaged. We note the diminishing return of increasing M , due to the square root relation. Thus, increasing M from 1 to

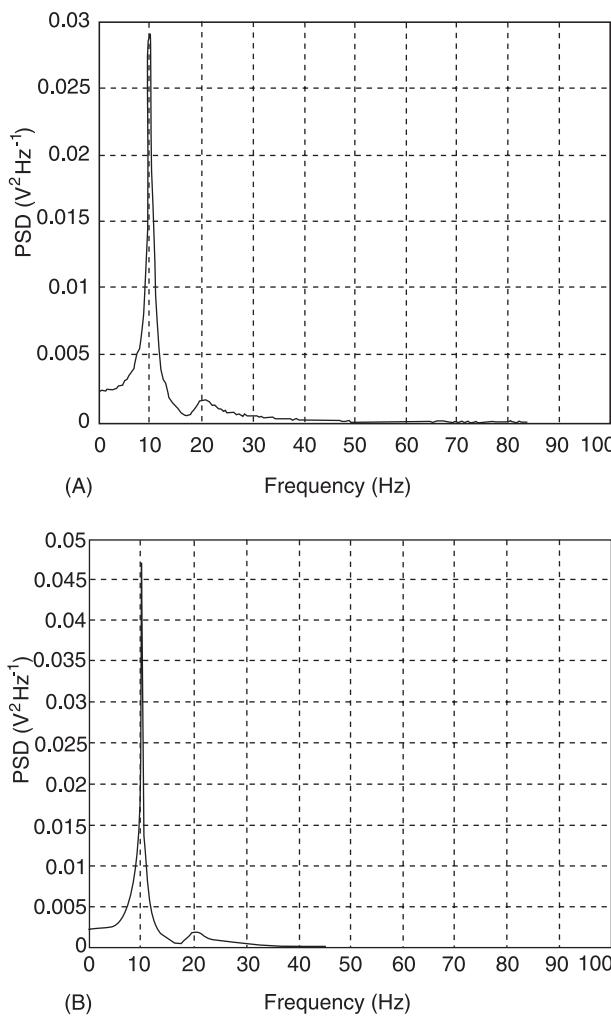

Figure 13 Bias error due to insufficient frequency resolution. (A) $\Delta f = 0.39 \text{ Hz}$, $N = 512$; (B) $\Delta f = 0.098 \text{ Hz}$, $N = 2048$.

100 will decrease the error by a factor of 10; a further doubling to $M = 200$ will only result in a reduction by a factor of $\sqrt{2}$.

The bias error is controlled by Δf versus the bandwidth of the signal, the controlled parameter being the number of samples per window N (the sampling interval is already fixed during data acquisition, to satisfy the required bandwidth).

We must consider two scenarios:

1. Scenario 1: the data are unlimited, and any required number of samples can be acquired. Such would be the case for rotating machinery, where the limitation would probably be the existence of a stationary vibratory regime. Specifications for analysis would be:
 - bandwidth of analysis, setting Δt during acquisition
 - frequency resolution, setting N the block length

- Random error, setting M , the number of averages

As an example, assume a required bandwidth of 100 Hz, analysis resolution of $\Delta f_{\text{res}} = 0.5 \text{ Hz}$ and a random error of 10%.

Assuming the existence of a sampling interval of (the exact values will depend on the actual hardware used):

$$\Delta t = 1/(2f_{\text{max}}) = 1/250 = 4 \text{ ms}$$

The block length would be:

$$1/(\Delta t \Delta f_{\text{res}}) = 1/(0.04 \cdot 0.5) = 500$$

and we would choose $N = 512$.

For a random error of 10% (eq. [23]) we would choose $M = 100$.

And the total number of samples is $NM = 512 \cdot 100 = 51200$, corresponding to a data duration of:

$$T_t = NM\Delta t = 208 \text{ s}$$

2. Scenario 2: assume data were acquired for 60 s, i.e., the number of data samples is $60/\Delta t = 15000$. As now M^*N is constant, we can only control one error, the bias via N , or the random one via M . Checking possibilities we get:

- Case 1: random error fixed, $M = 100$, $N = 150$. Thus we may choose: $N_1 = 128$ with a resultant resolution $\Delta f = 1.95 \text{ Hz}$ (and the actual $M = 117$, $\varepsilon_r = 9.3\%$)
 $N_2 = 256$ with the resultant resolution of $\Delta f = 0.95 \text{ Hz}$ (and the actual $M = 58$, $\varepsilon_r = 13.1\%$)
- Case 2: resolution fixed as in scenario 1: $N = 512$
With $M = 15000/512 = 29$ and $\varepsilon_r = 18.6\%$
Thus, for *a priori* fixed data length, the random error can only be balanced by the bias error.

Some practical remarks are warranted. The two scenarios show the importance of planning the analysis prior to the data acquisition; the necessary data duration can often be estimated. The question of bias versus random error is not straightforward, but many practitioners consider bias error more severe. Consider the underestimation of sharp maxima, as occurs with bias errors: this can be more troublesome than unsmooth spectra. Finally, it should be remembered that equations are asymptotic results, hence the results (as, for example, computed for the two scenarios) are only approximate.

Practice of Spectral Analysis

The analysis will depend on the type of signal at hand. Some *a priori* information will dictate the analysis and the choice of parameters.

Random Signals

The examples given above are ‘classical’. Overlapped processing, usually of 50%, can also be applied, requiring a window, usually the Hanning one. For zero overlap, a rectangular window could also be adequate. If a continuous spectrum is monitored, an exponential averaging scheme will be used, enabling one to follow slow changes in spectral characteristics. Additional peak spectral values will be kept (and updated continuously) for comparison.

Periodic Signals

Purely periodic signals are a theoretical concept. Any measured data will be contaminated to some extent by noises. These usually include a random component and often deterministic ones (for example, traceable to line interfere). Thus, some averaging is usually indicated. The number of averages will depend on the signal-to-noise ratio, and for reasonable situations can be much less than for purely random signals.

The analysis parameters are an integral part of any spectral analysis results. A triggered analysis is often preferable for periodic signals. A trigger signal is often available from external devices (like a one-per-rev signal in rotating machines), but can also be obtained from the analyzed signal itself, a so-called self-trigger. In contrast to free-running analysis, temporal patterns are preserved, and the phase is not randomized. Thus, in free running analysis, a PSD would be computed, while for triggered analysis, the DFT itself could be averaged, keeping the phase information.

In dedicated data acquisition and analysis instruments, triggered data acquisition would automatically imply a triggered spectral analysis.

Windows would normally be used, generally the Hanning one, to decrease leakage and increase the dynamic range. For very close components (say, separated by $2\Delta f$), the increased bandwidth using

windows has to be considered, and a rectangular window (or an increase in the analyzed data duration) is advised. Overlapped processing seems unnecessary, as it is easy to use sufficiently long signal durations, certainly in the case of rotating machines under steady-state conditions. Overlapped processing necessitates a window. The remark concerning very close components applies; overlapped processing may not enable separation).

The number of fundamental periods spanned dictates the location of the spectral line in the DFT presentation.

Transients

Only a straightforward DFT is computed. The use of a Hanning window is obviously erroneous, but special windows are often appropriate.

For repetitive transients, a triggered mode is necessary, and the analysis is performed as if a periodic signal is at hand.

A very important conclusion from the section on errors and their control is: comparisons and evaluations can sometimes be almost meaningless unless information such as analysis of Δf , degrees of freedom or estimated random error, use of window etc., is given.

Nomenclature

e_b	bias error
e_r	random error
E	energy
Δf	frequency spacing
Δt	sampling interval

Introduction

A good standard must represent a consensus of opinion among a broad spectrum of users, be simple to understand, be easy to use, and contain no ambiguities or loopholes. Any Standard must also contain vital information that leads to common measurement procedures and evaluations of data that are compared with agreed-upon criteria. Standards are intended to: (1) establish criteria for rating or classifying the performance of equipment or material; (2) provide a basis for comparison of the maintenance qualities of pieces of equipment of the same type; (3) test equipment whose continuous operation is necessary for industrial or public safety; (4) provide a basis for the selection of equipment or material; and (5) establish procedures for the calibration of equipment. Some standards establish classifications for equipment that is being rated, and indicate how measurements are to be made and how the data, so obtained, are to be analyzed. They may also indicate how the equipment is to operate during the test procedure. This paper is mainly concerned with standards related to machinery vibration and its classifications.

ISO standards are not intended to be specifications; however, equipment purchasers and users can use the applicable ISO standards for compliance when specifying machinery vibration levels or measurement procedures, either on new or in-service equipment. ISO standards, when identified as 'standards', include data that are based on the results of worldwide surveys and they usually have very specific vibration levels, zones, and measurement procedures for different types and sizes of machines. When experience and worldwide equipment manufacturer and/or user surveys cannot clearly establish accepted levels of vibration or measurement procedures, then these ISO standards are identified as 'guidelines'. These deci-

sions are made by the responsible ISO working groups preparing the standards and are sometimes based on the ratio of normative references (requirements) or informative references (information) contained in a particular standard. In addition, at times a new document being prepared for a new class of machines will include measurement procedures that can be used as a guideline until firm acceptable performance criteria can be established.

Standards Organizations and Groups

In the field of vibration, the two recognized international organizations are the International Organization for Standardization (ISO), which is technology-oriented, and the International Electro-technical Commission (IEC), which is product-oriented. ISO and the IEC make every attempt to coordinate their respective standards activities to avoid duplication and discrepancies. These organizations also work in cooperation with national standards organizations in various countries, such as: the American National Standards Institute (ANSI) in the USA; the British Standards Institution (BSI) in the UK; the Deutches Institut für Normung (DIN) in Germany; the Austrian Standards Organization (ON); the Danish Standards Association (DS) in Denmark; Standards of Australia; and so forth.

ISO and the IEC also work with trade associations within countries that develop Standards to fit their unique requirements. For example, in the USA the American Petroleum Institute (API), the Hydraulic Institute (HI), etc., have patterned their own set of standards to satisfy their respective industry needs. These standards are established by the consensus of users, customers, and manufacturers and their use is usually voluntary.

Finally, military organizations in most countries also develop standards applicable to their special requirements for procurement and operation. There are a myriad of military standards, or specifications (MILSpecs), in the USA and many are applied to the acceptance testing of new military hardware both

prior to delivery and, in some cases, in-service acceptance testing such as for shipboard machinery. There are also MILSpecs that address vibration levels that result in airborne noise that may have an adverse affect on the close-quarter environments of military personnel. There is a current trend in the USA for military organizations to use applicable ISO standards, in lieu of MILSpecs which are becoming outdated. In fact, in line with this trend, the USA military has been encouraging the ISO/ANSI standards committees to consider the needs of the USA military when preparing ISO/ANSI standards.

Vibration standards activities in the ISO are guided by Technical Committee 108, Mechanical Vibration and Shock. Vibration standards activities in the IEC are guided by Technical Committee 50. When individual countries, trade groups or military organizations prepare their national vibration standards, most countries do so in accordance with the comparable ISO or IEC standards.

Since the IEC standards are prepared primarily by the equipment manufacturers, they are a consensus of a common ground in which these producers all agree to operate within. However, the ISO committees are a balance between the manufacturers and the users, and therefore have a more universal audience. For this reason, and the fact that it would be virtually impossible to include all of the vibration standards in existence in all of the countries, within a reasonable space and to do them justice, it has been determined that it would be most beneficial to the larger audience that this paper focuses mainly on the ISO vibration standards.

General Machinery Vibration Standards and Criteria

In the development of standards, it has been found that machinery can be subdivided into four categories for the purposes of vibration measurement and evaluation:

1. Reciprocating machinery having both rotating and reciprocation components, such as diesel engines and certain types of compressors and pumps. Vibration is usually measured on the main structure of the machine at low frequencies.
2. Rotating machinery having rigid rotors, such as certain types of electric motors, single-stage pumps, and slow-speed pumps. Vibration is usually measured on the main structure (such as on the bearing caps or pedestals) where the vibration levels are indicative of the excitation forces generated by the rotor because of unbalance, thermal bows, rubs, and other sources of excitation.

3. Rotating machinery having flexible rotors, such as large steam turbine generators, multistage pumps and compressors. The machine may be set into different modes of vibration as it accelerates through one or more critical speeds to reach its service speed. On such a machine, the vibration amplitude measured on a structure member may not be indicative of the vibration of the rotor. For example, a flexible rotor may experience very large amplitude displacements resulting in failure of the machine, even though the vibration amplitude measured on the bearing cap is very low. Therefore, it is essential to measure the vibration on the shaft directly.
4. Rotating machinery having quasirigid rotors, such as low-pressure steam turbines, axial-flow compressors, and fans. Such machinery contains a special class of flexible rotor where vibration amplitudes measured on the bearing cap are indicative of the shaft vibration.

Classification of Severity of Machine Vibration

In the classification of severity of machine vibration, the motion variable that is used (displacement, velocity, or acceleration) depends on the type of standard, the frequency range, and other factors. In classifying machinery vibration in the range 10–1000 Hz, for example, vibration velocity is normally used because it is relatively independent in this range, and thus yields a simple measure of severity for a new operating machine.

For simple harmonic motion, either peak or RMS values of the motion variable may be used. However, for machines whose motion is complex, the use of these two indices provides distinctly different results, mainly because the higher frequency harmonics are given different weights. For rotating machinery whose rotational speed is in the range of 600 to 12 000 rpm, the RMS values of the velocity amplitudes correspond most closely with vibration severity. Therefore, ISO has a special measure, vibration severity, which is defined as the highest value of the broadband RMS value of the velocity amplitude in the frequency range 10–1000 Hz, as evaluated on the structure at prescribed points (generally triaxle arrays on the bearing caps or pedestals).

Measurement Procedures

Included in the ISO standards are procedures for measuring relative shaft-to-housing signals, absolute measurements, and seismic applications as shown in

Figures 1–3. The transducers recommended and described include displacement, velocity, and acceleration. Their mounted and unmounted ranges and limits of application, magnitudes, and frequencies are also included.

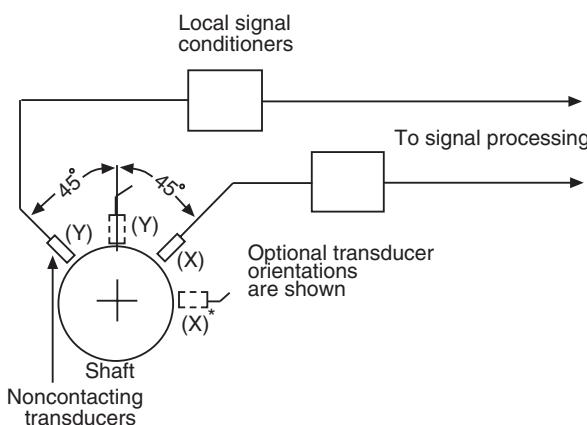

Figure 1 Schematic diagram of relative motion measurement system using non-contacting transducers.

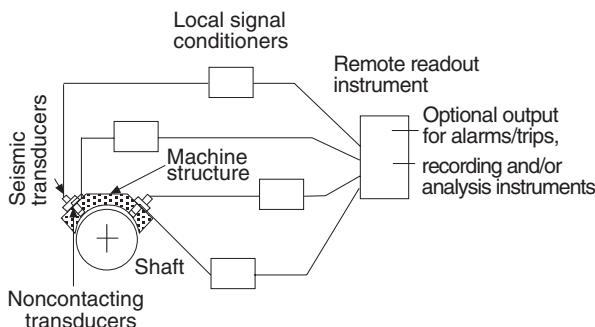

Figure 2 Schematic diagram of absolute/relative motion measurement system using a combination of noncontacting and seismic transducers.

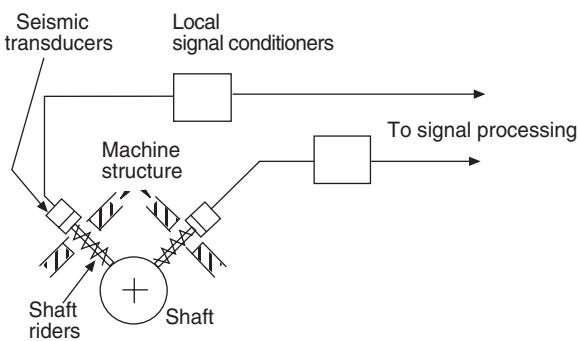

Figure 3 Schematic diagram of absolute motion measurement system using shaft-rider mechanism with seismic transducers.

Vibration Standards Summaries

The following sections contain brief descriptions of the most prominent vibration Standards, either issued or in process. The first section contains broadband measurement procedures and values, including: measurements on nonrotating parts; reciprocating machines; measurements on nonreciprocating rotating shafts; and, machines having gear units. Also considered are measurements on machines with rigid and flexible rotors. The second section contains descriptions of narrowband vibration condition monitoring standards that include spectrum analysis, trending, and diagnostics.

Broadband Vibration Standards

Early ISO vibration standards were ISO 2372, ISO 2954, and ISO 3945. These Standards have been superseded by the ISO10816 and 7917 series described in the following sections. However, these earlier standards still contain useful information.

Nonrotating Parts

ISO/10816/1; Mechanical vibration – evaluation of machine vibration by measurements on nonrotating parts, Part 1: General guidelines This provides general guidelines that describe procedures for the measurement and evaluation of vibration based on measurements made on the nonrotating parts of the machine. This is Part 1 of a series of standards that provide individual criteria for each general class of machine covered, which are unique to those machines. These criteria, which are presented in terms of both vibration magnitude and change of vibration, relate to operational monitoring and acceptance testing.

This series of standards has been written to: (1) cover the broadband frequency range of both low and high speed machines; (2) set the vibration criteria to include both the various operational zones, irrespective of whether they are increases or decreases; (3) incorporate vibration criteria through a worldwide survey; and, (4) include unique criteria and measurement procedures for specific types of machines.

The measure of vibration is broadband and the frequency range is sufficient to ensure that the particular machine is adequately covered, which depends on the type of machine under consideration. For example, the frequency range necessary to assess the integrity of a machine with rolling element bearings should include frequencies higher than those on machines with fluid film bearings.

In addition to vibration velocity measurements, which were the primary criteria in earlier Standards because they related to vibration energy, the 10816 series also includes alternate criteria such as displacement, acceleration, and peak values instead of RMS, as these criteria may be preferred for machines designed for extra low or high speed operation.

ISO/10816, Part 2: Guidelines for land-based steam turbine sets in excess of 50 MW This provides specific guidance for assigning the severity of vibrations measured on the bearings or pedestals of large steam turbine generating sets. Measurements at such specified locations reasonably characterize the overall state of vibration of these machines.

The vibration measurement system should be capable of measuring broadband vibration in mm s^{-1} RMS over a frequency range 10–500 Hz. If, however, the instrumentation is also to be used for diagnostic purposes, or for monitoring during machine run-up or run-down, or overspeed, a wider frequency may be required.

This standard includes the vibration criteria shown in Table 1 which is based on bearing housing/pedestal vibration velocity amplitude (mm s^{-1} , rms) for turbine generator sets exceeding 50 MW, and with nominal speeds of 1500, 1800, 3000, and 3600 rpm. The values apply to *in situ* application under steady-state conditions. Zone A represents new machines that can be operated without restriction; zone B is acceptable for long term operation; zone C represents machines that may be operated for a limited time until a suitable opportunity arises for remedial action to be taken; and, zone D is identified as a trip level as these values are considered to be of sufficient severity to cause damage.

ISO/10816, Part 3: Guidelines for coupled industrial machines with nominal power above 30 kW and nominal speeds between 120 and 15 000 rpm when measured in situ This provides specific guidance for assessing the severity of vibrations on bearings, bearing pedestals, or the housings of coupled industrial machines when measured *in situ*. This standard covers the following machines: steam turbines with power above 50 MW, compressors, industrial gas

turbines with power up to 3 MW, pumps with power up to 1 MW, generators, electric motors of any type, and blowers with power greater than 300 kW.

Significant differences in design, types of bearings, and types of support structures require a division of this standard into two machinery groups, namely: (1) large machines with rated power above 300 kW, or electrical machines with shaft heights over 315 mm; and, (2) medium size machines with a rated power above 30 kW up to and including 300 kW, or electrical machines with shaft heights from 180 mm to 315 mm. The larger machines normally have sleeve bearings and the range of operating or nominal speeds is relatively broad with ranges from 120 rpm to 15 000 rpm.

Classification of the vibration severity zones for large industrial machines with rated power from 300 kW to 50 MW (Group 1) are shown in Table 2. Classification of the vibration severity zones for medium size industrial machines with rated power from 30 to 300 kW (Group 2) are included in Table 3. The zone descriptions are the same as in 10816, Part 2.

ISO/10816, Part 4: Guidelines for gas turbine driven sets excluding aircraft derivative This provides specific guidance for assessing the severity of vibrations measured on the bearing housings or pedestals of gas turbine sets.

This standard applies to heavy-duty gas turbines used in electrical and mechanical drive applications covering the power range above 3 MW, and a speed range under load between 3000 and 20 000 rpm.

Table 2 Severity zones for large machines (group 1)

Support class	Zone boundary	Displacement (μm , RMS)	Velocity (mm s^{-1} , RMS)
Rigid	A/B	37	2.3
	B/C	72	4.5
	C/D	113	7.1
Flexible	A/B	56	3.5
	B/C	113	7.1
	C/D	175	11.0

Table 3 Severity zones for medium sized machines (group 2)

Support class	Zone boundary	Displacement (μm , RMS)	Velocity (mm s^{-1} , RMS)
Rigid	A/B	22	1.4
	B/C	45	2.8
	C/D	71	4.5
Flexible	A/B	37	2.3
	B/C	71	4.5
	C/D	113	7.1

Table 1 Recommended vibration velocity levels (mm s^{-1} , RMS)

Zone boundary	Shaft rotational speed (rpm)	
	1500–1800	3000 or 3600
A/B	2.8	3.8
B/C	5.3	7.5
C/D	8.5	11.8

Generally, the criteria applies to both the gas turbine and the driven equipment; however, for generators above 50 MW, the criteria of 10816, Part 2 should be used for assessing the vibration severity. For compressors in the power range from 30 to 300 kW, the criteria of 10816, Part 3 should be used for assessing vibration severity.

The evaluation of zone boundaries based on bearing housing/pedestal vibration for industrial gas turbines is given in **Table 4**. These criteria assume that the gas turbines incorporate fluid film bearings, and the vibration measurements are broadband values taken *in situ* under normal steady-state operating conditions. This standard encompasses machines which may have gears or rolling element bearings, but does not address the evaluation of the condition of those gears or bearings. The zone descriptions are the same as in 10816, Part 2.

ISO/10816, Part 5: (to be published) Guidelines for hydraulic machines with nominal power above 1 MW and nominal speeds between 120 and 1800 rpm when measured in situ This provides specific guidance for assessing the severity of vibrations measured on bearings, bearing pedestals, or housings of hydraulic machines when measured *in situ*. It applies to machine sets in hydraulic power generation, and pump plants where the hydraulic machines have speeds from 120 to 1800 rpm, shell- or shoe-type sleeve bearings, and main engine power of 1 MW or more. The position of the line shaft may be vertical, horizontal, or at an arbitrary angle between these two directions.

This Standard includes: turbines and generators, pumps, and electrical machines operating as motors, pump-turbines, and motor generators, including auxiliary equipment (e.g., starting turbines or excitors in line with the main shaft). The Standard also includes single turbines or pumps connected to generators or electric motors over gears and/or radially flexible couplings.

The recommended criteria values in mm s^{-1} , RMS vs shaft rotational speed in rpm for hydraulic machines with nominal power above 1 MW, and nominal speeds between 120 and 1800 rpm are shown in **Figure 4**. The zone descriptions are the same as in 10816, Part 2.

Table 4 Evaluation of zone boundaries based on bearing housing pedestal vibration

Shaft rotational speed (rpm)	Zone boundary		
	A/B	B/C	C/D
3000–20 000	4.5	9.3	14.7

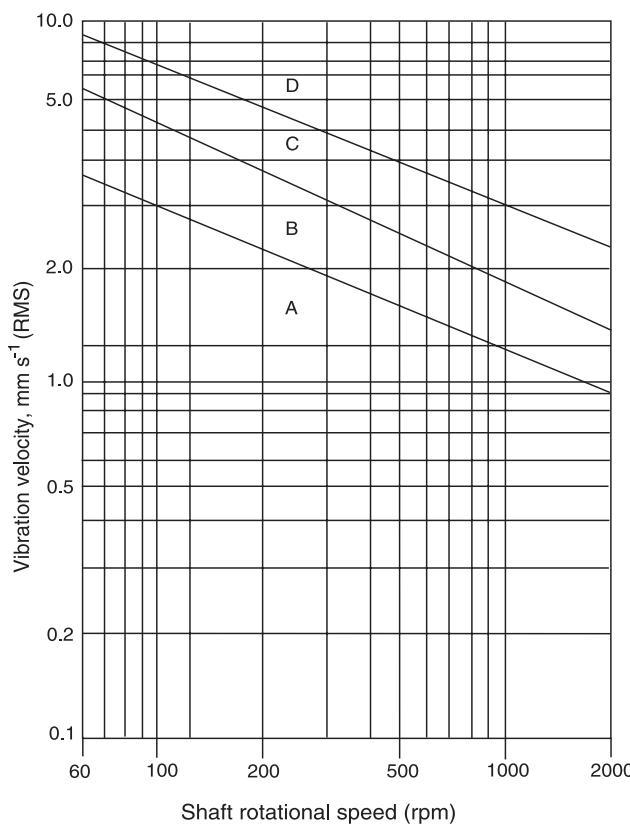

ISO/10816, Part 6: Reciprocating machines with power ratings above 100 kW This establishes procedures and guidelines for the measurement and classification of mechanical vibrations of reciprocating machines. In general, this standard refers to vibration measurements made on the main structure of the machine, and the guide values are defined primarily to secure a reliable and safe operation of the machine, and to avoid problems with the auxiliary equipment mounted on the structure.

In the case of reciprocating machines, the vibrations measured on the machine main structure, and qualified according to this standard, may only give a rough idea of the stresses and vibratory states of the components within the machine itself. For example, torsional vibrations of rotating parts cannot generally be determined by measurements on the structural parts of the machine. Based on experience with similar machines, the damage that can occur when exceeding the guide values is sustained predominately by the machine-mounted components (e.g., turbochargers, heat exchangers, governors, pumps, filters, etc.), connecting elements of the machine with peripherals (e.g., pipelines), or monitoring instruments (e.g., pressure gauges, thermometers, etc.).

This standard generally applies to reciprocating piston machines mounted either rigidly or resiliently with power ratings above 100 kW. The vibration criteria for different classes of reciprocating machines are presented in **Table 5**. The class definitions are: (1) balanced opposed type rigidly mounted reciprocating gas compressors; (2) multithrow type rigidly mounted reciprocating gas compressors; (3) single-throw type rigidly mounted reciprocating gas compressors; (4) no example; (5) and (6) industrial and marine diesel engines (<2000 rpm); and, (6) and (7) industrial and marine diesel engines (>200 kW). The zone descriptions are the same as in 10816, Part 2.

Rotating Parts

ISO/7919-1, Mechanical vibration of non-reciprocating machines – measurement on rotating shafts and evaluation – Part 1: General guidelines This provides specific guidelines for vibration measurements on the rotating members of machines. Such machines generally contain flexible rotor-shaft systems. Changes in the vibration condition may be detected more decisively and more sensitively by measurements on these rotating elements. Also, machines having relatively stiff and/or heavy casings, in comparison to the rotor mass, are typical of those classes of machines for which shaft vibration measurements are frequently preferred.

**Figure 4** Recommended criteria values.**Table 5** Reciprocating machinery class definitions

Vibration severity grade	Maximum levels of overall vibration Measured on the machine structure			Machine vibration classification number						
	Displacement (μm , RMS)	Velocity ($mm s^{-1}$, RMS)	Acceleration ($m s^{-2}$, RMS)	1	2	3	4	5	6	7
1.1										
1.8	17.8	1.12	1.76							
2.8	28.3	1.78	2.79	A/B						
4.5	44.8	2.82	4.42		A/B					
7.1	71.0	4.46	7.01	C		A/B				
11	113	7.07	11.1	D	C		A/B			
18	178	11.2	17.6		D	C		A/B		
28	283	17.8	27.9			D	C		A/B	
45	448	28.2	44.2				D	C		A/B
71	710	44.6	70.1					D	C	
112	1125	70.7	111						D	C
180	1784	112	176							D

Machines such as industrial steam turbines, gas turbines, and turbocompressors, all of which have several modes of vibration in their service speed range; and, their responses due to unbalance, misalignments, thermal bows, rubs, and the unloading of bearings may be better observed by measurements on the shafts.

There are three principle factors by which the vibration level of a machine is judged, namely: (1) bearing kinetic load; (2) absolute motion of the rotor; and, (3) rotor clearance relative to the bearing. If the bearing kinetic load is of concern to ensure against bearing damage, the vibration of the shaft relative to the bearing structure should be monitored

as the overriding criteria. If the absolute motion of the shaft (a measure of rotor bending stress) or rotor-bearing clearance are of concern, the type of measurement used depends on the vibration level of the structure which supports the relative motion transducer. Hence, if the vibration level of this support structure is less than 20% of the relative shaft vibration, the absolute shaft vibration must be measured; and, if this is found to be larger than the relative shaft vibration, then this will be the more valid measurement. The rotor clearance to the bearing must be monitored to ensure against rotor seal and blading rubs which can cause rotor or blading failures.

The shaft vibrations of machines, measured close to the bearings, are evaluated on the basis of two criteria. (1) The reliable and safe running of a machine under normal operating conditions requires that the shaft vibration displacement remain below certain limits consistent with, for example, acceptable kinetic loads and adequate margins on the radial clearance envelope for the machine. Generally, this criterion is taken as the basis for the evaluation of a new machine, in the absence of any other established knowledge of the satisfactory running characteristics for a machine of that type. (2) Changes in shaft vibration displacement, even though the limits in (1) are not exceeded, may point to incipient damage or some other irregularity. Consequently, such changes relative to a reference value should not be allowed to exceed certain limits. If this reference value changes by a significant amount, and certainly if it exceeds 25% of the reference level, steps should be taken to ascertain the reasons for the change and, if necessary, appropriate action should be taken. In this context, a decision on what action to take, if any, should be made after consideration of the maximum value of vibration, and whether the machine has stabilized at a new condition.

ISO Standard 10817, Part 1 describes the sensing device (transducer), signal conditioning, attachment methods, and calibration procedures for instrumentation to measure shaft vibration.

ISO 7919, Part 2: Guidelines for large land-based steam turbine-generating sets provides the special features required for measuring shaft vibrations on the coupled rotor systems of steam turbine-generating sets for power stations, having rated speeds in the range 1500–3600 rpm, and power outputs greater than 50 MW. Evaluation criteria, based on previous experience, are presented which may be used as guidelines for assessing the vibratory conditions of such machines.

The vibration levels specified here define four quality zones for both relative and absolute shaft vibration measured at, or close to, the main load-carrying bearings, at rated speed and under steady state conditions. Higher levels of vibration can be permitted at other measuring positions and under transient conditions, such as start-up and run-down (including passing through critical speed ranges).

The recommended shaft vibration amplitude values for large steam turbine-generator sets, in micrometers peak-to-peak measured relative to the bearings, are shown in Table 6 for relative shaft to bearing vibrations, and in Table 7 for absolute vibrations. In both tables, zone A represents new machines that can be operated without restriction; zone B is acceptable for long-term operation; zone C represents machines that may be operated for a limited time until a suitable opportunity arises for remedial action to be taken; and, zone D is identified as a trip level as these values are considered to be of sufficient severity to cause damage.

ISO 7919, Part 3: Guidelines for coupled machines These are given for application of shaft vibration evaluation criteria measured close to the bearings under normal operating conditions. These guidelines are presented in terms of both steady running conditions, and any changes that may occur in these steady values. This standard applies to coupled industrial machines with fluid film bearings, comprising: turbo-compressors, turbines, turbine-generators, and electric drives, all having maximum rated speeds in the range 1000–30 000 rpm, and powers between 30 kW and 50 MW.

Table 6 Relative shaft to bearing vibrations

Zone boundary	Shaft rotational frequency ($r\text{min}^{-1}$)			
	1500	1800	3000	3600
<i>Maximum shaft relative displacement</i>				
A	100	90	80	75
B	200	185	165	150
C	320	290	260	240

Table 7 Absolute vibrations

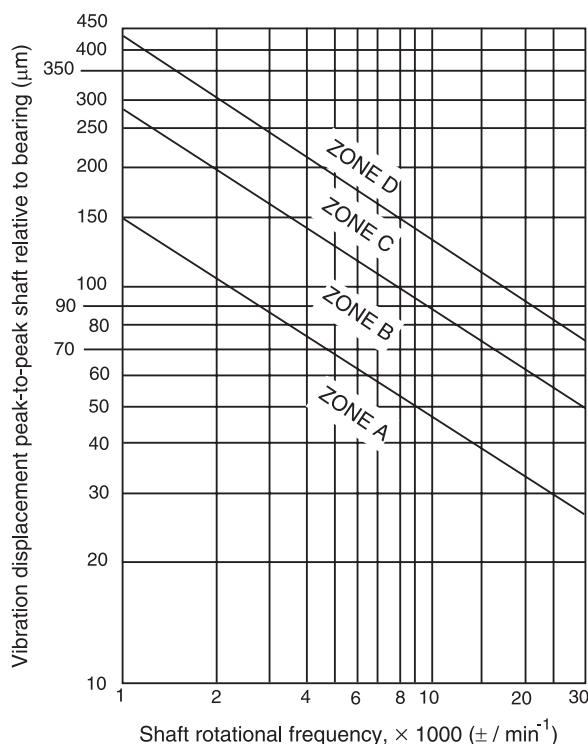

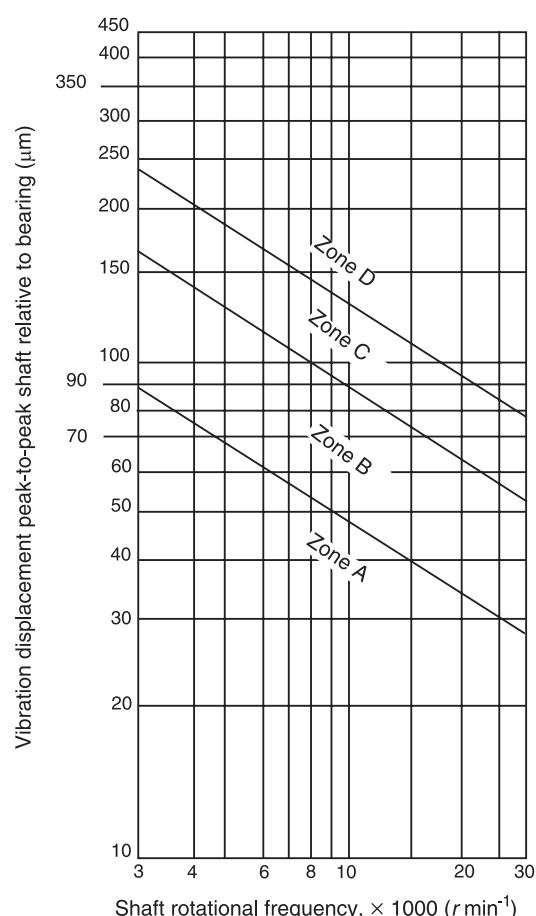

Zone boundary	Shaft rotational frequency ($r\text{min}^{-1}$)			
	1500	1800	3000	3600
Maximum shaft relative displacement				
A	120	110	100	90
B	240	220	200	180
C	385	350	320	290

The numerical values specified in **Figure 5** are not intended to serve as the only basis for acceptance specifications. In general, the vibratory condition of these machines is usually assessed by consideration of both the shaft vibration and the associated structural vibration. As a result, this Standard should be used in conjunction with 10816, Part 3. The zone descriptions of **Figure 5** are the same as in 7919, Part 2.

ISO 7919, Part 4: *Guidelines for Gas-Turbines* applies to industrial gas turbine sets (including those with gears) with fluid film bearings, power outputs greater than 3 MW, and shaft rotational speeds from 3000 to 30 000 rpm. Aircraft type gas turbines are excluded, since they differ fundamentally from industrial gas turbines, both in the types of

bearings (rolling element), and in the stiffness and mass ratios of the rotors and support structures. Depending on the construction and mode of operation, there are three types of industrial gas turbines: (1) single-shaft constant-speed; (2) single-shaft variable-speed; and, (3) gas turbines having separate shafts for hot-gas generation and power delivery.

Guidelines are given in **Figure 6** for the application of shaft vibration criteria measured close to the bearings of industrial gas turbines under normal operating

**Figure 5** Recommended vibration amplitude values for coupled machines.**Figure 6** Recommended shaft vibration amplitudes for gas turbines.

conditions. The zone descriptions are the same as in 7919, Part 2.

ISO 7919, Part 5: Guidelines for hydraulic machine sets This lists the special features required for measuring shaft vibrations on coupled hydraulic sets. This standard applies to all types of hydraulic machines having nominal speeds between 60 and 3600 rpm, with fluid film bearings and rated powers of 1 MW or more. These machines may consist of turbines, pumps, pump-turbines, generators, motors, and motor-generators, including couplings, gears, or auxiliary equipment in the shaft line. The position of the shaft may be vertical, horizontal, or at an arbitrary angle between these two directions.

The guidelines are given for the application of shaft vibration criteria as measured close to the bearings of coupled hydraulic sets, under normal operating and steady state conditions, and any changes that may occur in these steady values. The numerical values specified in Figure 7 present rotor displacements relative to the bearings in micrometers peak-to-peak vs shaft rotational speed in rpm. The zone descriptions are the same as in 7919, Part 2.

Gear Units

ISO 8578, Acceptance code for gears, Part 2: Determination of mechanical vibration of gear units during acceptance testing This provides a method for determining the mechanical vibration of enclosed gear units which are individually housed. This Standard applies to a gear unit under test and operating within its design speed, load, temperature range, and lubrication specifications for acceptance testing. Two types of vibration measurements are made on gear units that operate with oil-film journal bearings: (1) shaft vibration; and (2) housing vibration.

Proximity-type transducers are usually used to measure the peak-to-peak value of the shaft's displacement relative to the housing, in the frequency range 0–500 Hz. The transducers are located as close as practical to a bearing. The measurements should be made in three orthogonal directions, one of which is parallel to the shaft axis. Only one axial transducer per shaft is necessary. The housing vibration is measured with a seismic transducer in the frequency range 10–10 000 Hz. A classification

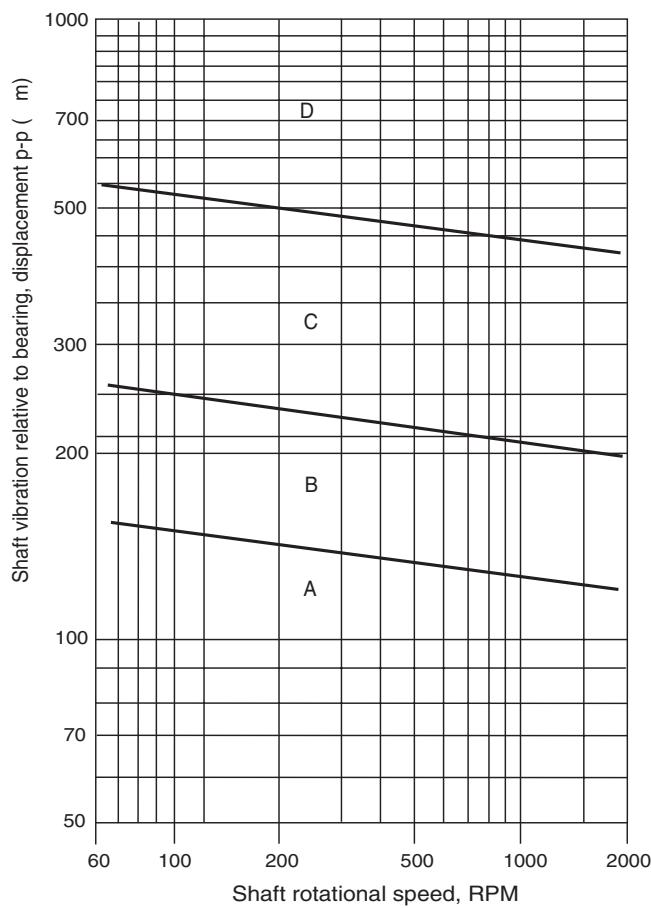

Figure 7 Recommended shaft vibration amplitudes for hydraulic machine sets.

system for gear boxes on the basis of shaft displacement and housing velocity measurements is given in Figures 8 and 9.

This standard also provides a subjective assessment of the acceptable vibration rating for typical applications during acceptance testing at the manufacturer's facility. The vibration of a properly manufactured gear unit will vary according to the particular design, size, and application. For example, what may be perfectly suitable for a large low-speed mill drive may not be acceptable for a precision high-speed or marine drive; and, what may be acceptable for a precision high-speed drive may be unjustifiably expensive for a low-speed drive. Therefore, care must be taken when applying a given grade as an acceptance criterion. Figure 10 gives subjective levels of vibration for typical gear applications.

Vibration Condition Monitoring

ISO 13373-1 (to be published), Condition monitoring and diagnostics of machines – Vibration condition monitoring – Part 1: Guidelines for condition monitoring of machines This includes the general guidelines for the measurement and data collection functions necessary for the vibratory assessment of machinery vibration for condition monitoring and diagnostics. It is intended to promote consistency of the measurement procedures and practices, with concentration on rotating machines. The standard is applicable to all types of rotating machines and sizes. It also describes the types of typical monitoring systems (permanent, semipermanent, and portable); and, the various methods of data collection (continuous or periodic).

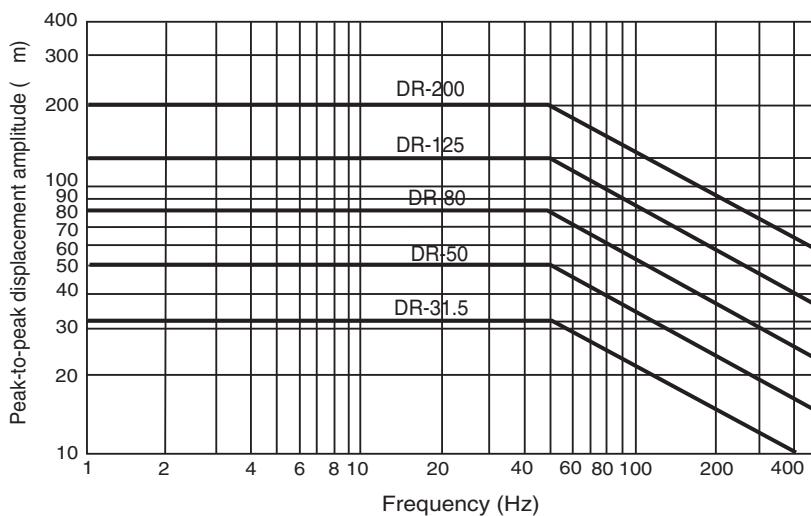

Figure 8 Gear shaft vibration amplitudes.

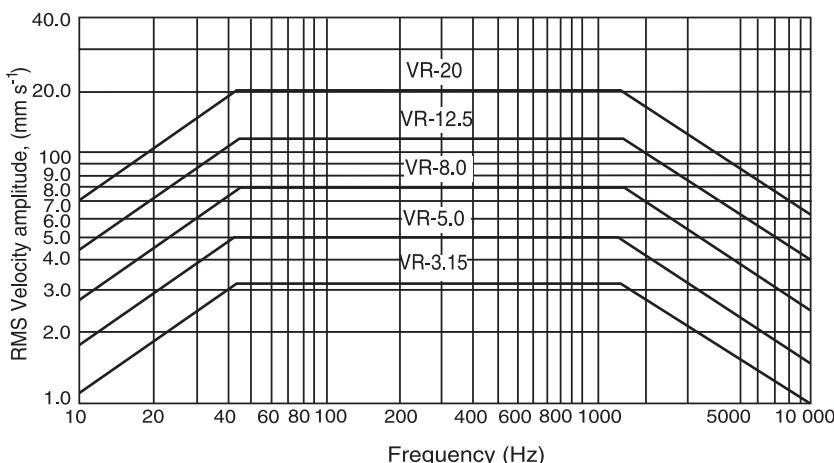

Figure 9 Gear housing vibration amplitudes.

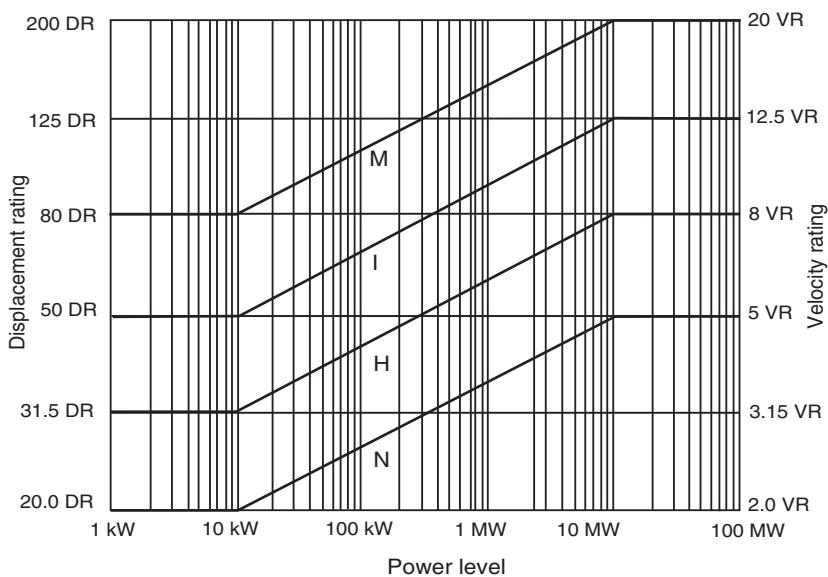

Figure 10 Subjective gear ratings.

The measurements and the transducers described are selected to provide the taking of data for recording and trending purposes (condition monitoring), and for discrete frequency analysis for the purposes of diagnostics. The trending guidelines include tracking the vibration levels and the frequencies of data collection; and, how these frequencies may change with changes in the vibration levels, and their rates of changes. A typical frequency spectrum is shown in Figure 11 which can be used for diagnostic purposes. It can also be used for discrete frequency trending.

Recommended ranges for displacement, velocity, and acceleration transducers are specified, as well as

frequency ranges of operation. Figure 12 demonstrates the typical envelope ranges of velocity vs frequency for several type transducers.

The standard also includes guidance for transducer resonant frequency characteristics, and mounted frequency concerns.

The recommended transducer types and their locations and directions for various type machines are included in Annex A of the standard. Only p. 1 of Annex A, Table 8, is included here for information purposes. It is noted that the sizes of the machines usually indicate common construction characteristics, such as fluid film vs rolling element bearings,

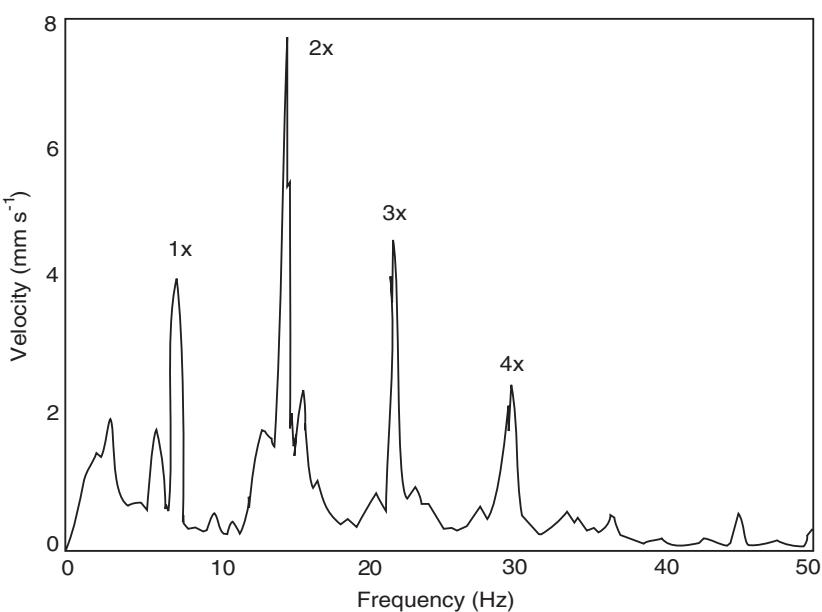

Figure 11 Frequency spectrum.

Table 8 Guidelines for transducer applications for various types of machine^a

Machine type	Evaluation parameters	Transducer type	Measurement locations	Direction	ISO standard reference	Notes
Large steam turbine generator sets with fluid film bearings	Relative displacement or absolute displacement	Noncontacting transducer	Shaft at each bearing	Radial ±45 deg or X and Y	7919-Part 2	^a
		Noncontacting and seismic transducer combination				
Power generation	Velocity or acceleration	Velocity transducer or accelerometer	Each bearing housing	Radial X and Y	10816-Part 2	
	Shaft axial displacement	Noncontacting transducer or axial probe	Thrust collar	Axial Z		
	Phase reference and rpm	Eddy current/inductive/optical transducer	Shaft	Radial		
Medium and small industrial steam turbines with fluid film bearings	Relative displacement	Noncontacting transducer	Shaft at each bearing	Radial ±45 deg or X and Y	7919-Part 3	
	Velocity or acceleration	Velocity transducer or accelerometer	Each bearing housing and turbine housing	Radial X and Y		10816-Part 3
Mechanical drive						
Power generation	Shaft axial displacement	Noncontacting transducer or axial probe	Thrust collar	Axial Z		
	Phase reference and rpm	Eddy current/inductive/optical transducer	Shaft	Radial		

^a Orthogonal measurements at ±45 deg are normally used for condition monitoring. Vertical and horizontal (X and Y) locations are acceptable alternatives.

Table 9 Most common causes of lateral vibration

Cause	Characteristic vibration frequencies	Remarks
Unbalance	1 × (once per revolution)	Changes in balance will give changes in the 1 × vector. Vibration will be highest when running speed coincides with a rotor system critical speed. Significant vibration phase change will occur when passing through critical speeds. At a fixed speed vibration levels are constant
Misalignment	1 × , 2 × , 3 ×	Various types and causes for misalignment are: angular, parallel, foundation movement. The axial vibration component may be as significant as the radial component, particularly for geared systems
Bearing wear	40–50% of operating speed or at first rotor critical speed	Excessive clearance due to wear, damage or improper assembly can cause bearing oil film destabilizing forces to act on the rotor
Oil film bearings		Vibration levels will be unsteady and can quickly reach high magnitudes
Rolling element bearings	Various frequencies, particularly high orders of running speed and ball pass frequencies	Vibration tends to be localized to the region of the defective bearing
		Vibration readings are usually unsteady and increase with time
Stiffness dis-symmetry (e.g., axial winding slots in generator/motor rotors)	2 ×	Vibration peaks when a 2 × stimulus is coincident with a rotor critical speed. At a fixed rotor speed vibration levels are constant.
		Compensating grooves are used on large machines to minimize this stimulus
Bent rotor (see also thermal dis-symmetry)	1 × , 2 × , or higher orders	If the rotor is bent near the coupling, a high 2 × axial vibration is frequently observed. At a fixed speed, the rotor vibration levels are constant
Cracked rotor	1 × , 2 × , or higher harmonics	A growth in the 2 × vector is an indication that the growth of a transverse crack is getting critical. Changes in the 1 × or higher harmonic vectors can also occur
Component looseness in rotor	1 × and harmonics of running speed frequency	Vibration levels may be erratic and inconsistent between successive start-stop cycles. Sometimes subharmonic frequencies are also observed
Eccentric or noncircular bearing journals	1 × and for noncircular journals at harmonics of running speed frequency	Vibration levels can be abnormal or excessive at low rotor speeds as well as at rotor critical speeds. At a fixed rotor speed, the vibration levels are constant

and these considerations normally dictate the type(s) of transducers recommended.

Annex C of the standard provides guidance regarding the most common causes of lateral and torsional vibration. Only p. 1 of Annex C (**Table 9**) is included here for information.

ISO 13373-2 (to be published), Part 2: Processing, analysis, diagnostics, and display of data for vibration condition monitoring of machines This provides guidelines for processing vibration data in the time and frequency domains, analyzing the vibration signatures, displaying the data and applying the results

of the analyses to machinery vibration diagnostics. Different techniques are described for different applications. Signal enhancement techniques and analysis methods used for the investigation of particular machine dynamic phenomenon are included. Many of these techniques can be applied to other machine types including reciprocating machines. Standard formats for the parameters that are commonly plotted for evaluation and vibration diagnostic purposes are given. These should be used for computer display screens and for hard copy presentations (line printers, laser plotters).

The signal-processing and analysis procedures applied to vibration condition monitoring are as varied as the processes to be monitored, the degree of certainty desired, the resources available, etc. A well conceived condition monitoring program will include the consideration of many factors such as process priority, criticality and complexity of the system, cost-effectiveness, probability of various failure mechanisms and identification of incipient failure indicators, etc. The standard defines the appropriate process analysis that dictates the types of data required to suitably monitor and diagnose particular types of equipment.

The standard stresses in that the vibration analyst should accumulate as much pertinent information as possible about the machine to be monitored. For example, knowing the vibration resonant frequencies from design and analytical information will provide an insight regarding the vibration frequencies anticipated, and, consequently, the frequency range that should be monitored. Also, knowing the operating conditions tells the analyst what the excitations will be. Other advantages to this pretest planning process are that it provides guidance as to what types of sensors are needed, where they should be located optimally, what kind of signal conditioning equipment is required, what types of analyses would be most appropriate, and what the relevant criteria are.

The basic signals from the displacement, velocity, and accelerometer transducers are recorded as amplitude vs time, which is the primary vibration signature, and this is termed the 'time domain'. The standard then proceeds to identify the conversion of the analog signals to the more recent techniques of digitizing the signals, which is done automatically with present-day analyzers. In this manner, analog excursions are directly converted to numerical values.

The next basic step addressed in the standard is the process of applying the FFT to the time signal to obtain a frequency spectrum of the signal, which identifies the amplitudes of the distinct repetitive frequencies that can be analyzed regarding their source(s), and this is called the 'frequency domain'. This process then leads to vibration analysis and diagnostics which can determine the machine component that is producing the dominant signal, and is therefore the likely candidate causing the machine problem.

Other factors pertaining to the signal processing in the standard include: beating, modulation, integration and differentiation, crest factor, amplifiers, filtering, dynamic range, real and imaginary, resolution, modulation, and aliasing.

The standard identifies that the discrete frequency peaks can result from a sine wave representing the

fundamental frequency of a rotating shaft, or higher frequencies related to blade pass, gear mesh, or rolling element ball passing. Since these intelligent signals may be difficult to detect at times, due to noise levels or other obscuring phenomenon, the standard contains many analysis techniques that can be applied to help obtain the intelligent diagnostic information, such as: orbit analysis, Bode plots, polar plots, waterfall (cascade) plots, zoom analysis, Campbell diagram, cepstrum, kurtosis, and others.

Introduction

This article is concerned with nonlinear dynamical systems whose response to excitations is random; namely, it can only be described in terms of probability and statistics. The cause for random system response may be random excitations, random properties of the system, random initial conditions, random boundary conditions, or various combinations of the above. However, only random excitations will be considered herein, of which turbulent winds, earthquakes, rough roadways, and irregular sea waves are some examples. The system nonlinearity may result from, but not be limited to, large deformation. Specifically, governing differential equations of the following type for discrete nonlinear systems will be considered:

$$\ddot{Y}_j + \beta_j(\mathbf{Y}, \dot{\mathbf{Y}}) = \sum_k \gamma_{jk}(\mathbf{Y}, \dot{\mathbf{Y}}) \xi_k(t); \quad j = 1, 2, \dots, N \quad [1]$$

where $\beta_j(\cdot, \cdot)$ and $\gamma_{jk}(\cdot, \cdot)$ are generally nonlinear, and $\xi_k(t)$ are stochastic processes (random functions). Letting $X_j = Y_j$ and $X_{j+N} = \dot{Y}_j$, eqns [1] may be transformed into a system of first-order equations:

$$\dot{X}_i = f_i(\mathbf{X}) + \sum_j g_{ij}(\mathbf{X}) \xi_j(t); \quad i = 1, 2, \dots, 2N \quad [2]$$

Comparing [1] and [2]:

$$f_i = \begin{cases} X_{i+N}, & i = 1, 2, \dots, N \\ -\beta_{i-N}(\mathbf{X}), & i = N+1, N+2, \dots, 2N \end{cases} \quad [3]$$

$$g_{ij} = \begin{cases} 0, & i = 1, 2, \dots, N \\ \gamma_{i-N,j}(\mathbf{X}), & i = N+1, N+2, \dots, 2N \end{cases} \quad [4]$$

The form [1] or [2] suggests that the stochastic excitations $\xi_j(t)$ can be additive, or multiplicative (also known as parametric), or both. An additive excitation is one whose accompanying coefficient is merely a constant; namely, the coefficient is independent of the state \mathbf{X} .

Solutions to system [2] may be classified into two types: (i) the probabilistic properties of $\mathbf{X}(t)$, and (ii) the statistical properties of $\mathbf{X}(t)$. For each type, solutions may be obtained for properties at one time instant, and for joint properties at more than one time instant.

Exact Probability Solutions

Some exact solutions for the probability density of the system response $\mathbf{X}(t)$ have been obtained for system [2] when the excitation processes $\xi_j(t)$ are Gaussian white noises, to be denoted specially as $W_j(t)$, which are defined in terms of the following statistical properties:

$$E[W_j(t)] = 0 \quad E[W_j(t)W_k(t+\tau)] = 2\pi S_{jk}\delta(\tau) \quad [5]$$

where $E[\cdot]$ denotes an ensemble average, $\delta(\cdot)$ is the Dirac delta function, and each S_{jk} is a constant, representing the cross spectral density of $W_j(t)$ and $W_k(t)$. It represents the spectral density of $W_j(t)$ when $j = k$. Under Gaussian white-noise excitations, the response $\mathbf{X}(t)$ is a diffusive Markov vector, whose

conditional probability density $q(\mathbf{x}, t | \mathbf{x}_0, t_0)$ is governed by the following Fokker–Planck–Kolmogorov (FPK) equation:

$$\frac{\partial q}{\partial t} + \sum_i \frac{\partial}{\partial x_i} (a_i q) - \frac{1}{2} \sum_i \sum_j \frac{\partial^2}{\partial x_i \partial x_j} (b_{ij} q) = 0 \quad [6]$$

The unknown q is the transition probability density, and is treated as a function of the state variable \mathbf{x} (possible value of \mathbf{X}) and time t , on the condition that $\mathbf{X}(t_0) = \mathbf{x}_0$, where $t_0 \leq t$. This condition is indicated specifically as $|\mathbf{x}_0, t_0$. Eqn [6] is solved under some suitable boundary conditions for the probability density, and the initial condition:

$$q(\mathbf{x}, t_0 | \mathbf{x}_0, t_0) = \Pi \delta(x_i - x_{i0}) \quad [7]$$

where the x_i are components of \mathbf{x} , and the x_{i0} are components of \mathbf{x}_0 . The main ingredients in eqn [6] are the coefficients a_i and b_{ij} . They are known as the first and second derivate moments, respectively, defined as:

$$a_i = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} E[X_i(t + \Delta t) - X_i(t) | \mathbf{X}(t) = \mathbf{x}] \quad [8]$$

$$b_{ij} = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \times E \left\{ [X_i(t + \Delta t) - X_i(t)] [X_j(t + \Delta t) - X_j(t)] | \mathbf{X}(t) = \mathbf{x} \right\} \quad [9]$$

which can be obtained from the system governing eqns [2]. Specifically:

$$a_i = f_i(\mathbf{x}) + \pi \sum_j \sum_k \sum_r K_{jr} g_{kr}(\mathbf{x}) \frac{\partial}{\partial X_k} g_{ij}(\mathbf{x}) \quad [10]$$

$$b_{ij} = 2\pi \sum_k \sum_r K_{kr} g_{ik}(\mathbf{x}) g_{jr}(\mathbf{x}) \quad [11]$$

Unfortunately, eqn [6] is difficult to solve analytically. Therefore, the special case for which the following stationary-state solution exists is considered:

$$p(\mathbf{x}) = \lim_{t \rightarrow t_0 \rightarrow \infty} q(\mathbf{x}, t | \mathbf{x}_0, t_0) \quad [12]$$

The existence of the stationary probability density $p(\mathbf{x})$ requires that the boundary conditions to be imposed on eqn [6] must be such that the total probability is preserved within the domain for \mathbf{x} . For this special case, the stationary probability $p(\mathbf{x})$ is governed by:

$$\sum_i \frac{\partial}{\partial x_i} (a_i p) - \frac{1}{2} \sum_i \sum_j \frac{\partial^2}{\partial x_i \partial x_j} (b_{ij} p) = 0 \quad [13]$$

Equation [13] is known as the reduced FPK equation.

Solution for eqn [13] is relatively easy to obtain for the following system of nonlinear stiffness but linear damping:

$$\ddot{Y}_j + c_j \dot{Y}_j + \frac{\partial}{\partial y_j} U(\mathbf{Y}) = W_j(t); \quad j = 1, 2, \dots, N \quad [14]$$

where $W_j(t)$ are uncorrelated Gaussian white noises; namely, $S_{ij} = 0$ if $i \neq j$. It can be seen by comparing eqns [1] and [14] that, in this case, all excitations are additive, and that the function $U(\mathbf{Y})$ represents the potential energy in the system. Under the condition:

$$\frac{c_j}{S_{jj}} = \kappa \text{(a constant)}, \quad \text{for all } j \quad [15]$$

eqn [13] can be solved to yield:

$$p = C \exp \left\{ -\frac{\kappa}{\pi} \left[\frac{1}{2} \sum_{j=1}^N x_{j+N}^2 + U(x_1, x_2, \dots, x_N) \right] \right\} \quad [16]$$

where x_j is the state variable for Y_j , x_{j+N} is the state variable for \dot{Y}_j , and C is a constant to be determined under the normalization condition of unit total probability. Equation [16] shows that the kinetic energies $\frac{1}{2} \dot{Y}_j^2$ of different modes are identically distributed, known as equipartitioning of energy in statistical mechanics.

For more complicated cases, including nonlinear damping and/or parametric excitations, an exact solution can be found if the system belongs to a special class, called the class of generalized stationary potential. To obtain such a solution, we split both the first and second derivate moments as follows:

$$a_i = a_i^{(1)} + a_i^{(2)} \quad [17]$$

$$b_{ij} = b_{ij}^{(i)} + b_{ji}^{(j)} \quad [18]$$

Note that the symmetry property of the second derivative moment, $b_{ij} = b_{ji}$, is maintained in eqn [18]. Equation [13] can then be replaced by:

$$\sum_i \frac{\partial}{\partial x_i} \left(a_i^{(1)} p - \sum_j \frac{\partial}{\partial x_j} b_{ij}^{(i)} p \right) + \sum_i \frac{\partial}{\partial x_i} \left(a_i^{(2)} p \right) = 0 \quad [19]$$

Equation [19] is satisfied under the following more restrictive conditions:

$$a_i^{(1)} p - \sum_j \frac{\partial}{\partial x_j} b_{ij}^{(i)} p = 0 \quad [20]$$

$$\sum_i \frac{\partial}{\partial x_j} \left[a_i^{(2)} p \right] = 0 \quad [21]$$

A system is said to belong to the class of generalized stationary potential if a consistent solution p can be found which satisfies both eqns [20] and [21].

In the case of a single-degree-of-freedom system:

$$\dot{X}_1 = X_2 \quad [22]$$

$$\dot{X}_2 = -\beta(X_1, X_2) + \gamma_k(X_1, X_2) W_k(t) \quad [23]$$

it can be shown that the exact solution satisfying eqns [20] and [21] can be cast in the form of:

$$p = C \exp [-\phi(\lambda)] \quad [24]$$

where ϕ , known as the probability potential, is a function of the total energy λ (to be explained shortly). This exact solution is obtainable if the β and γ_k functions in eqn [23] are related as follows:

$$\begin{aligned} \beta(x_1, x_2) &= \pi x_2 \sum_i \sum_j K_{ij} \gamma_i(x_1, x_2) \gamma_j(x_1, x_2) \phi'(\lambda) \\ &- \pi \sum_i \sum_j K_{ij} \gamma_i(x_1, x_2) \frac{\partial \gamma_j(x_1, x_2)}{\partial x_2} + u(x_1) \end{aligned} \quad [25]$$

in which function $u(x_1)$ contains all the terms on the right hand side depending only on x_1 , and:

$$\lambda = \frac{x_2}{2} + \int_0^{x_1} u(v) dv = \frac{x_2}{2} + U(x_1) \quad [26]$$

It can be seen from [25] that if all the γ_i functions are independent of x_2 , then $u(x_1)$ must be the stiffness term in $\beta(x_1, x_2)$. In this case, λ represents clearly the total (kinetic plus potential) energy in the system. However, if some γ_i functions depend on x_2 , then $u(x_1)$ may include terms which are not originally present in $\beta(x_1, x_2)$. In other words, the stiffness term is effectively modified due to a parametric excitation on the velocity term in the original equation of motion.

As an example, consider the following system:

$$\ddot{Y} + Y^2 \left(\beta + \frac{4\alpha}{Y^2 + \dot{Y}^2} \right) \dot{Y} + [1 + W(t)Y] = 0 \quad [27]$$

Note that only a parametric excitation $W(t)$ is present in this example. The stationary probability density of the response obtained from the above procedure is given by:

$$p(x_1, x_2) = C(x_1^2 + x_2^2)^{-2\alpha/\pi S} \exp \left[-\frac{\beta}{2\pi S} (x_1^2 + x_2^2) \right] \quad [28]$$

where x_1 is the state variable for Y , and x_2 is the state variable for \dot{Y} , and where S is the spectral density of white noise $W(t)$. A nontrivial stationary probability density exists only if $S > 2\alpha/\pi$; otherwise, the stationary solution is trivial, i.e., $p(x_1, x_2) = \delta(x_1)\delta(x_2)$. When a nontrivial stationary probability density exists, its shape depends on whether $\alpha \geq 0$ or $\alpha < 0$. If $\alpha \geq 0$, the stationary probability density has a peak at $x_1 = x_2 = 0$. If $\alpha < 0$, the peak occurs on a circle $x_1^2 + x_2^2 = 4|\alpha|/\beta$, as shown in Figure 1, which is the stochastic analogue of a limit cycle.

Approximate Probability Solutions

It is interesting to note that rather restrictive conditions are imposed, such as eqns [15] or [25], in order to obtain an exact probability solution. Such conditions are seldom met; therefore, approximate solution techniques are important. One general scheme in obtaining approximate probability solutions makes use of the principle of weighted residuals, which will now be described.

Let the original governing equations for the system be given by:

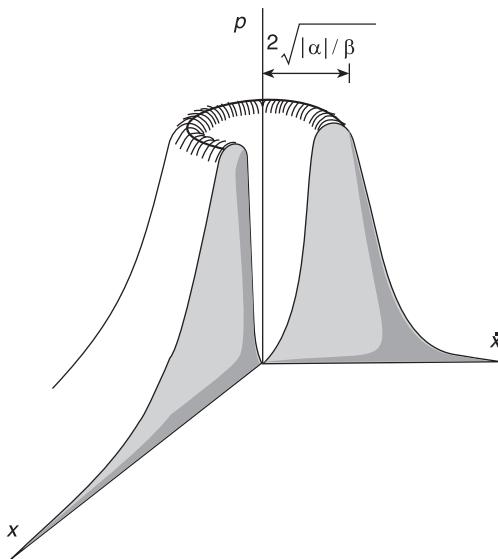

Figure 1 Stationary probability density of system [28] (with the right-front quarter removed).

$$\dot{X}_i = F_i(\mathbf{X}) + \sum_j g_{ij}(\mathbf{X}) W_j(t); \quad i = 1, 2, \dots, N \quad [29]$$

for which an exact probability solution is presently unavailable. We wish to obtain an approximate solution by replacing eqn [29] with another set of equations:

$$\dot{X}_i = f_i(\mathbf{X}) + \sum_j g_{ij}(\mathbf{X}) W_j(t); \quad i = 1, 2, \dots, N \quad [30]$$

which belongs to the solvable class of problems. The conditions to be satisfied in the replacement are:

$$E \left\{ \sum_i [F_i(\mathbf{X}) - f_i(\mathbf{X})] N_i(\mathbf{X}) \right\} = 0 \quad [31]$$

where $N_i(\mathbf{X})$ are weighting functions, and the ensemble average $E\{\}$ is computed on the basis of the probability density p_s for the response of the replacement system, eqn [30]. By judiciously selecting a set of $N_i(\mathbf{X})$ functions, we obtain a set of constraints from which the parameters in p_s can be determined.

One approximation scheme is well-known equivalent linearization. In this scheme, the substituting system is linear and under purely additive random excitations. It is suitable only if the nonlinearity in the original system is weak, and if no parametric excitations are present. However, the excitations need not be white noises, as long as they are Gaussian. For illustration, this scheme will now be applied to the following single-degree-of-freedom systems.

Consider:

$$\dot{X}_1 = X_2 \quad [32]$$

$$\dot{X}_2 = -\beta(X_1, X_2) + \xi(t) \quad [33]$$

where $\xi(t)$ is a stationary Gaussian process with zero mean. Let eqns [32] and [33] be replaced by a linear system:

$$\dot{X}_1 = X_2 \quad [34]$$

$$\dot{X}_2 = -c_e X_2 - k_e X_1 + \xi(t) \quad [35]$$

With two different choices $N_2(\mathbf{X}) = X_1$ and $N_2(\mathbf{X}) = X_2$ for the weighting functions, we obtain from eqn [31]:

$$E\{[\beta(X_1, X_2) - c_e X_2 - k_e X_1] X_1\} = 0 \quad [36]$$

$$E\{[\beta(X_1, X_2) - c_e X_2 - k_e X_1] X_2\} = 0 \quad [37]$$

Since $E[X_1 X_2] = 0$ in the stationary state, eqns [36] and [37] can be solved to yield:

$$k_e = \frac{E[X_1 \beta(X_1, X_2)]}{E[X_1^2]} \quad [38]$$

$$c_e = \frac{E[X_2 \beta(X_1, X_2)]}{E[X_2^2]} \quad [39]$$

The stationary solution for the substituting linear system governed by eqns [34] and [35] has the well-known Gaussian distribution, namely:

$$p(x_1, x_2) = C \exp \left[-\frac{c_e}{2\pi K} (x_2^2 + k_e x_1^2) \right] \quad [40]$$

where K is the spectral density of $W(t)$. This probability density is now treated as an approximate solution for the original system governed by eqns [32] and [33]. From eqn [40], is obtained $E[X_1^2] = \pi K / c_e k_e$, and $E[X_2^2] = \pi K / c_e$, with which eqns [38] and [39] are reduced to:

$$E[X_1 \beta(X_1, X_2)] = \frac{\pi K}{c_e} \quad [41]$$

$$E[X_2 \beta(X_1, X_2)] = \pi K \quad [42]$$

Equations [41] and [42] are a set of nonlinear algebraic equations for the unknowns c_e and k_e . In particular, if $\beta(X_1, X_2)$ is a polynomial of X_1 and X_2 , then the ensemble averages indicated on the left hand sides of these equations can be carried out analytically using the approximate probability density given in eqn [40], and in many cases c_e and k_e can be solved in closed form.

If the system is strongly nonlinear and/or parametric excitations are present, a substituting system from the solvable class of generalized stationary potential may be selected. In this case, however, the excitations are restricted to Gaussian white noises. Consider the following single-degree-of-freedom system:

$$\dot{X}_1 = X_2 \quad [43]$$

$$\dot{X}_2 = -B(X_1, X_2) + \sum_k \eta_k(X_1, X_2) W_k(t) \quad [44]$$

for which an exact probability solution is not available at the present time. Let this system be replaced by a solvable system within the class of generalized stationary potential:

$$\dot{X}_1 = X_2 \quad [45]$$

$$\dot{X}_2 = -\beta(X_1, X_2) + \sum_k \eta_k(X_1, X_2) W_k(t) \quad [46]$$

namely, $\beta(X_1, X_2)$ can be cast in the form of eqn [25]. The constraints, eqn [31], to be imposed for obtaining the approximate stationary probability density are now:

$$E \left\{ \left[B(\mathbf{X}) - \pi X_2 \sum_i \sum_j K_{ij} \eta_i(\mathbf{X}) \eta_j(\mathbf{X}) \phi'(\lambda) \right. \right. \\ \left. \left. + \pi \sum_i \sum_j K_{ij} \eta_i(\mathbf{X}) \frac{\partial \eta_j(\mathbf{X})}{\partial X_2} - u(X_1) \right] N(\mathbf{X}) \right\} = 0 \quad [47]$$

The above ensemble average is computed with the approximate probability density, eqn [24].

A physically meaningful choice for the weighting function is $N(\mathbf{X}) = X_2$. This choice implies that the

average work done by the forces in $B(\mathbf{X})$ is the same as that by the forces in $\beta(\mathbf{X})$, when computed using the approximate probability density. Now, since $E[X_2 f(X_1)] = 0$ at the state of statistical stationarity for any function $f(X_1)$, only the damping components in $B(\mathbf{X})$ and $\beta(\mathbf{X})$ need to be included when evaluating the left hand side of eqn [47]. Thus, the choice of $N(\mathbf{X}) = X_2$ is to equate the average dissipative energy of the substituting system with that of the original system; thus, the procedure has been given a physically meaningful name, ‘dissipation energy balancing’. Now, using eqn [24] to compute the ensemble average in eqn [47]:

$$\int \int \left[B(\mathbf{x}) - \pi x_2 \sum_i \sum_j K_{ij} \eta_i(\mathbf{x}) \eta_j(\mathbf{x}) \phi'(\lambda) \right. \\ \left. + \pi \sum_i \sum_j K_{ij} \eta_i(\mathbf{x}) \frac{\partial \eta_j(\mathbf{x})}{\partial x_2} \right] x_2 \exp[-\phi(\lambda)] dx_1 dx_2 \\ = \int_0^\infty \exp[-\phi(\lambda)] d\lambda \\ \times \int_{\mu_1(\lambda)}^{\mu_2(\lambda)} \left[B(\mathbf{x}) - \pi x_2 \sum_i \sum_j K_{ij} \eta_i(\mathbf{x}) \eta_j(\mathbf{x}) \phi'(\lambda) \right. \\ \left. + \pi \sum_i \sum_j K_{ij} \eta_i(\mathbf{x}) \frac{\partial \eta_j(\mathbf{x})}{\partial x_2} \right] dx_1 = 0 \quad [48]$$

where $\mu_1(\lambda)$ and $\mu_2(\lambda)$ are two extreme values for x_1 , given a total energy level λ . A sufficient condition for eqn [48] is that:

$$\int_{\mu_1(\lambda)}^{\mu_2(\lambda)} \left[B(\mathbf{x}) - \pi x_2 \sum_i \sum_j K_{ij} \eta_i(\mathbf{x}) \eta_j(\mathbf{x}) \phi'(\lambda) \right. \\ \left. + \pi \sum_i \sum_j K_{ij} \eta_i(\mathbf{x}) \frac{\partial \eta_j(\mathbf{x})}{\partial x_2} \right] dx_1 = 0 \quad [49]$$

Of course, when carrying out the above integration, the variable x_2 must be expressed in terms of $x_2 = \pm[2\lambda - 2U(x_1)]^{1/2}$. It is of interest to note that eqn [49] leads directly to an expression for $\phi'(\lambda)$:

$$\phi'(\lambda) = \frac{\int_{\mu_1(\lambda)}^{\mu_2(\lambda)} \left\{ \left[\mathbf{B} + \pi \sum_i \sum_j \mathbf{K}_{ij} \eta_i (\partial \eta_j / \partial x_2) \right]_{x_2=\sqrt{(2\lambda-2U)}} \right.}{\int_{\mu_1(\lambda)}^{\mu_2(\lambda)} \pi \left\{ \left[x_2 \sum_i \sum_j K_{ij} \eta_i \eta_j \right]_{x_2=\sqrt{(2\lambda-2U)}} \right.} \\ \left. - \left[\mathbf{B} + \pi \sum_i \sum_j K_{ij} \eta_i (\partial \eta_j / \partial x_2) \right]_{x_2=\sqrt{(2\lambda-2U)}} \right\} dx_1 \\ \frac{\int_{\mu_1(\lambda)}^{\mu_2(\lambda)} \left\{ \left[x_2^2 \sum_i \sum_j K_{ij} \eta_i \eta_j \right]_{x_2=\sqrt{(2\lambda-2U)}} \right.}{\int_{\mu_1(\lambda)}^{\mu_2(\lambda)} \pi \left\{ \left[x_2^2 \sum_i \sum_j K_{ij} \eta_i \eta_j \right]_{x_2=\sqrt{(2\lambda-2U)}} \right.} \\ \left. - \left[x_2^2 \sum_i \sum_j K_{ij} \eta_i \eta_j \right]_{x_2=\sqrt{(2\lambda-2U)}} \right\} dx_1 \quad [50]$$

The probability potential $\phi(\lambda)$ is obtained readily upon an indefinite integration on λ .

Approximate Solutions for Statistical Moments

As indicated earlier, the response $\mathbf{X}(t)$ of a dynamical system is a Markov vector if the random excitations are Gaussian white noises. In this case, the transition probability density q of $\mathbf{X}(t)$ is governed by the FPK eqn [6]. For obtaining various statistical moments of the response, it is more convenient to work with the Itô-type stochastic differential equations of the form:

$$dX_i(t) = m_i(\mathbf{X}) + \sum_j \sigma_{ij}(\mathbf{X}) dB_j(t) \quad [51]$$

where $B_j(t)$ are known as the Wiener (or Brownian motion) processes, and m_i and σ_{ij} are known as drift and diffusion coefficients, respectively, which can be determined in the same manner as the first and second derivate moments. Specifically, $m_i(\mathbf{X})$ can be obtained by replacing the state vector \mathbf{x} on the right hand side of eqn [10] with the random vector \mathbf{X} ; namely, $m_i = (a_i)_{\mathbf{x}=\mathbf{X}}$. Similarly, the (i, j) element of the product of the diffusion coefficient matrix Σ and its transpose Σ' can be obtained by replacing \mathbf{x} by \mathbf{X} on the right hand side of [11], namely, $(\Sigma\Sigma')_{ij} = (b_{ij})_{\mathbf{x}=\mathbf{X}}$.

The greatest advantage in using stochastic differential eqns [51] of the Itô type is the ease with which another Itô equation for an arbitrary scalar function $F(\mathbf{X}, t)$ can be obtained:

$$\begin{aligned} dF(\mathbf{X}, t) = & \\ & \left(\frac{\partial F}{\partial t} + \sum_j m_j \frac{\partial F}{\partial X_j} + \frac{1}{2} \sum_j \sum_k \sum_l \sigma_{jl} \sigma_{kl} \frac{\partial^2 F}{\partial X_j \partial X_k} \right) dt \\ & + \sum_j \sum_k \sigma_{jk} \frac{\partial F}{\partial X_j} dB_k(t) \end{aligned} \quad [52]$$

Equation [52] is known as the Itô differential rule. The applicability of this rule requires that F is differentiable with respect to t , and twice differentiable with respect to the components of \mathbf{X} . For the purpose of obtaining statistical moments, we let $F(\mathbf{X}, t) = X_r^{n_r} X_s^{n_s} \dots$, where $n_r, n_s \dots$, are nonnegative integers, and then take ensemble average of the resulting Itô equations.

As an example, consider a two-dimensional Markov vector $\mathbf{X} = \{X_1, X_2\}$. Let $F(\mathbf{X}, t) = X_1^{n_1} X_2^{n_2}$. Application of Itô differential rule yields:

$$\begin{aligned} d(X_1^{n_1} X_2^{n_2}) = & \left\{ n_1 m_1 X_1^{n_1-1} X_2^{n_2} + n_2 m_2 X_1^{n_1} X_2^{n_2-1} \right. \\ & + \frac{1}{2} \left[n_1(n_1-1) \sum_l \sigma_{1l} \sigma_{1l} X_1^{n_1-2} X_2^{n_2} \right. \\ & + n_2(n_2-1) \sum_l \sigma_{2l} \sigma_{2l} X_1^{n_1} X_2^{n_2-2} \\ & \left. \left. + 2n_1 n_2 \sum_l \sigma_{1l} \sigma_{2l} X_1^{n_1-1} X_2^{n_2-1} \right] \right\} dt \\ & + \sum_k \left(n_1 X_1^{n_1-1} X_2^{n_2} \sigma_{1k} + n_2 X_1^{n_1} X_2^{n_2-1} \sigma_{2k} \right) dB_k(t) \end{aligned} \quad [53]$$

Taking ensemble average of eqn [53], and recognizing that the ensemble average of the last term is zero, we obtain:

$$\begin{aligned} & \frac{d}{dt} E[X_1^{n_1} X_2^{n_2}] \\ &= n_1 E[m_1 X_1^{n_1-1} X_2^{n_2}] + n_2 E[m_2 X_1^{n_1} X_2^{n_2-1}] \\ &+ n_1 n_2 E \left[\sum_l \sigma_{1l} \sigma_{2l} X_1^{n_1-1} X_2^{n_2-1} \right] \\ &+ \frac{1}{2} n_1(n_1-1) E \left[\sum_l \sigma_{1l} \sigma_{1l} X_1^{n_1-2} X_2^{n_2} \right] \\ &+ \frac{1}{2} n_2(n_2-1) E \left[\sum_l \sigma_{2l} \sigma_{2l} X_1^{n_1} X_2^{n_2-2} \right] \end{aligned} \quad [54]$$

A sequence of equations for the statistical moments can be obtained by substituting nonnegative integers for n_1 and n_2 . Of course, any X_j with a negative power on the right hand side of eqn [54] should be replaced by zero.

It is of interest to note that eqn [54] is valid even when $\mathbf{X}(t)$ is still in the transient nonstationary state. When $\mathbf{X}(t)$ reaches the state of stationarity, however, eqn [54] reduces to an algebraic equation, since its left hand side reduces to zero.

Note that the drift coefficients m_j and the diffusion coefficients σ_{ij} are generally nonlinear functions of X_1 and X_2 . Let such nonlinear functions be of the polynomial type. Then at least some statistical moments appearing on the right hand side of eqn [52] are of orders higher than $n_1 + n_2$. It is clear that the sequence of equations for the statistical moments so obtained constitute an infinite hierarchy; therefore, they cannot be solved exactly. Several schemes have been proposed for obtaining approximate solutions, one of which is known as Gaussian closure. In this scheme, higher statistical moments are expressed in

terms of the first- and second-order moments, using the same relationships as if they were moments of Gaussian random variables, or equivalently, neglecting those cumulants of X_1 and X_2 of an order higher than the second. In the case of additive white-noise excitations, Gaussian closure leads to the same results as would be obtained from equivalent linearization. Therefore, it is not very accurate if the system nonlinearity is strong and/or if parametric excitations are present. In principle, greater accuracy can be achieved by raising the cut-off order of the cumulants when simplifying eqn [54], as described in the general scheme called cumulant-neglect-closure. However, caution should be exercised when applying higher-order closure schemes if strong parametric excitations are present such that motion instability is a distinct possibility.

Averaging Methods

The solvability of a nonlinear stochastic system is enhanced if the dimensionality of the system can be reduced. This is accomplished with two averaging techniques, applicable under certain conditions. The first, known as stochastic averaging, is applied to systems with linear or weakly nonlinear stiffness. The method is now illustrated with the following single-degree-of-freedom-system of linear stiffness:

$$\ddot{Y} + \omega_0^2 Y = \varepsilon f(Y, \dot{Y}) + \varepsilon^{1/2} \sum_k g_k(Y, \dot{Y}) \xi_k(t) \quad [55]$$

where ε is a small parameter, indicating that the damping term is of order ε , and the random excitations $\xi_k(t)$ are of order $\varepsilon^{1/2}$. We assume that $\xi_k(t)$ are weakly stationary process, namely:

$$E[\xi_r(u)\xi_s(v)] = R_{rs}(v-u) \quad [56]$$

Note that the excitations need not be white noises. Using the transformation:

$$\begin{aligned} Y &= A(t) \cos \theta; & \theta &= \omega_0 t + \phi(t) \\ \dot{Y} &= -A(t)\omega_0 \sin \theta \end{aligned} \quad [57]$$

eqn [55] may be replaced by two first-order equations:

$$\begin{aligned} \dot{A} &= -\frac{\sin \theta}{\omega_0} \left[\varepsilon f(A \cos \theta, -A\omega_0 \sin \theta) \right. \\ &\quad \left. + \varepsilon^{1/2} \sum_k g_k(A \cos \theta, -A\omega_0 \sin \theta) \xi_k(t) \right] \end{aligned} \quad [58]$$

$$\begin{aligned} \dot{\phi} &= -\frac{\cos \theta}{\omega_0 A} \left[\varepsilon f(A \cos \theta, -A\omega_0 \sin \theta) \right. \\ &\quad \left. + \varepsilon^{1/2} \sum_k g_k(A \cos \theta, -A\omega_0 \sin \theta) \xi_k(t) \right] \end{aligned} \quad [59]$$

The right hand side of eqns [58] and [59] are associated only with ε and $\varepsilon^{1/2}$ terms. Physically, $A(t)$ represents the random amplitude, and $\phi(t)$ represents the random phase, and their values are nearly unchanged within a time-span $1/\varepsilon$.

Define a correlation time between random excitations $\xi_r(t)$ and $\xi_s(t)$:

$$\tau_{rs} = \frac{1}{[R_{rr}(0)R_{ss}(0)]^{1/2}} \int_{-\infty}^0 |R_{rs}(\tau)| d\tau \quad [60]$$

which is a measure of memory of the present $\xi_r(t)$ with respect to the past $\xi_s(t)$. If the system variables $\{A, \phi\}$ are observed at time instants at Δt apart, and if $\Delta t \gg \tau_{rs}$ for all r and s , then the observed variation of the system variables is Markov-like. However, Δt should be much smaller than ε^{-1} in order that sufficient details of the system behavior can be observed. In other words, the observed $\{A, \phi\}$ is approximately a Markov vector if $\varepsilon^{-1} \gg \tau_{rs}$ for all r and s . If this condition is satisfied, then the amplitude process may be approximated as a one-dimensional Markov process, governed by an Itô equation:

$$dA = m(A) dt + \sigma(A) dB(t) \quad [61]$$

where the drift and diffusion coefficients $m(A)$ and $\sigma(A)$ can be obtained as follows:

$$\begin{aligned} m(A) &= \varepsilon \left\langle -\frac{\sin \theta_t}{\omega_0} f(A \cos \theta_t, -A\omega_0 \sin \theta_t) + \int_{-\infty}^0 \frac{1}{\omega_0^2} \sum_k \sum_j \left\{ \frac{\partial}{\partial A} [\sin \theta_t g_k(A \cos \theta_t, -A\omega_0 \sin \theta_t)] \sin \theta_{t+\tau} \right. \right. \\ &\quad \left. \left. + \frac{1}{A} \frac{\partial}{\partial \theta_t} [\sin \theta_t g_k(A \cos \theta_t, -A\omega_0 \sin \theta_t)] \cos \theta_{t+\tau} \right\} g_j(A \cos \theta_{t+\tau}, -A\omega_0 \cos \theta_{t+\tau}) R_{kj}(\tau) d\tau \right\rangle \end{aligned} \quad [62]$$

$$\sigma^2(A) = \varepsilon \left\langle \frac{1}{\omega_0^2} \sum_k \sum_j \int_{-\infty}^{\infty} \sin \theta_t \sin \theta_{t+\tau} g_k(A \cos \theta_t, -A \omega_0 \sin \theta_t) g_j(A \cos \theta_{t+\tau}, -A \omega_0 \cos \theta_{t+\tau}) R_{kj}(\tau) d\tau \right\rangle_t [63]$$

in which θ_t and $\theta_{t+\tau}$ are abbreviations for $\omega_0 t + \phi(t)$ and $\omega_0(t+\tau) + \phi(t)$, respectively, and $\langle \cdot \rangle_t$ denotes a time-averaging operation:

$$\langle [\cdot] \rangle_t = \frac{\omega_0^2}{2\pi} \int_0^{2\pi/\omega_0^2} [\cdot] dt [64]$$

The validity of eqns [61] to [63] stems from the fact that the value of each correlation function $R_{kj}(\tau)$ is significant only if $|\tau| \ll \varepsilon^{-1}$, within which $A(t)$ and $\phi(t)$ can be treated as constants. Strictly speaking, eqn [61] governs the averaged amplitude over a pseudo-period $2\pi/\omega_0$, not the original amplitude.

With the knowledge of the Itô eqn [61], or equivalently, the corresponding FPK equation, one obtains the probability density of the averaged amplitude as follows:

$$p(\alpha) = \frac{C}{\sigma^2(\alpha)} \exp \left[\int \frac{2m(\alpha)}{\sigma^2(\alpha)} d\alpha \right] [65]$$

where α is the state variable for A , and C is a normalization constant. This probability density exists only if it is integrable; otherwise, the system is unstable in probability (assuming that multiplicative random excitation is present). As is well-known with deterministic excited systems, dynamic instability can occur when parametric excitations of high enough magnitudes are present. However, stability of randomly excited systems can be interpreted in more than one sense, each corresponding to one mode of convergence of a sequence of random variables.

The second averaging technique, known as quasi-conservative averaging, is applicable even when the stiffness term in the governing physical equation is strongly nonlinear. In the case of a single-degree-of-freedom system, the governing equation has the form:

$$\ddot{Y} + h(Y) = \varepsilon f(Y, \dot{Y}) + \varepsilon^{1/2} \sum_k g_k(Y, \dot{Y}) W_k(t) [66]$$

Note that the excitations are now restricted to Gaussian white noises. In this case, the total energy in the system:

$$\Lambda(t) = \frac{1}{2} \dot{Y}^2 + \int_0^Y b(u) du [67]$$

is slowly varying, instead of the amplitude process $A(t)$. Differentiating [67] with respect to t , and combining the result with [66], we obtain:

$$\frac{d}{dt} \Lambda = \dot{Y} \left[\varepsilon f(Y, \dot{Y}) + \varepsilon^{1/2} \sum_k g_k(Y, \dot{Y}) W_k(t) \right] [68]$$

Equation [68] can now be converted into an Itô equation:

$$d\Lambda t = m(\Lambda) dt + \sigma(\Lambda) dBt [69]$$

where:

$$\begin{aligned} m(\Lambda) &= \varepsilon \left\langle \pm \{2[\Lambda - U(Y)]\}^{1/2} \right. \\ &\quad \times f(Y, \pm \{2[\Lambda - U(Y)]\}^{1/2}) + \pi \sum_k \sum_r K_{kr} \frac{\partial}{\partial \Lambda} \\ &\quad \times [\{2[\Lambda - U(Y)]\}^{1/2} g_k(Y, \pm \{2[\Lambda - U(Y)]\}^{1/2})] \\ &\quad \left. \times [\{2[\Lambda - U(Y)]\}^{1/2} g_r(Y, \pm \{2[\Lambda - U(Y)]\}^{1/2})] \right\rangle_t \end{aligned} [70]$$

$$\begin{aligned} \sigma^2(\Lambda) &= \varepsilon 2\pi \sum_k \sum_r K_{kr} \left\langle 2[\Lambda - U(Y)] \right. \\ &\quad \times g_k \left(Y, \pm \left\{ 2[\Lambda - U(Y)] \right\}^{1/2} \right) \\ &\quad \left. \times g_r \left(Y, \pm \left\{ 2[\Lambda - U(Y)] \right\}^{1/2} \right) \right\rangle_t \end{aligned} [71]$$

and where the time averaging over a quasi-period is carried out equivalently in Y , namely:

$$\langle [\cdot] \rangle_t = \frac{1}{T} \int_{-A}^A \frac{([\cdot]_{\dot{Y}=\{2[\Lambda-U(Y)]\}^{1/2}} + [\cdot]_{\dot{Y}=-\{2[\Lambda-U(Y)]\}^{1/2}})}{\{2[\Lambda - U(Y)]\}^{1/2}} dY [72]$$

It may be noted that, in eqns [68] to [70], the velocity process \dot{Y} has been replaced by $\pm \{2[\Lambda - U(Y)]\}^{1/2}$.

The quasi-conservative averaging technique has been extended to the case of nonwhite excitation, which is not discussed here in due to space limitation.

This article describes an important approach to analysis of random vibration problems, which does not rely on the explicit convolution integral relation between response and excitation. It is based on a theory of Markov random processes and stochastic differential equation (SDE) calculus. It can be applied through reduction of the equations of motion with random excitations to the form, where all these excitations are white noises. This can be done by using shaping filters, if necessary, to obtain the extended SDE set, which may include state variable(s) of the shaping filter(s) as additional state variables.

Let a scalar process $x(t)$ be governed by SDE $\dot{x} = f(x, t) + g(x, t)\xi(t)$, where $\xi(t)$ is a stationary zero-mean normal white noise of unit intensity. Whenever the function g is not independent of x , the response is correlated with the excitation as follows:

$$\langle x(t)\xi(t) \rangle = (1/2) \left\langle \frac{dg}{dx}(x, t)g(x, t) \right\rangle \quad [1]$$

Process $x(t)$ is called a diffusional Markov process, with drift and diffusion coefficients a, b , respectively, where $a = f + (1/2)g(dg/dx)$ and $b = g^2$. (The original SDE with added quantity [1], written in the form of differentials, is called the Ito SDE.) Eqn [1] illustrates a possibility for extending method of moments to linear systems with parametric excitation, as long as both $f(x, t)$ and $g(x, t)$ are linear in x , provided that the original excitations are white-noises. The expectation operator is applied at first to the original SDE directly, using the multidimensional counterpart of formula [1] (eqn [10] in **Random vibration, basic theory** to evaluate all relevant excitation-response correlations. This results in a linear

deterministic set of equations for expected values of state variables. Thus, for a scalar case with $f(x, t) = px, g(x, t) = qx$, eqn [1] yields the following deterministic equation for $m(t) = \langle x(t) \rangle: \dot{m} = (p + q^2/2)m$. The new state variables u may be introduced then as $u_{jk} = x_j x_k, \dot{u}_{jk} = x_j \dot{x}_k + x_k \dot{x}_j$ for every pair of state variables. The RHSs of the given SDEs are substituted for the derivatives then, resulting in the set of SDEs for values of u . The set is linear, as long as the given set of equations for multiple state variables x contains linear functions f and g only. The expectation operator can be applied to the latter accordingly, using once again the multidimensional counterpart of eqn [1]. This results in a linear set of deterministic equations for second-order moments of the response.

The power of the Markov theory approach also lies in the possibility of analysis of the response probability density functions for systems, described by SDEs. Thus, a vector \mathbf{X} diffusional Markov process, is described by vector of its drift coefficients $a_i(\mathbf{X}, t)$ and matrix of its diffusion coefficients $b_{ij}(\mathbf{X}, t)$. If the SDEs for components of $\mathbf{X}(t)$ are:

$$\begin{aligned} X_i &= f_i(\mathbf{X}, t) + g_i(\mathbf{X}, t)\xi_i(t); \langle \xi_i(t)\xi_j(t+\tau) \rangle \\ &= D_{\xi,ij}; \quad i, j = 1, 2, \dots, n, \\ \text{then :} \quad a_i(\mathbf{X}, t) &= f_i(\mathbf{X}, t) + (1/2) \sum_{k=1}^n g_k(\mathbf{X}, t) \frac{\partial g_i(\mathbf{X}, t)}{\partial X_k} D_{\xi,ik} \\ b_{ij}(\mathbf{X}, t) &= g_i(\mathbf{X}, t)g_j(\mathbf{X}, t) \end{aligned} \quad [2]$$

and the joint pdf of these components satisfies certain partial differential equations, which would be considered somewhat later.

Linear systems with white-noise random parametric excitation(s) may become unstable due to a so-called stochastic instability. This can be seen for a SDOF system:

$$\ddot{X} + 2\alpha\dot{X} + \Omega^2 X(1 + z(t)) = 0 \quad [3]$$

where the simplest case of excitation is one of a white noise $z(t)$ with intensity D_z . The method of moments yields a set of homogeneous deterministic ordinary differential equations (ODEs) for the response moments of a given order. Thus any one of these sets may have a zero steady-state solution, which may be either stable or unstable. The corresponding instability boundary in the response moments of the corresponding order can be predicted accordingly, using the common deterministic stability analysis. However, instability in any one of the response moments should not be regarded as ‘catastrophic’ for the structure (contrary to the case of common instability of deterministic systems). It simply implies, that any transients due to initial disturbances should have infinite moments of this order (and of higher orders as well). However, the response will decay eventually if the system is stable in probability. Mean square stochastic stability analysis, is used most often, i.e., one for the second-order response moments, since it usually provides the conservative boundary with respect to a ‘real’ or ‘catastrophic’ instability in probability.

For eqn [3] with a white-noise $z(t)$ the stability condition for mean square responses is found, by the method of moments, to be $D_z < D_{z**} = 4\alpha/\Omega^2$. (This stability boundary is seen to be the same as one obtained in the article **Random vibration, basic theory** from the condition of the infinite mean square response of the system [3] to an external white-noise excitation). Critical values of D_z for instability boundaries in higher-order moments are found to be higher than D_{z**} . The highest stability threshold is, however, one that corresponds to instability in probability. It is found to be $D_{z*} = 2D_{z**} = 8\alpha/\Omega^2$. Exceeding this threshold implies an unbounded growth of the response level with time. This will be illustrated later, by analyzing the stationary probability density function (pdf) of the system’s (eqn [3]) response to an external white-noise excitation. The single-starred stability threshold will be seen to correspond to the normability condition of this pdf (the latter diverges at infinity if the threshold is exceeded).

Besides providing a relatively simple conservative estimate of reliability, the condition for mean square stability may also be important in yet another respect. Whilst a structure may operate safely provided it is stable in probability, its mean square instability may imply inadequacy of a linear model. In particular, online measurement results of second-order response moments should be interpreted with caution in this case, as long as these moments should be infinite if $D_{z**} < D_z < D_{z*}$ (for the linear system, eqn [3]). The measured values should therefore be strongly dependent on nonlinearity(ies) in the system.

Direct application of the method of moments to problems with nonwhite random parametric excitation is found to be impossible since an attempt to use shaping filter equation(s) to represent the excitation(s) makes the expanded system nonlinear, with product-type nonlinearity(ies). Important reduction of the underlying SDE(s) (eqn [2]) is possible, however, through the use of the stochastic averaging method, which is also very important for nonlinear systems. Namely, let the functions f and g in the RHSs be periodic in time t , with period T , and proportional to μ and $\sqrt{\mu}$, respectively, where μ is a small parameter. Then the expressions (eqn [2]) for the drift and diffusion coefficients a and b can be approximately averaged over time within the period T (with fixed ‘slow’ state variables X). Solution to the corresponding ‘shortened’ SDEs should approach the exact one with $\mu \rightarrow 0$.

Whilst the above averaging principle over explicit ‘rapid’ time is the same one as for deterministic systems, one specific feature of the stochastic averaging should be mentioned. The condition for white-noise excitation may be relaxed somewhat, as long as the random force with a finite correlation time leads to the same response as a ‘real’ white noise for a system with indefinitely increasing time constant (with $\mu \rightarrow 0$). Thus, for a quasilinear system – one with all nonlinearities and/or excitations being proportional to a small parameter – the direct excitation may usually be assumed to be broadband with respect to the system’s bandwidth. Proper transformation of the original system’s SDEs to those for slowly varying state variables is required, in order to have a small parameter at the RHS(s).

Consider the mean square stability of the SDOF system [3] for the case of a narrowband sinusoidal excitation with random phase modulation:

$$z(t) = \lambda \sin 2q(t), \dot{q} = v + \xi(t)$$

so that:

$$S_{zz}(\omega) = \frac{(\lambda^2 D_\xi/2)(\omega^2 + v^2 + D_\xi^2/4)}{(v^2 + D_\xi^2/4 - \omega^2)^2 + \omega^2 D_\xi^2} \quad [4]$$

with zero-mean white noise $\xi(t)$ of intensity D_ξ and small $\alpha/\Omega, \lambda$ and $\Delta = (\Omega - v)$. In-phase and quadrature components of the response $X(t)$ can be introduced conveniently as:

$$X(t) = X_c(t) \cos q + X_s(t) \sin q$$

$$\dot{X}(t) = v[-X_c(t) \sin q + X_s(t) \cos q]$$

The original equation [3] with the above excitation $z(t)$ is reduced then to a set of two SDEs for the new

state variables $X_c(t)$, $X_s(t)$. The RHSs of these SDEs contain trigonometric functions of $q(t)$. After averaging over the mean period $2\pi/\nu$ these SDEs are found to be:

$$\begin{aligned}\dot{X}_c &= -(\alpha - \lambda\Omega/4)X_c - \Delta X_s - X_s \xi(t) \\ \dot{X}_s &= -(\alpha + \lambda\Omega/4)X_s + \Delta X_c + X_c \xi(t)\end{aligned}\quad [5]$$

In the case of a perfectly periodic parametric excitation the stability boundary corresponds to the zero value of the determinant of the coefficients of the RHSs with the last terms excluded in both equations. The threshold excitation amplitude in this case is found to be:

$$\lambda_{*0}\Omega/4 = \sqrt{(\alpha^2 + \Delta^2)} \quad [6]$$

so that the system is stable if $\lambda < \lambda_{*0}$ (the star subscript indicates the critical value of the excitation amplitude, and the additional zero subscript indicates the case of a perfect periodicity).

Three ODEs for second-order moments of the state variables $X_c(t)$, $X_s(t)$ can now be derived by the method of moments. The condition for the vanishing determinant of their RHS coefficients yields the critical excitation amplitude as:

$$\lambda_* = \lambda_{*0} \left[1 + \frac{(D_\xi/\alpha)(\alpha^2 + \alpha D_\xi - \Delta^2/4)}{\alpha^2 + \alpha D_\xi + \Delta^2/4 + \Delta^2 D_\xi/4\alpha} \right]^{1/2} \quad [7]$$

The stability boundary (eqn [7]) is seen to reduce to one for the case of perfect periodicity (eqn [6]) for vanishingly small excitation/system bandwidth ratio ($D_\xi/\alpha \rightarrow 0$). The other extreme case of a broadband random excitation, where $D_\xi/\alpha \gg 1$, is clearly seen to reduce to one with a white noise $z(t)$, of intensity $D_z = 2\pi S_{zz}(2\Omega)$: the formula $D_{z**} = 4\alpha/\Omega^2$ is obtained from eqn [7] by using eqn [4] for the PSD of $z(t)$. It can be seen, that component with frequency 2Ω , and not Ω as in case of a resonant external excitation, is filtered out by the system from the whole continuous excitation PSD, whereas all other components of the excitation do not contribute to the system's stochastic stability threshold.

Analysis of stochastic stability in probability is also possible for the system of eqns [3] and [4], based on solution for the pdf of the response phase. The resulting curve of the critical value of the parametric excitation amplitude λ_{PR} vs the excitation/system bandwidth ratio is presented in Figure 1 (whilst this curve is calculated for a certain selected value of a

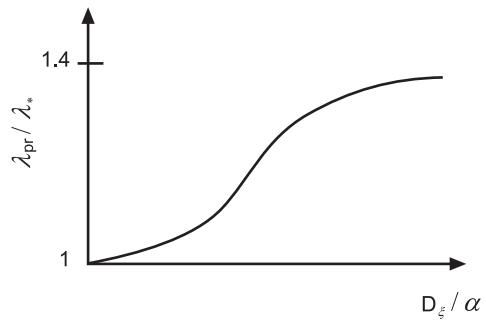

Figure 1 Ratio of stability thresholds in probability and in the mean square vs. excitation/system bandwidth ratio.

relative detuning Δ/Ω , curves for other values were found to be very close to it). The ratio λ_{PR}/λ_* is presented in Figure 1, with λ_* being predicted by eqn [7]. Therefore the curve illustrates the margin, or safety factor, as provided by the threshold for mean square instability with respect to that for the ‘catastrophic’ instability, that is, λ_{PR} . The factor is seen to increase monotonically from unity for the case of perfect periodicity to its maximal value $\sqrt{2}$ for the ‘most random’ case of a broadband excitation.

The imperfect periodicity is also seen to be stabilizing if $\Delta^2 < 4(\alpha^2 + \alpha D_\xi)$ and destabilizing otherwise. The former effect may be interpreted as being due to ‘smearing’ excitation energy in the frequency domain, which results in moving it away from the range of parametric resonance. However, if the initial detuning from the parametric resonance is relatively large, the above smearing brings more energy towards the resonance. This pattern is illustrated in Figure 2, where the generalized Ince–Strutt chart for the system of eqns [3] and [4] is shown schematically, that is, the stability boundary in the plane $\lambda\nu$. Moreover, a similar pattern is also observed for the stability boundary in probability. Of course, the above stabilization effect for large detunings exists only as long as the excitation PSD is narrow-band by itself, that is for small D_ξ/Ω ; it certainly disappears, if the extreme case of a white-noise excitation is approached.

The power of the Markov theory approach lies in the possibility for analysis of response probability density functions for systems, described by SDEs. Thus, let $\mathbf{X}(t)$ be an n -dimensional vector diffusional Markov process, with drift and diffusion coefficients $a_i(\mathbf{X}, t)$ and $b_{ij}(\mathbf{X}, t)$ respectively, as defined by eqns [2]. Then its pdf $p(\mathbf{x}, t)$ satisfies the following partial differential equation, which is called the Fokker–Planck–Kolmogorov (FPK) equation:

$$\partial p / \partial t = - \sum_{i=1}^n \frac{\partial(a_i p)}{\partial x_i} + \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \frac{\partial^2(b_{ij} p)}{\partial x_i \partial x_j} \quad [8]$$

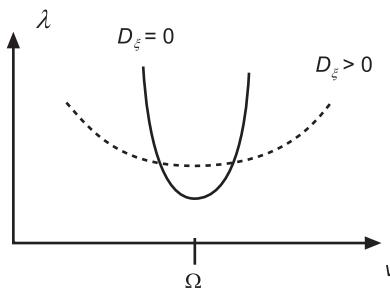

Figure 2 Generalized Ince–Strutt chart for imperfectly periodic excitation.

(small letters instead of the capital ones may be used for arguments of the deterministic function $p(\mathbf{x}, t)$, introduced for a random vector $\mathbf{X}(t)$). If the solution to this equation satisfies a deterministic initial condition of the form $p(\mathbf{x}, t) \rightarrow \delta(\mathbf{x} - \mathbf{x}_0)$ with $t \rightarrow t_0$, it is called the transition probability density. It is actually a conditional pdf $p(\mathbf{x}, t|\mathbf{x}_0, t_0)$, the condition being a given initial state \mathbf{X}_0 . A stationary process has a pdf, which becomes independent both of time and of initial state with $t - t_0 \rightarrow \infty$, i.e. a stationary pdf $p(\mathbf{x})$. The FPK equation is usually considered within infinite domain, with boundary conditions (BCs) of proper decay at infinity; the solution also should be normable in order to qualify for being the pdf.

The transition pdf, considered as a function of \mathbf{x}_0, t_0 , also satisfies the so-called backward Kolmogorov equation. This equation is used for first-passage-type reliability analyses. In particular, it can be used to derive the PDE for the mean time before failure (MTBF) $T(\mathbf{x})$. In a special case of a scalar $X(t)$, with time-independent-drift and diffusion coefficients a, b , the general PDE is reduced to the following ordinary differential equation

$$(b(x)/2) \left(d^2 T / dx^2 \right) + a(x) (dT / dx) = -1 \quad [9]$$

The boundary conditions $T(x_1) = T(x_2) = 0$ are usually assigned at the boundaries of the safe domain x_1, x_2 in cases of constant $b(x)$ (some modifications are possible for certain special cases of $b(x)$). Here x is the initial state within the safe domain, and the above BCs simply imply zero MTBF if the system is already at its boundary. A similar zero BC at the safe boundary is assigned for the MTBF for a vector diffusional Markov process, with the multidimensional counterpart of eqn [9] being a PDE.

In many cases of systems with high reliability – particularly when all components of the matrix \mathbf{B} are small – the solution $T(\mathbf{x})$ is found to be of a boundary-layer type. Namely, it is almost constant within

most of the safe domain and drops to zero only within a narrow region along the boundary. The interpretation is clear: a characteristic time for reaching stationary pdf $p(\mathbf{x})$ of the $\mathbf{X}(t)$ (which is independent of the initial state) is much smaller than the MTBF.

The response vector \mathbf{X} in random vibration problems should be regarded as at least an n -dimensional Markov process, where n is the total number of DOFs, since for each degree-of-freedom with a white-noise excitation both displacement and velocity are involved in the original SDE. The simplest case of an exact analytical solution to the FPK equation for random vibration problems is that of a linear system: the transition pdf of the response is found to be normal, with its vector of mean values and the correlation matrix being the same as those obtained by the method of moments.

For nonlinear systems, however, the approach faces difficulties with solving the FPK equation. The best known exact analytical solution is available for a SDOF system with a restoring force $f(X)$ and viscous damping with factor 2α , excited by a white-noise force of intensity D :

$$\begin{aligned} p(x, v) &= C \exp [-(4\alpha/D)H] \\ &= C \exp [-(4\alpha/D)(v^2/2 + U(x))] \end{aligned} \quad [10]$$

where:

$$v = \dot{x}, \quad dU/dx = f(x), \quad H = v^2/2 + U(x)$$

Here $U(x)$ is the system's potential energy, whereas H is a total energy and C is a normalizing constant. For systems with random parametric excitation, even linear ones, exact solutions to the FPK equations are very scarce.

The approximation by the stochastic averaging method is important for lightly damped systems. This averaging over the period (of the order $2\pi/\Omega$) in ‘fast’ time, can be made after introducing the slowly varying response amplitude (or total energy) and phase as new state variables. In the absence of any periodic excitation this results in a single first-order SDE for the amplitude in a ‘slow’ time. The resulting stationary FPK for the pdf of the amplitude has an analytical solution. In particular, for the linear system with combined external and parametric excitation $\xi(t)$ and $\zeta(t)$ this solution results in:

$$\begin{aligned} p(x, v) &= \frac{(\delta - 1)k^{\delta-1}}{(\kappa + x^2 + v^2/\Omega^2)^{\delta-1}} \\ \kappa &= 4S_{\xi\xi}(\Omega)/[\Omega^4 S_{\xi\xi}(2\Omega)] \\ \delta &= 4\alpha/[\pi\Omega^2 S_{\xi\xi}(2\Omega)] \end{aligned} \quad [11]$$

This function is integrable, and can therefore be the joint stationary pdf of the displacement and velocity, if and only if $\delta > 1$, or $D_\xi < D_{\xi**} = 8\alpha/\Omega^2$, where $D_\xi = 2\pi S_{\xi\xi}(2\Omega)$ is the intensity of approximating parametric white noise. If the above threshold is exceeded, the integral of the stationary pdf (eqn [11]) diverges at infinity. This corresponds to the instability in the probability, which is clearly accompanied by the infinite growth of the response with time.

As $\delta \rightarrow \infty$ the solution (11) approaches a normal pdf. However, in the presence of the parametric excitation, and thus for finite values of δ , $X(t)$ has infinite moments of order $2n$ and higher whenever $\delta \leq n + 1$. In particular, the stationary pdf of $X(t)$ with infinite variance is established if $1 < \delta < 2$. The conditions for finite subcritical response moments correspond to stability conditions in these moments, whereas the condition for the existence of the (integrable) stationary response pdf corresponds to the stochastic stability in probability. It is the latter condition that should be used in design to prevent a ‘catastrophic’ failure, whereas the condition for mean-square stability may be regarded as a useful conservative bound for the ‘real’ instability threshold.

Thus, the presence of a stochastic parametric excitation clearly amplifies the response of the structure to an external excitation, thereby reducing its reliability. This effect can clearly be seen for fatigue-type failures, as described by the linear damage accumulation rule, since the corresponding MTBF is governed by some higher-order moment of the (stress) response.

Another version of the stochastic averaging will be illustrated now, which is adequate for lightly damped systems with nonlinear restoring forces. The system is regarded as a ‘quasiconservative’ one, with damping and excitation forces being proportional to μ and $\sqrt{\mu}$, respectively, where μ is a small parameter. The response energy $H(t)$ is then introduced as a ‘slow’ state variable according to eqn [10]. The shortened SDE for this state variable is obtained by averaging over the energy-dependent period of the corresponding nonlinear conservative system.

Thus, for a SDOF system:

$$\ddot{X} + h(X, \dot{X}) + dU/dX = \zeta(t) \quad [12]$$

with zero-mean Gaussian white-noise $\zeta(t)$ of intensity D_ζ this equation is found to be (the actual integration is performed within a half-period, which is possible in view of symmetry in the absence of hysteretic nonlinearities):

$$\begin{aligned} \dot{H} &= -Q(H)/T_0(H) + D_\zeta/2 + [S(H)/T_0(H)]\zeta_1(t) \\ Q(H) &= \int_{x_-}^{x_+} h(x, \sqrt{(2H - 2U(x))}) dx \\ S(H) &= \int_{x_-}^{x_+} [2H - 2U(x)]^{1/2} dx \\ T_0(H) &= \int_{x_-}^{x_+} [2H - 2U(x)]^{-1/2} dx \end{aligned} \quad [13]$$

where $\zeta_1(t)$ is a white noise of unit intensity, whereas x_+ and x_- are the maximal and minimal roots, respectively, of the equation $U(x) = H$. The response amplitude $A(t)$ may also be considered, which is related to the total and potential energies as $U(A) = H$. In particular, $A = \sqrt{(2H)/\Omega}$ in case of a linear restoring force, with natural frequency Ω .

The FPK equation for total energy, which corresponds to the SDE (eqn [13]), has the following stationary solution:

$$p(H) = CT_0(H) \exp \left[-\frac{2}{D_\zeta} \int_0^H \frac{Q(H') dH'}{S(H')} \right] \quad [14]$$

This pdf may be reduced to the exact one (eqn [10]) in the case of linear damping, where $h(x, \dot{x}) = 2\alpha\dot{x}$. A simple exponential pdf of energy is obtained in this case if the restoring force is also linear. In case of a system with linear restoring force and dry-friction damping, where $h(x, \dot{x}) = R \operatorname{sgn} \dot{x}$, the shortened SDE (eqn [13]) is found to be:

$$\dot{H} = -\left(2R\sqrt{2}/\pi\right)\sqrt{H} + D_\zeta/2 + \sqrt{(D_\zeta H)}\zeta_1(t) \quad [15]$$

and therefore:

$$p(H) = (\gamma^2/2) \exp(-\gamma\sqrt{H}), \quad \gamma = 8R\sqrt{2}/\pi D$$

so that:

$$\langle H \rangle = 6/\gamma^2 = (3\pi^2/64)(D/R)^2$$

This case of a dry-friction damping may be of a special interest for systems with active feedback vibration control. It appears, that if the available control force is of a bounded magnitude, with R being its maximal value, the dry-friction control law $R \operatorname{sgn} \dot{X}$ is found to be the optimal one if the steady-state response energy is minimized.

Consider now a first-passage problem for a vibrating component with possibility for a first-passage failure after exceeding a certain given response energy threshold H_* . Assuming the initial energy H to be smaller than this threshold, consider an expected time T for reaching it by the system, whose dynamics is described approximately by the first-order SDE (eqn [15]). The deterministic ODE (eqn [9]) for the function $T(H)$ for this case of a linear restoring force is then:

$$(DH/2) \left(\frac{d^2T}{dH^2} \right) + [D/2 - (2R\sqrt{2}/\pi)\sqrt{H}] \left(\frac{dT}{dH} \right) = -1 \quad [16]$$

The BCs for this equation are (the first one implies a finite value of T in the case $H = 0$) $dT/dH = -2/D$ at $H = 0$; $T(H_*) = 0$.

Eqn [16] has a simple quadrature solution for dT/dH , which then can be integrated numerically. Figure 3 illustrates, by a dotted line, the dependence of the MTBF, in the number of cycles to failure $N = \Omega T/2\pi$, on the nondimensional initial energy $\bar{H} = H/\langle H \rangle$. These results are compared here with those for a system with an ‘equivalent’ linear viscous damping, or a linear velocity feedback control (solid line). The latter had been obtained by replacing term with R in brackets in eqn [16] by $-2\alpha H$. The damping ratio α/Ω of the benchmark linear system has been calculated from the condition $D\gamma/4\alpha = \sqrt{6}$, or $\alpha/\Omega = (3/16)\pi^2\mu^2$, where $\mu^2 = R^2/D\zeta\Omega$. This condition implies the same expected response energy $\langle H \rangle$, or same RMS responses of the two systems to white-noise excitation of the same intensity. It can be seen from Figure 3, that the system with dry-friction control should be regarded as less reliable than one with the simple linear feedback control and same RMS

response level. This reduction of reliability may be interpreted as the price for the imposed bound on the control force, or for ‘weak’ actuators.

Another example for the application of this solution to a first-passage problem in engineering mechanics is as follows. Consider two random processes $Y(t)$ and $X(t)$, where Y is a multivalued S-shaped function of X . This inertialness relation is illustrated in Figure 4. The intermediate branch is shown here by a dashed line, as long as the equilibrium states are usually unstable along such decreasing branches. Therefore, the function $Y = f(X)$ is double-valued, and its upper and lower branches will be identified with subscripts U and L , respectively. Thus, two inverse functions $X = g(Y)$ will be considered: $X = g_U(Y)$ for $Y_2 < Y < \infty$ and $X = g_L(Y)$ for $-\infty < Y < Y_1$. Examples of this kind of relation are: the force–displacement curve of a shallow elastic arch or thin panel with a potential ‘snap-through’; the relation between the amplitude of sinusoidal excitation and that of the (almost) sinusoidal response of a SDOF with a small smooth nonlinearity in the restoring force; the vibration amplitude of a system with ‘hard’ self-excitation as a function of the system’s parameter, which controls transitions between stable equilibrium state and the limit cycle (the lower branch is just $Y = 0$ in the last example).

Consider now the following problem: find the pdf of Y if the pdf of X is known. The corresponding relation (eqn [4] of **Random processes**), which contains the inverse function $X = g(Y)$, can only be used in case of a single-valued $f(X)$. It may be generalized to the case of S-shaped $f(X)$ though, by applying the relation separately to the upper and lower branches of Y . The resulting two pdfs for two different ranges of Y are then treated as the conditional ones, each condition being that Y stays on the corresponding branch. Thus:

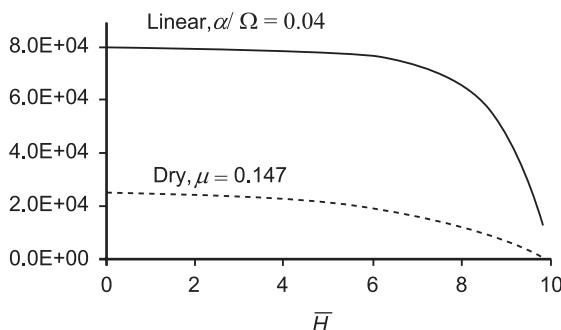

Figure 3 Expected number of cycles to failures for elastic systems with linear viscous and dry-friction damping.

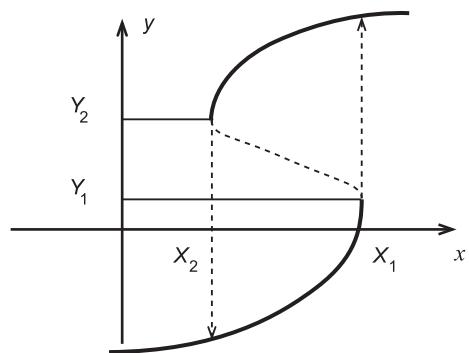

Figure 4 Multivalued function $y = f(x)$.

$$p_Y(y) = \frac{P_U \cdot p_X(g_U(y)) |dg_U/dy|}{\int_{y_2}^{\infty} p_X(g_U(y)) |dg_U/dy| dy}, y > y_2$$

$$p_Y(y) = \frac{P_L \cdot p_X(g_L(y)) |dg_L/dy|}{\int_{-\infty}^{y_1} p_X(g_L(y)) |dg_L/dy| dy}, y < y_1$$

$$P_U + P_L = 1$$

Here P_U and P_L are the total probabilities for staying on the upper and lower branch, respectively. Although their sum is unity, in view of a single normalization condition, nothing more can be said about the pdf of a random variable Y .

However, if $X(t)$ is a random process, the individual probabilities for $Y(t)$ staying on each of the branches can be predicted as solutions to the appropriate first-passage problems. (Note that applications to dynamic problems are possible only if $X(t)$ is slowly varying, so that the quasistatic approach is warranted.) In this case transitions between the upper and lower branches are possible, as illustrated by arrows in Figure 4: from lower to upper after upcrossing level x_1 by $X(t)$ and from lower to upper after downcrossing level $x_2 < x_1$, where $x_1 = g_L(y_1)$ and $x_2 = g_U(y_2)$ are the limit points of the lower and upper branches, respectively. Identifying the desired probabilities as the relative stay times of the $X(t)$ on the upper and lower branches, the ratio of these stay times may be predicted as $P_U/P_L = T_{12}/T_{21}$. Here T_{ij} , $i, j = 1, 2$ is the expected time for crossing level x_j by the process $X(t)$ if its initial value is $X = x_i$. If $X(t)$ is a scalar Markov process, the ODE for these expected times with relevant boundary conditions can simply be solved numerically.

Just one comment seems to be relevant here, on the relation between expected times for reaching and for crossing certain given level x_* . They are usually the same, if the drift coefficient of the Markov process $X(t)$ does not vanish at $X = x_*$. However, in a special case $a(x_*) = 0$ the expected time for crossing this ‘potential barrier’ is found to be twice as high as for reaching it. This fact is proved by asymptotic evaluation of the quadrature solution for T , and has a simple explanation: in the absence of regular forces at the potential barrier the process has equal chances for going further and for returning back.

Nomenclature

$A(t)$	response amplitude
C	normalizing constant
H	total energy
$H(t)$	response energy
$U(x)$	potential energy
Ω	natural frequency

doi:10.1006/rwvb.2001.0100

Aim of Structural Dynamic Modification

The possibility of changing the dynamic behavior of structures to control the vibration response or reduce the noise radiated by a vibrating system is a real challenge, particularly when these requirements are not of primary concern in the function of the structure, and significant variations to the main features of the system are not permitted.

Such control tasks can be obtained by either passive or active procedures: these last are becoming quite common because of the use of smart structures, but imply the development of control feedback that must verify important conditions of robustness and stability. Passive tools are much simpler and can accomplish surprisingly good results at a lower cost. Among them, simple structural modifications can often produce the expected goals, and by structural dynamic modification a well-known tool of modal analysis is indicated.

The enhancement of the structural or acoustic response is one of the common goals of the structural modification process. This can be related to any of the following elements: the source, the transmission path, or the receiver.

In structural dynamic modification, two problems have a particular interest: the direct problem and the inverse problem. The direct problem consists of determining the effect of established modifications on the dynamic properties, without requiring a new computation (or measurement) on the changed system. Therefore this is a ‘what if’ problem aimed to establish the effect of given changes on the dynamic behavior of the considered system. The inverse problem, which is more complex, tries to identify the most appropriate among many possible modifications to obtain a desired dynamic behavior. This is a typical design problem, consisting of specifying the required action to obtain an improvement of the structural or acoustic response.

Knowledge of the original system, whose dynamic behavior is amenable to modification, can derive from a theoretical analysis usually obtained from a finite element model of the system. However, in many

practical situations, neither a reliable finite element database nor the modal parameters of the system are known, either because the system is too complex or because an updated finite element model is not available. In such cases, one can try to determine the system experimentally, considering it as a black box system identified through its frequency response function (FRF) matrix, from which some suitable knowledge of the structure upon which to perform modifications can eventually be obtained (see **Modal analysis, experimental, Applications**).

Since the identification of spatial parameters (mass and stiffness matrices) derived from an FRF model is a highly ill-conditioned problem, most of the work has been concentrated on modal parameters. Excluding particular situations (high modal density, strongly coupled modes), modal parameters can be identified quite efficiently in the frequency band tested, and produce useful – albeit incomplete – modal models. Once such a model is available, many structural modification algorithms can be developed and used with some advantage.

Probably due to the degree of development of modal techniques, many formulations apply to changes of modal characteristics, i.e., resonance shifts, Q-factor reduction, etc., and make use of the identified modal parameters (modal synthesis). This approach does not complete the wide field of applications that can be expected from structural modification. Among them, some concern the need to reduce the vibration behavior of particular points of the structure in a frequency band of interest, or the possibility of narrowing the rigid-body natural frequencies of a suspended system to achieve the maximum isolation efficiency. Moreover, the incomplete knowledge of the modal model identified from a continuous structure severely affects the results of structural modification analysis. A large amount of research on the subject has established the following points:

- When using modal parameters, the accuracy of the modified dynamic properties is largely affected by the quality of the modal model derived from experimental data.
- The effect of modal truncation on structural modifications is quite critical. A major role in the effectiveness of modification analysis is played by a selected number of modes rather than by the quantity of modes included in the database, and it is not possible to obtain an exact solution for structural modification when using an incomplete set of eigenvectors.

For the above reasons, in addition to modal synthesis, a frequency domain approach is also presented here. This method avoids a modal identification process and the pitfalls deriving from it. Moreover, it may handle useful applications and it permits optimal modifications for different dynamic requirements.

The modifications considered here are discrete modifications, i.e., they consist of any combination of lumped masses, stiffnesses (obtained by springs connecting two different points of the structure or one point of the structure to an external fixed point), and dampers.

Direct Problem

The data necessary to solve the direct problem are:

- the dynamic behavior of the original structure
- a knowledge of the modifications

The dynamic behavior of the original structure can be expressed:

- as a modal database, comprising natural frequencies and mode shapes (real or complex) identified by a curve-fitting of experimental data or determined from a theoretical analysis
- as an FRF database, determined experimentally or theoretically

First, the approach that uses the modal database to represent the dynamic behavior of the system is described. Next, the approach based on the frequency response function database is presented.

Let \mathbf{M} , \mathbf{K} , and \mathbf{C} represent the $N \times N$ mass, stiffness, and viscous damping matrices of the original (unmodified) system: they are necessary to develop the theory, but we will find that they are not needed to solve the structural modification problem in practice. Furthermore, let $\Delta\mathbf{M}$, $\Delta\mathbf{K}$, and $\Delta\mathbf{C}$ be the matrices with entries representing mass, stiffness, and damping modifications, respectively. These matrices must have the same dimensions as \mathbf{M} , \mathbf{K} , and \mathbf{C} and must contain nonzero elements only in those locations where the modifications are acting. For example, on a three degrees of freedom (3-DOF) system, a modification Δm_3 on the third mass will be represented by a 3×3 matrix, $\Delta\mathbf{M}$, whose only nonzero element is $m_{33} = \Delta m_3$. The modification consisting of a spring, Δk , between the first and third mass will be represented by the matrix:

$$\Delta\mathbf{K} = \begin{bmatrix} \Delta k & 0 & -\Delta k \\ 0 & 0 & 0 \\ -\Delta k & 0 & \Delta k \end{bmatrix}$$

Modal Database

When using the modal database, typically the case of real modes, related to an undamped or proportionally damped system, is considered. The case of a nonproportionally damped system leading to complex modes could be similarly addressed by using a state space approach. However the problem is much more intricate because the modal identification task becomes much more difficult as damping and/or modal coupling increases. Therefore, in practice the use of a complex modal database is not convenient.

Theory for real modes The equation of motion of the original system is:

$$\mathbf{M}\ddot{\mathbf{x}}_0 + \mathbf{C}\dot{\mathbf{x}}_0 + \mathbf{K}\mathbf{x}_0 = \mathbf{f} \quad [1]$$

where proportional viscous damping $\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K}$ is assumed.

The related undamped eigenvalue problem:

$$(\mathbf{K} - \lambda\mathbf{M})\phi = 0 \quad [2]$$

provides N eigenvalues $\lambda_i = \omega_{ni}$ and eigenvectors (modes) ϕ_i :

$$\Lambda = \begin{bmatrix} \omega_{n_1}^2 & & & \\ & \ddots & & \\ & & \ddots & \\ & & & \omega_{n_N}^2 \end{bmatrix} \quad [3]$$

$$\Phi = [\phi_1 \quad \phi_2 \quad \cdots \quad \phi_m]$$

that satisfy the orthonormal conditions:

$$\begin{aligned} \Phi^T \mathbf{M} \Phi &= \mathbf{I} \\ \Phi^T \mathbf{K} \Phi &= \Lambda \\ \Phi^T \mathbf{C} \Phi &= \alpha \mathbf{I} + \beta \Lambda = \Xi \end{aligned} \quad [4]$$

By introducing the coordinate transformation Φ from the physical space (\mathbf{x}_0 coordinates) to the modal space (\mathbf{q}_0 coordinates) in eqn [1]:

$$\mathbf{x}_0 = \Phi \mathbf{q}_0 \quad [5]$$

one obtains, after premultiplying by Φ^T :

$$\Phi^T \mathbf{M} \Phi \ddot{\mathbf{q}}_0 + \Phi^T \mathbf{C} \Phi \dot{\mathbf{q}}_0 + \Phi^T \mathbf{K} \Phi \mathbf{q}_0 = \Phi^T \mathbf{f} \quad [6]$$

i.e., in view of the orthonormal conditions:

$$\ddot{\mathbf{q}}_0 + \Xi \dot{\mathbf{q}}_0 + \Lambda \mathbf{q}_0 = \Phi^T \mathbf{f} \quad [7]$$

This is a system of N uncoupled equations representing the modal model of the original system.

The equation of motion of the modified structure can be written as:

$$(\mathbf{M} + \Delta\mathbf{M})\ddot{\mathbf{x}} + (\mathbf{C} + \Delta\mathbf{C})\dot{\mathbf{x}} + (\mathbf{K} + \Delta\mathbf{K})\mathbf{x} = \mathbf{f} \quad [8]$$

where it is assumed $\Delta\mathbf{C} = \alpha\Delta\mathbf{M} + \beta\Delta\mathbf{K}$ to maintain proportional damping.

If the same coordinate transformation, Φ , such that $\mathbf{x} = \Phi\mathbf{q}$ is introduced into eqn [8], one obtains after premultiplying by Φ^T :

$$(\mathbf{I} + \Delta\tilde{\mathbf{M}})\ddot{\mathbf{q}} + (\Xi + \Delta\tilde{\mathbf{C}})\dot{\mathbf{q}} + (\Lambda + \Delta\tilde{\mathbf{K}})\mathbf{q} = \Phi^T \mathbf{f} \quad [9]$$

i.e., the equation of motion of the modified structure is written in terms of the modal coordinates of the original structure, having defined:

$$\begin{aligned} \Delta\tilde{\mathbf{M}} &= \Phi^T \Delta\mathbf{M} \Phi \\ \Delta\tilde{\mathbf{C}} &= \Phi^T \Delta\mathbf{C} \Phi \\ \Delta\tilde{\mathbf{K}} &= \Phi^T \Delta\mathbf{K} \Phi \end{aligned} \quad [10]$$

Note that the above matrices are not usually diagonalized by the coordinate transformation based on the eigenvectors of the original structure.

To uncouple the equations of motion of the modified system, it is necessary to solve the undamped eigenvalue problem related to eqn [9], i.e.:

$$[(\Lambda + \Delta\tilde{\mathbf{K}}) - \lambda^I(\mathbf{I} + \Delta\tilde{\mathbf{M}})]\phi^I = 0 \quad [11]$$

It provides new eigenvalues Λ^I and eigenvectors Φ^I , for which the following orthonormal conditions hold:

$$\begin{aligned} (\Phi^I)^T(\mathbf{I} + \Delta\tilde{\mathbf{M}})\Phi^I &= \mathbf{I} \\ (\Phi^I)^T(\Lambda + \Delta\tilde{\mathbf{K}})\Phi^I &= \Lambda^I \\ (\Phi^I)^T(\Xi + \Delta\tilde{\mathbf{C}})\Phi^I &= \Xi^I \end{aligned} \quad [12]$$

Therefore, the new coordinate transformation:

$$\mathbf{q} = \Phi^I \mathbf{q}^I \quad [13]$$

from the modal space of the original system to the modal space of the modified system, yields the following uncoupled set of equations:

$$\ddot{\mathbf{q}}^I + \Xi^I \dot{\mathbf{q}}^I + \Lambda^I \mathbf{q}^I = \Phi^{I^T} \Phi^T \mathbf{f} \quad [14]$$

The natural frequencies of the modified structure can be obtained from the eigenvalue matrix Λ^I , whilst the mode shapes of the modified structure are given by:

$$\Psi = \Phi \Phi^I \quad [15]$$

In fact, the transformation $\mathbf{x} = \Psi \mathbf{q}^I$ from the physical coordinates to the modal coordinates of the modified structure can be written as:

$$\mathbf{x} = \Phi \mathbf{q} = \Phi(\Phi^I \mathbf{q}^I) \Rightarrow \Psi = \Phi \Phi^I \quad [16]$$

and the modal matrix of the modified structure can be put in the form:

$$\Psi = [\psi_1 \ \psi_2 \ \dots \ \psi_m] \quad [17]$$

It can easily be verified from the previous relationships that $\Psi^T(\mathbf{M} + \Delta\mathbf{M})\Psi = \mathbf{I}$, i.e., the new mode shapes are mass-normalized. Note also that the new modes are a linear combination of the modes of the original structure. In fact a given term ψ_{rs} of the matrix Ψ is:

$$\psi_{rs} = \sum_{l=1}^N \phi_{rl} \phi_l^I \quad [18]$$

and the mode shape, i.e., a given column of Ψ , is:

$$\psi_s = \sum_{l=1}^N \phi_{ls}^I \phi_l \quad [19]$$

Notes on practical implementation Natural frequencies and mode shapes of the modified system are derived from eqn [11], which does not involve the mass, stiffness, and damping matrices, \mathbf{M} , \mathbf{K} , and \mathbf{C} , of the original structure. Therefore, there is no need to know these matrices in order to determine the modal parameters of the modified structure, provided that the original modal parameters are known and suitable lumped modifications involving any variation of mass, stiffness, and/or damping are established so that $\Delta\mathbf{M}$, $\Delta\mathbf{K}$ (and $\Delta\mathbf{C}$) are given.

The original modal parameters can either be derived experimentally, i.e., identified from measured FRFs, or computed theoretically from a model of the structure. In both cases, a number $m \ll N$ of modes is used in practice.

In fact, it is not possible to identify the whole set of modal parameters of a continuous system, but only those included in a given frequency bandwidth: in other words, for continuous systems, N is infinite. Even in the so-called reanalysis problem, in which an N -DOF finite element model is used, relationship (11) is only useful if the involved computation is less time-consuming than the analysis of a new finite element model. This happens when in the reanalysis a number of modes $m \ll N$ is considered.

Truncation effect If $m = N$, the modal parameters of the modified system are determined exactly, whilst they are only approximate when $m < N$ (mode truncation effect). In fact, since eqn [9] is a set of coupled equations, some coupling terms are lost by truncating it to m modes, i.e., by considering only m rows and m columns of the coefficient matrices: therefore the results obtained are only approximate.

Another way to look at the problem is to consider eqn [19]. It shows that the modified structure mode shapes are linear combinations of the mode shapes of the original system. If all N modes are considered, they represent a complete basis in the N -dimensional space, meaning that every N -dimensional vector, and therefore also all the new mode shapes, can be described by a linear combination of the vectors in the basis. In contrast, if $m < N$, the summation in eqn [19] is truncated to m terms. Therefore the vector basis is not complete and the new mode shapes are described with some error.

It has been observed that the amount of error due to mode truncation can be quite large. The following example highlights the origin of the truncation error.

In Figure 1, a lumped parameter system with 7 DOF is considered. The modal model of such system is shown, representing the uncoupled system [7].

In Figure 2, the system of Figure 1 has been modified by adding a spring between masses 1 and 5. Since $\Delta\mathbf{M} = 0$, the homogeneous problem of the modified system, written in the modal coordinates of the original system, is:

$$\ddot{\mathbf{q}} + (\Lambda + \Delta\tilde{\mathbf{K}})\mathbf{q} = 0 \quad [20]$$

The model corresponding to eqn [20] is also shown in Figure 2. The static coupling is provided by the off-diagonal terms of $\Delta\tilde{\mathbf{K}}$, represented by the springs interconnecting the modal masses.

The effect of truncation is shown in Figure 3.

If the seventh mode of the original system is neglected, the corresponding modal model is made of the first six modes only (Figure 3 left). If the model of the modified system is expressed in the modal

coordinates of the original system (Figure 3 center), the truncation of the seventh mode does not permit accounting for the coupling terms among the first six modes and the omitted one (Figure 3 right). These terms, the first six in the last column of the matrix $\Delta\tilde{\mathbf{K}}$ shown in Figure 2, are by no means negligible with respect to those of the first six columns.

Frequency Response Function Database

The difficulty of identifying the modal parameters, especially for complex structures and/or high modal densities, and the effect of mode truncation on the structural modification problem suggest that the use of the modal database should be avoided.

Then it can be appropriate to use directly the frequency response function matrix of the structure $\mathbf{H}_0(\omega)$, experimentally determined for N DOF, thus having dimensions $N \times N$. However, the matrix $\mathbf{H}_0(\omega)$ is symmetric due to the reciprocity theorem. Consequently, the elements that must be determined are only $N \times (N + 1)/2$ (elements of the upper or lower triangular part of the matrix), instead of N^2 .

It is now shown how the FRF matrix of a modified structure can be determined from knowledge of the original structure and the imposed modifications.

Using the FRF matrix, the response $\mathbf{X}_0(\omega)$ of the original structure to an external excitation $\mathbf{F}(\omega)$ is given by:

$$\mathbf{X}_0(\omega) = \mathbf{H}_0(\omega)\mathbf{F}(\omega) \quad [21]$$

In eqn [21], $\mathbf{H}_0(\omega)$ is the FRF matrix of the original structure, whose elements can be receptances, mobilities, or inertances. Accordingly, the elements of $\mathbf{X}_0(\omega)$ are displacements, velocities, or accelerations, respectively, of the N considered DOFs, while the elements of $\mathbf{F}(\omega)$ are the forces acting on the structure at those DOFs.

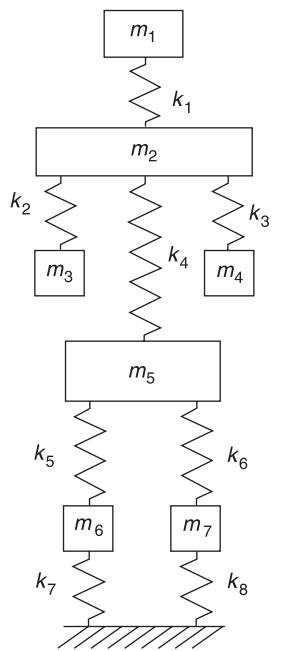

After formally introducing the impedance-like matrix of the structure $\mathbf{Z}_0(\omega) = \mathbf{H}_0^{-1}(\omega)$ the equation of motion of the original structure in the frequency domain can be written as:

$$\mathbf{F}(\omega) = \mathbf{Z}_0(\omega)\mathbf{X}_0(\omega) \quad [22]$$

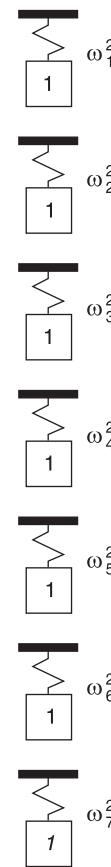

Let the modifications be described by the matrix $\Delta\mathbf{Z}(\omega)$, that can be expressed, for the dynamic stiffness as:

$$\Delta\mathbf{Z}(\omega) = \Delta\mathbf{K} + j\omega\Delta\mathbf{C} - \omega^2\Delta\mathbf{M} \quad [23]$$

The above expression of $\Delta\mathbf{Z}$ holds when \mathbf{H}_0 is a receptance matrix. For mobility or inertance matrices, $\Delta\mathbf{Z}$ must be changed accordingly, by dividing by $j\omega$ or $-\omega^2$, respectively.

$$\begin{aligned}
 k_1 &= 5 \text{ N m}^{-1} & m_1 &= 15 \text{ kg} \\
 k_2 &= 10 \text{ N m}^{-1} & m_2 &= 15 \text{ kg} \\
 k_3 &= 10 \text{ N m}^{-1} & m_3 &= 5 \text{ kg} \\
 k_4 &= 20 \text{ N m}^{-1} & m_4 &= 5 \text{ kg} \\
 k_5 &= 10 \text{ N m}^{-1} & m_5 &= 15 \text{ kg} \\
 k_6 &= 10 \text{ N m}^{-1} & m_6 &= 10 \text{ kg} \\
 k_7 &= 1 \text{ N m}^{-1} & m_7 &= 10 \text{ kg} \\
 k_8 &= 1 \text{ N m}^{-1}
 \end{aligned}$$

$$K = \begin{bmatrix} 5 & -5 & & & & & \\ -5 & 45 & -10 & -10 & -20 & & \\ & -10 & 10 & & & & \\ & -10 & & 10 & & & \\ & -20 & & & 40 & -10 & -10 \\ & & & & -10 & 11 & & \\ & & & & -10 & & 11 & \end{bmatrix}$$

$$M = \begin{bmatrix} 15 & & & & & & \\ & 15 & & & & & \\ & & 5 & & & & \\ & & & 5 & & & \\ & & & & 15 & & \\ & & & & & 10 & \\ & & & & & & 10 \end{bmatrix}$$

$$\Lambda = \begin{bmatrix} 0.16 & & & & & & \\ & 0.61 & & & & & \\ & & 0.97 & & & & \\ & & & 1.05 & & & \\ & & & & 1.41 & & \\ & & & & & 1.69 & \\ & & & & & & 2.21 \end{bmatrix}$$

$$\Phi = \begin{bmatrix} -0.127 & -0.216 & 0.059 & 0.000 & 0.000 & -0.009 & -0.014 \\ -0.118 & 0.025 & -0.107 & 0.000 & 0.000 & 0.072 & 0.188 \\ -0.119 & 0.031 & -0.201 & 0.000 & 0.316 & -0.165 & -0.130 \\ -0.119 & 0.031 & -0.201 & 0.000 & -0.316 & -0.165 & -0.130 \\ -0.112 & 0.072 & 0.022 & 0.000 & 0.000 & 0.174 & -0.134 \\ -0.104 & 0.100 & 0.135 & -0.224 & 0.000 & -0.098 & 0.035 \\ -0.104 & 0.100 & 0.135 & 0.224 & 0.000 & -0.098 & 0.035 \end{bmatrix}$$

Figure 1 7-DOF system.

Since modifications must only involve DOFs in which the $\mathbf{H}_0(\omega)$ matrix has been measured, the equation of motion of the modified structure, excited by the same forces $\mathbf{F}(\omega)$, can be written as:

$$\mathbf{F}(\omega) = [\mathbf{Z}_0(\omega) + \Delta\mathbf{Z}(\omega)]\mathbf{X}(\omega) \quad [24]$$

in which $\mathbf{X}_0(\omega)$ is the response of the modified structure. Therefore:

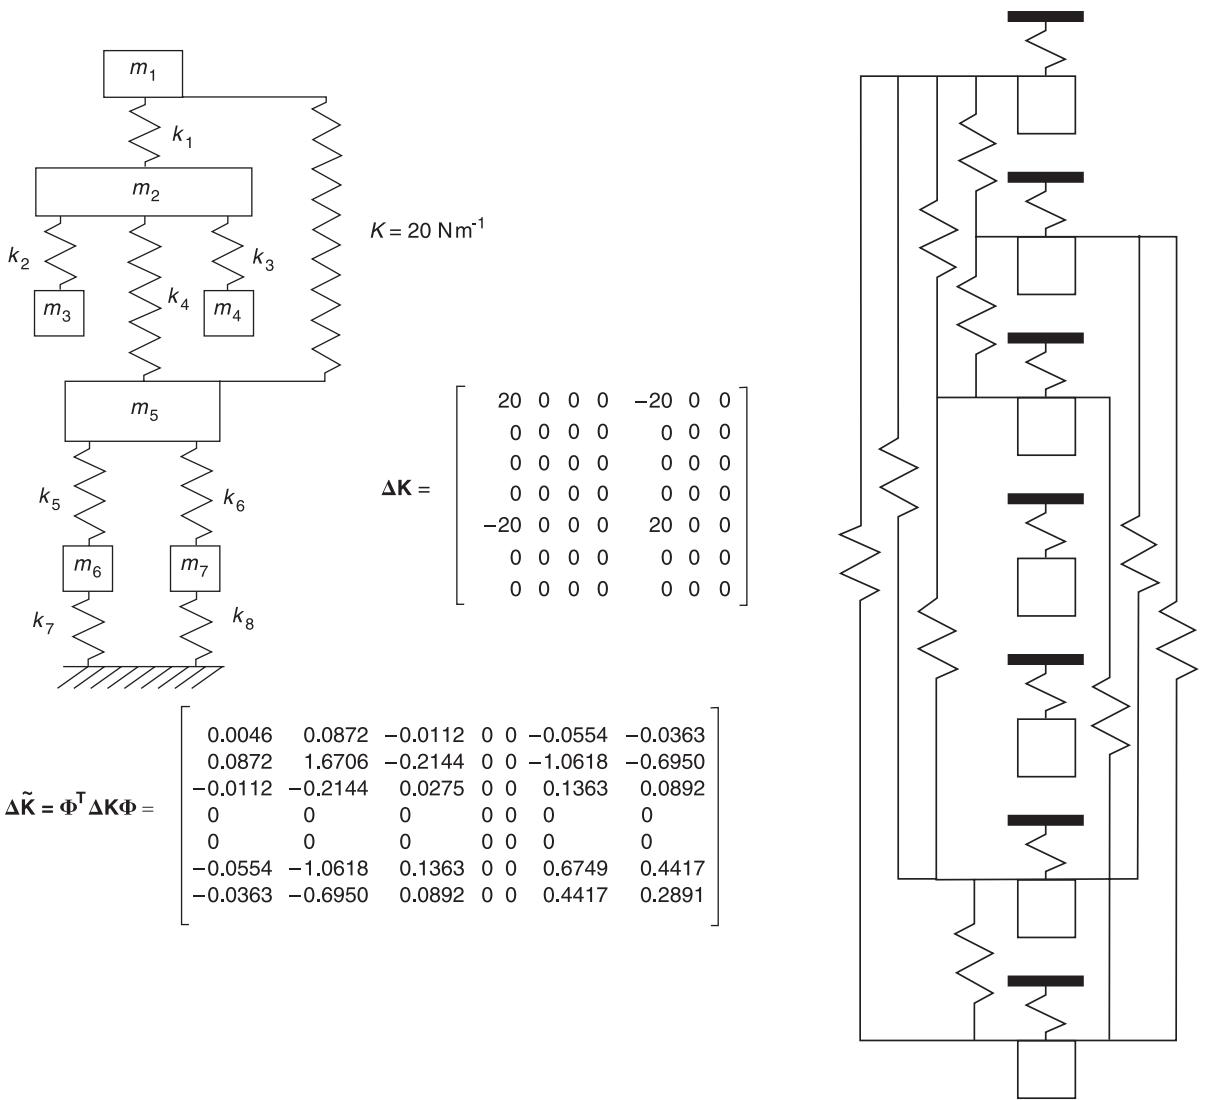

Figure 2 Modified 7-DOF system.

$$\mathbf{X}(\omega) = [\mathbf{Z}_0(\omega) + \Delta\mathbf{Z}(\omega)]^{-1} \mathbf{F}(\omega) \quad [25]$$

Because of the relationship $\mathbf{X}(\omega) = \mathbf{H}(\omega)\mathbf{F}(\omega)$, where $\mathbf{H}(\omega)$ is the (unknown) FRF matrix of the modified structure, one has:

$$\mathbf{H}(\omega) = [\mathbf{Z}_0(\omega) + \Delta\mathbf{Z}(\omega)]^{-1} \quad [26]$$

Recalling that the impedance-like matrix of the original structure is not practically available, one can write:

$$\mathbf{H}(\omega) = [\mathbf{H}_0^{-1}(\omega) + \Delta\mathbf{Z}(\omega)]^{-1} \quad [27]$$

Instead of using directly eqn [27], involving two matrix inversions, it is more convenient to premultiply eqn [24] by $\mathbf{H}_0(\omega)$, thus obtaining:

$$\begin{aligned} \mathbf{H}_0(\omega)\mathbf{F}(\omega) &= \mathbf{H}_0(\omega)[\mathbf{Z}_0(\omega) + \Delta\mathbf{Z}(\omega)]\mathbf{X}(\omega) \\ &= [\mathbf{I} + \mathbf{H}_0(\omega)\Delta\mathbf{Z}(\omega)]\mathbf{X}(\omega) \end{aligned} \quad [28]$$

in which \mathbf{I} is the unit matrix. From eqn [28] one obtains:

$$\mathbf{X}(\omega) = [\mathbf{I} + \mathbf{H}_0(\omega)\Delta\mathbf{Z}(\omega)]^{-1}\mathbf{H}_0(\omega)\mathbf{F}(\omega) \quad [29]$$

which implies:

$$\mathbf{H}(\omega) = [\mathbf{I} + \mathbf{H}_0(\omega)\Delta\mathbf{Z}(\omega)]^{-1}\mathbf{H}_0(\omega) \quad [30]$$

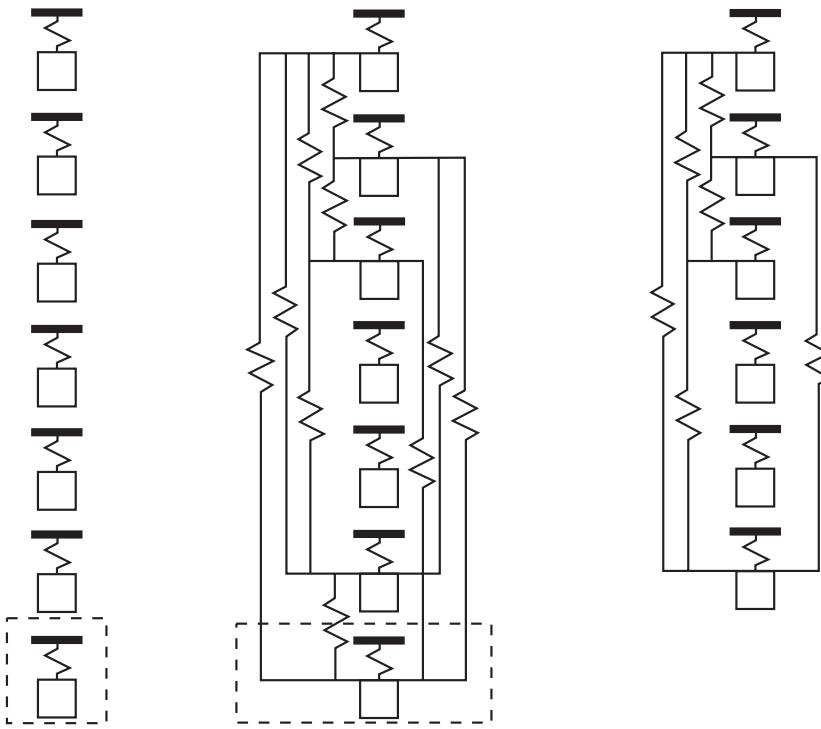

Figure 3 Truncation effect.

Eqn [30] provides the FRF matrix of the modified structure from the original FRF $\mathbf{H}_0(\omega)$ and the impedance-like matrix of the modifications $\Delta\mathbf{Z}(\omega)$: this is the prediction relationship we were looking for. With respect to eqn [27], it involves a single matrix inversion, so that it is computationally more efficient. Furthermore, it avoids the inversion of matrix \mathbf{H}_0 , which is ill-conditioned around the resonances of the original system.

It is worth pointing out that, for a given set of modifications, the computation performed in eqn [30] must be repeated at all the frequencies of interest: these frequencies are established by the analyst among those used to determine experimentally the FRF. Since the experimental data are normally sampled at discrete time instants (and frequencies), these frequencies represent a discrete set of values.

Inverse Problem

The inverse problem must be formulated in terms of the FRF database. In fact, it is not generally possible to establish the physical goal of an inverse problem through the modal parameters, while this is quite simple by means of the response or FRF of the system. To make this point clear, consider the case of **Figure 4**, which represents the FRF modulus of a given structure. If this response is, for any reason, unacceptable,

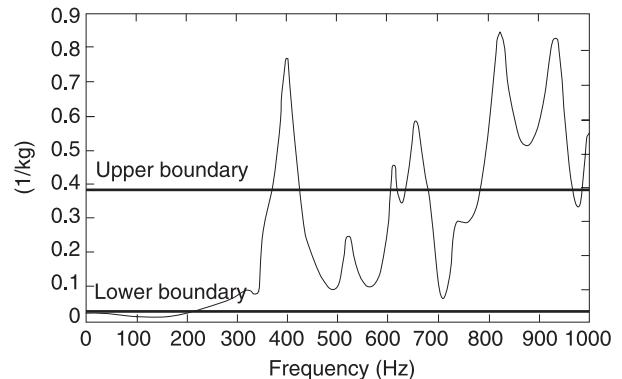

Figure 4 Establishing the wished dynamic behavior of a structure.

it is quite simple to define an upper (and lower) boundary for it (e.g., those shown in the figure), and to require that the FRF of the modified structure lies within these boundaries.

In contrast, these requirements cannot be defined in terms of the modal parameters. For this reason, the FRF of the structure is generally the only practical database to formulate the inverse problem, so that the required dynamic behavior will be defined by means of parameters connected with the FRF matrix. Only the case of an FRF optimization is presented here: the possibility of extending the approach to other

response optimization is a simple exercise once the considered case is understood.

The parameters which are dependent on the structural modifications will be located in a vector \mathbf{z} . They can represent mass, stiffness, and/or damping modifications at or between any of the points of the measured FRF matrix, i.e., the possible modifications must be applied to points where the FRF matrix has been measured.

Definition of the Required Dynamic Behavior

The dynamic behavior of a structure may be described by means of its FRF characteristics. Through these, it is possible to determine the response of the structure when an estimate of the exciting forces is available.

In the present case, it is sufficient to examine the magnitudes of some FRFs: more precisely, the FRFs measured between the points in which the forces are supposed to act and the points where the response(s) must be controlled.

Since any element H_{ij} of the modified FRF matrix, here written as $\mathbf{H}(\mathbf{z}, \omega)$ to express that it depends on the set of modifications \mathbf{z} , can be determined from eqn [30], the elements amenable to optimization can be established as:

$$p_r(\mathbf{z}) = |H_{ij}(\mathbf{z}, \omega_k)| \quad \omega_k \in S_F, \quad (i, j) \in S_E, \quad r = 1 \dots N_F, \quad N_P = N_F \times N_E \quad [31]$$

where S_F is the discrete set of N_F frequencies involving the bandwidth where a modification is required to act and S_E the set of N_E pairs of indices (i, j) determining the elements of H_{ij} that must be modified.

Formulation of the Problem

The goal of the structural modification (or optimization) process, i.e., the desired dynamic behavior of a structure, can be more simply established in negative rather than in positive terms: in other words, for a given structure, it is preferable to stress what must be avoided instead of what is actually required. For example, to control the modulus of an FRF on the basis of the performance required of the system, it is rather natural to seek to avoid excessively high resonant peaks and thus to establish an upper boundary for the FRF modulus that should not be overcome; in contrast it is not natural to define a detailed behavior for the response. Therefore the conditions that are usually required are not equality conditions that would imply exact wished values, but rather inequality conditions, such as:

$$b_r^L \leq p_r(\mathbf{z}) \leq b_r^U, \quad r = 1 \dots N_P$$

where b_r^L and b_r^U are lower and upper boundaries for each $p_r(\mathbf{z}) = |H_{ij}(\mathbf{z}, \omega_k)|$.

Generally, the existence of a vector $\tilde{\mathbf{z}}$ satisfying the conditions imposed is not guaranteed. In fact, it cannot be supposed that the required behavior is physically possible, either in the absolute sense or, for more reasonable requirements, in relation to the feasible set of modifications.

In contrast, if some $\tilde{\mathbf{z}}$ which satisfies the imposed conditions does exist, in general it will not be unique, especially if the requirements imposed are expressed as inequalities. It is then necessary to establish a criterion to discriminate amongst the possible solutions and to choose consequently the most convenient of them.

The above considerations exclude the possibility of formulating the problem as the simple solution of the set of inequality equations like the ones shown above. An argument stressing the relative inconvenience of this formulation relies on the circumstance that, if one finds different solutions (e.g., when starting from different initial estimates of $\tilde{\mathbf{z}}$), the proposed scheme does not provide any criteria to choose the most appropriate of them.

A criterion to operate a comparison among different solutions can be based on considerations involving the cost of the alternative modifications. If more modification sets exist satisfying the required conditions, the preferable set would be that which costs least.

The introduction of a cost minimization condition implies a formulation of the inverse problem as a problem of mathematical programming (or optimization). To this end it is quite natural to formulate the following problem of constrained minimum:

$$\min_{\mathbf{z}} C(\mathbf{z})$$

with the constraints:

$$b_r^L \leq |H_{ij}(\mathbf{z}, \omega_k)| \leq b_r^U \quad r = 1 \dots N_P$$

and the technological boundaries:

$$z_i^L \leq z_i \leq z_i^U$$

An appropriate choice of technological boundaries avoids an impossible realization of the resulting modifications (such as springs or dampers with negative values) or just not practical (e.g., a subtraction of mass). Moreover, they can avoid modifications which

are not compatible with the system architecture, such as too-large modifications altering some important features of the system.

The solution of the optimization problem can be achieved by different methods proposed in the literature to solve nonlinear optimization problems. Among them, classical procedures that search for the steepest gradient can be used as well as new methods that make use of the genetic algorithms that have been proven to be quite robust and efficient for these kinds of problem.

Cost of Modifications

Let $C(\mathbf{z})$ be the cost associated with the modifications represented by the vector, \mathbf{z} . This cost would not just be the cost of the material and production: in fact, it is worth pointing out that the structure to be modified is usually already designed and, often, optimized to satisfy other requirements. Thus, any change from the original design implies *per se* a cost.

A reasonable expression for $C(\mathbf{z})$ is the following additive form, in which the cost of any elementary variable modification z_i is independent of the value of the other modifications:

$$C(\mathbf{z}) = \sum_{i=1}^{N_V} c_i(z_i)$$

Among the many possibilities for $c_i(z_i)$, two deserve particular attention:

- Constant marginal cost: in this case it is:

$$c_i(z_i) = w_i |z_i| \quad [32]$$

in which the cost of the i th design variable is proportional to the absolute value of the same variable through the coefficients w_i allowing one to give different weights to the different variables.

- Proportional marginal cost: in this case the cost is:

$$c_i(z_i) = w_i z_i^2 \quad [33]$$

in which the cost of the i th design variable is proportional to the square of the same variable through a weight coefficient w_i .

The relationship [33] is more appropriate than the constant marginal cost [32], in that it more closely satisfies the condition of not affecting too much the general architecture of the original structure. In fact, it inflicts a higher penalty to large isolated modifications than to modifications spread over several points.

Let us consider a modification consisting of adding a given mass: the expression of the constant marginal cost [32], for equal coefficients w_i , provides the same cost either when the mass is entirely concentrated in a single point or when it is split among several points. In contrast, the proportional marginal cost [33] provides a lower cost for the mass spread over several points. This is preferable because the general architecture of the system is less affected by such a solution.

Reduction of the Number of Design Variables

The solution of linear optimization problems with hundreds of variables and constraints can easily be obtained. In contrast, the solution of nonlinear optimization problems is much more complex, and only a few dozen variables and constraints can usually be considered. Therefore, before trying to solve the optimization problem, it is convenient to reduce the number of design variables, neglecting those having a small effect on the controlling parameters. This preliminary analysis of the modifications effectiveness can be performed using sensitivities.

Sensitivity analysis Using sensitivity analysis, one can determine the effectiveness of any modification in performing the required dynamic goals, through the analysis of the specific effect of any modification.

To this end, the increment of any $|H_{ij}|$ as a function of the increment of any design variable can be considered, excluding from the optimization process those modifications producing the lowest parameters' variations. Therefore, a first-order sensitivity analysis can be formulated through the derivatives:

$$\left. \frac{\partial}{\partial z_i} p_r(\mathbf{z}) \right|_{\mathbf{z}=0}$$

For application purposes, since $p_r(\mathbf{z}) = |H_{ij}(\mathbf{z}, \omega_k)|$ is frequency-dependent, it is convenient to plot the sensitivity as a function of frequency. In Figure 5, the derivatives of the FRF magnitude with respect to two different modifications are considered.

One can observe the fluctuations of the sensitivity between negative and positive values. Therefore it can be troublesome to establish the effectiveness of a given modification: in fact, if the goal is a reduction of the FRF modulus, the sensitivity zones higher than zero would worsen the result. However, a comparison between the two curves shows that the oscillations of one of them are higher than the other, so that one can stress that the modifications corresponding to the lower oscillations have a poor effect on the considered FRF.

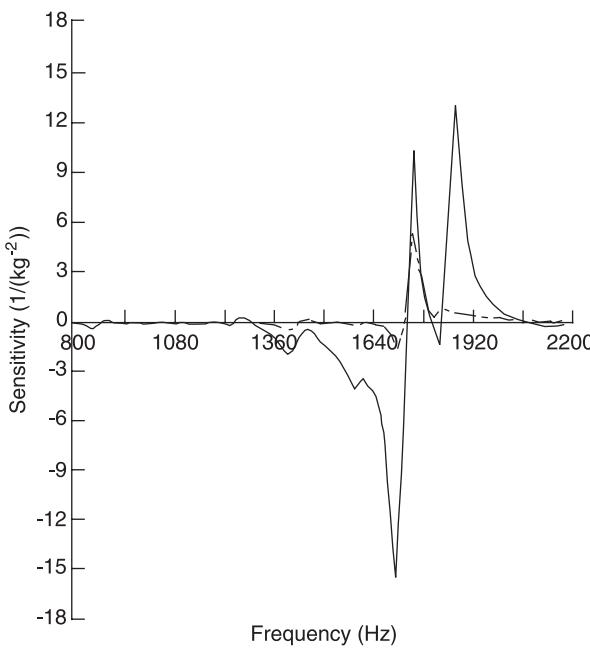

Figure 5 Example of a first-order sensitivity: derivative of the inertance FRF with respect to mass.

This suggests estimation of the potential effectiveness of a modification in the considered frequency bandwidth by its root mean square value, i.e.:

$$\left[\sum_{r=1}^{N_p} \left(\frac{\partial}{\partial z_i} p_r(\mathbf{z}) \Big|_{z=0} \right)^2 \right]^{1/2} \quad [34]$$

Applications of the Optimization Procedure

2-DOF system To clarify the approach proposed so far for the optimization problem, consider the 2-DOF system shown in **Figure 6**. Following the point of view adopted, the FRF of the system would be known experimentally whilst the physical model (\mathbf{M} , \mathbf{C} , and \mathbf{K}) would be unknown. In the present case

these matrices are known but are only used to determine the FRF matrix. From the modulus of any element of the inertance matrix (e.g., H_{12} shown in **Figure 7** (thin line) the two resonant peaks are determined at $\omega_{n1} = 364 \text{ rad s}^{-1}$ (58 Hz) and $\omega_{n2} = 931 \text{ rad s}^{-1}$ (148 Hz).

Let us now define a problem of structural modification with the following goal:

- It is required that the FRF modulus of the inertance H_{12} in the bandwith 55–150 Hz should have an upper boundary of $b^U = 1.2 \text{ kg}^{-1}$, as shown in **Figure 7**. This requirement is imposed at discrete frequency points with a frequency step of 1 Hz. Consequently, $N_F = 96$ and $N_E = 1$, so that $N_P = 96 \times 1$.
- It is established that the admissible modifications are an increment of the mass m_2 and an increment of the stiffness k_2 between the two masses. Maximum admissible values are imposed for both variables: they are $m_2 \leq 2 \text{ kg}$ and $k_2 \leq 400,000 \text{ N m}^{-1}$.

The parameters to control are:

$$p_k(\mathbf{z}) = |H_{12}(\mathbf{z}, \omega_k)|_{\omega_k \in [55-150] \text{ Hz}}$$

The proportional marginal cost expression is used with appropriate weights determined in such a way that the cost associated with the maximum values of m_2 and k_2 are comparable and their sum is approximately equal to 1. This implies the values $w_1 = 0.125$, associated with m_2 , and $w_2 = 0.313 \times 10^{-11}$.

Consequently, the inverse problem is formulated as follows.

- Objective function:

$$C(\mathbf{z}) = \sum_{i=1}^2 w_i z_i^2 = 0.125m_2^2 + 0.313 \times 10^{-11}k_2^2$$

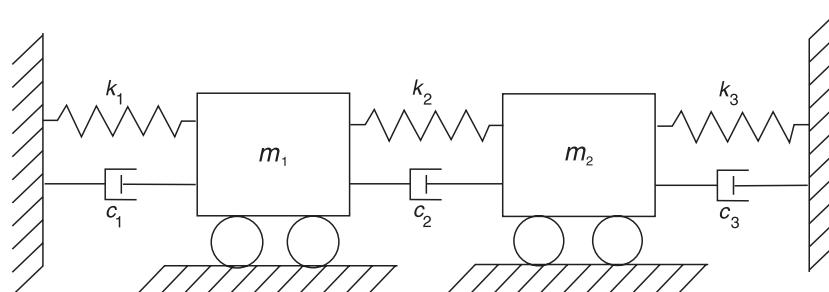

Figure 6 The 2-DOF system.

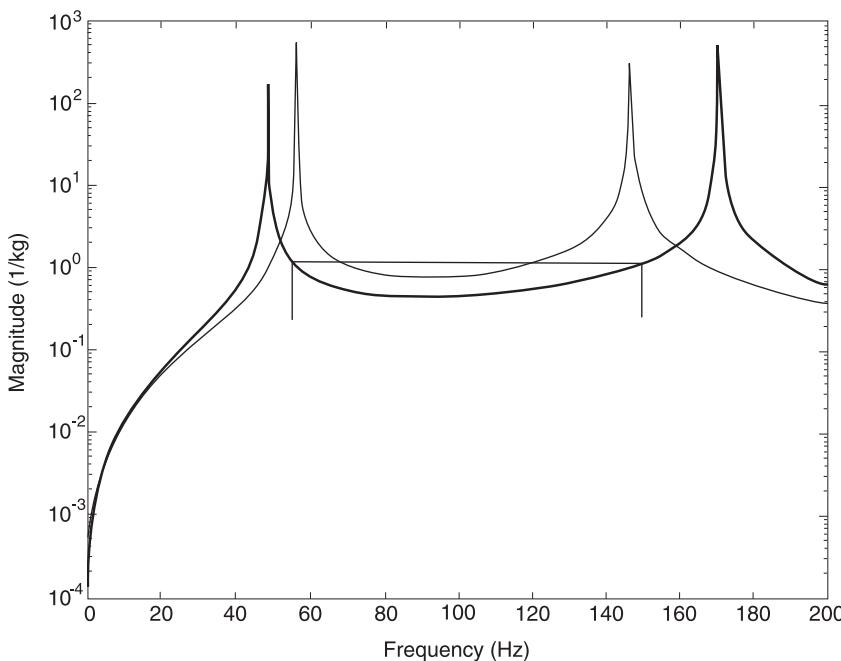

Figure 7 Modification of a 2-DOF system: original (thin line) and modified (thick line).

- Constraints:

$$p_k(m_2, k_2) = |H_{12}(m_2, k_2, \omega_k)|_{\omega_k \in [55-150] \text{ Hz}}$$

$$0 \leq m_2 \leq 2$$

$$0 \leq k_2 \leq 4 \times 10^5$$

Since the problem involves two variables only, a sensitivity analysis is not necessary.

The solution of this problem provides the two optimal values for the mass and the stiffness, i.e., $m_2 = 1 \text{ kg}$ and $k_2 = 300 000 \text{ N m}^{-1}$. With these values the goal of the optimization problem is fully achieved, as can be observed in Figure 7, where the original FRF is compared with the new one (thick line), obtained after modification. It can be observed that the optimal solution implies a shift of the two natural frequencies outside the considered bandwidth.

Engine block The same approach was successfully applied to reduce the vibrations of an internal combustion engine, and thus the noise radiated by its engine block.

Practical considerations show that the engine block is the most appropriate element of the engine to modify, since it is the sole element designed with merely static criteria.

Therefore, experimental tests were performed on the block: 12 points were selected, and the FRF matrix was determined experimentally at and between these points. These were also supposed to

be the points at which to locate the lumped modifications. Among them, only the positions corresponding to the journal bearings were considered not to be amenable to modifications.

In order to reduce the computation burden of the optimization algorithm and to avoid the analysis of points having a poor effect on the considered FRF, a sensitivity analysis with respect to both masses and stiffnesses was performed on the 10 points of the block. It was observed that only six points presented a significant sensitivity either to mass or stiffness variations.

The FRF to change was between the input on the journal and the response on the zone of the block which was vibrating most seriously. The frequency band of interest encompassed the range between 900 and 2000 Hz. In this frequency band, mass modifications are effective to reduce the magnitude $|H|$ of the considered FRF element.

At this point the optimization problem was formulated as follows. Find:

$$\min \sum_{i=1}^6 (z_i)^2 \quad [35]$$

with constraints:

$$|\mathbf{H}(\mathbf{z}, \omega)| \leq b^U = 0.4 \text{ kg}^{-1}$$

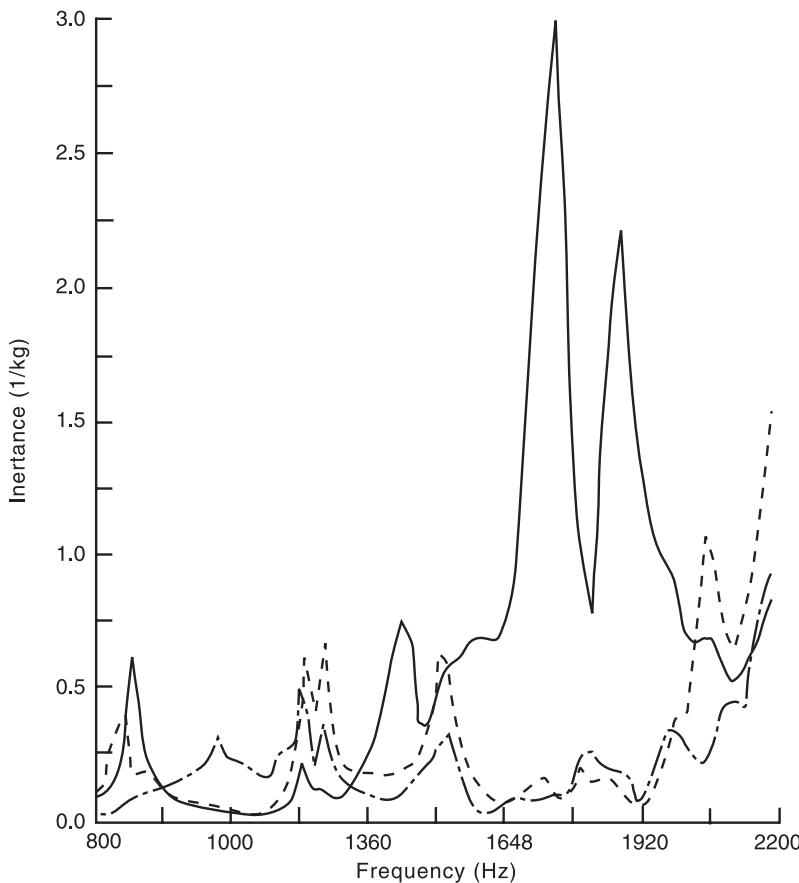

Figure 8 Modification of an engine block. Continuous line, original; dashed line, computed after modification; dots and dashes, measured after modification.

in the frequency band of interest, and boundaries:

$$z_i \geq 0$$

on the optimization variables, corresponding to mass variations only.

In order to check the computed results, the engine block, modified with the prescribed masses determined from optimization, was experimentally tested. Lumped lead masses were bolted on the established positions of the block. Of course, these masses are not the ideal masses used in the computation, so that some changes can be observed in the experimental response with respect to the theoretical one. However, the agreement between the computed modified system and the experimental one is quite satisfactory (Figure 8).

STRUCTURE-ACOUSTIC INTERACTION, HIGH FREQUENCIES

A Sestieri, Università Degli Studi di Roma, Roma, Italy

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0154

In the previous companion paper, it was shown that the structural-acoustic interaction at high frequencies implies short acoustic wavelengths ($\lambda = c/f$) with respect to a typical dimension of the acoustic medium (cavity dimensions or distance between source and observer). Therefore, as the frequency of interest increases, the number of degrees of freedom necessary to solve numerically the problem becomes very large, so that the computational burden is more and more demanding, increasing over convenient or acceptable limits. Moreover, because of inherent uncertainties in the physical and geometrical parameters and in the boundary and joint conditions, the dynamic behavior of a complex system differs unpredictably from those of similar systems when the modal density and modal overlap are high. In this case, there is little possibility of obtaining accurate results, whatever numerical model is used: a statistical rather than a deterministic description would be more appropriate.

Consequently, the numerical solution of the high-frequency structural-acoustic interaction is much more complex than the one discussed for low frequencies, and, in fact, no approach is yet considered reliable for application at a design stage.

The interest in high-frequency problems is not recent: in 1961 a group of scientists – Noiseux, Lyon, Maidanik, Heckl, Smith, and others – met together to discuss how to predict rocket noise and vibrations of launch vehicles, and one year later Lyon and Maidanik published the first systematic work on statistical energy analysis (SEA), presenting a completely new point of view for the solution of vibroacoustic problems, able to estimate the energy flow between vibrating systems, and thus including the interaction between structures and fluids. Since then a long way has been traveled, but SEA is not yet completely accepted, even though, for its statistical character, it describes the dynamic behavior of a population of similar structures rather than a single case.

It is important to stress that, to overcome the limitations related to the large number of degrees of freedom involved, one is required to think through

the high-frequency problem differently, avoiding any approach based on standard discretizations. To this aim, the techniques developed for structural-acoustic interaction at high frequencies try to use, instead of the displacement and/or acoustic pressure, a new field descriptor. Then, new governing equations must be determined, that are expected to be numerically more convenient than the original wave equations. The definition of a new descriptor implies, in general, a solution of lower informative content, but this seems to be the price to pay to solve this complex numerical problem.

In most of the developed methods, the new variable capable of describing both the sound and the structural vibrations is energy. However, the use of this variable introduces some drawbacks that will be discussed in the next sections. In the envelope method the new descriptor is a complex envelope displacement that does not have such problems.

Statistical Energy Analysis

Although recent developments have shown that SEA can be applied to different situations from those originally depicted, in that some basic assumptions seem not to be strictly necessary, SEA is supposed to be a procedure to tackle coupled problems (either fluid-structure systems or coupled structures) with broad-band excitation, capable of inducing a response characterized by several modes. In other words, SEA is a high-frequency approach for studying the interaction between highly resonant systems, as well as the interaction between resonant structures and reverberant sound fields in acoustic cavities. Unlike the deterministic methods based on partial differential equations describing wave propagation in structures and fluids, the SEA equations are simply energy flow relationships among resonant subsystems.

The traditional SEA assumptions are hereafter recalled for a better understanding of the energy relationships between coupled systems.

- The whole system is subdivided into modal groups. The modal groups (subsystems) do not necessarily coincide with a single structure that can sustain bending, longitudinal, and transverse modes, so different sets of modal groups can be generated from a single physical system.

- It is assumed that the coupling between subsystems is linear and conservative.
- The system is excited by broad-band random excitations formed by uncorrelated forces that are statistically independent (rain-on-the-roof excitation).
- It is assumed that the forces induce equipartition of energy within each modal group in a given band of frequencies.

Of course, it is not easy to establish *a priori* whether the above assumptions are satisfied for any system of interest, and this is a weak point of SEA.

Energy Flow Balance Between Two Elementary Oscillators

Together with the previous hypotheses, it is stated that any oscillator in steady-state condition stores potential and kinetic energy, and the time-average power dissipated in a frequency band (usually octave or one-third octave band) is given by:

$$P_d = \omega E \eta_d \quad [1]$$

where E is the time-average energy (sum of potential and kinetic energies) in a frequency band, ω the mean centre frequency of the band and η_d the mean loss factor in the band. This concept is an extension of the power dissipated by a damped oscillator excited harmonically.

Moreover, it is assumed that the time-average energy flow exchange, P_{12} , between two oscillators is proportional to the difference between the total time-average energies of the individual oscillators, i.e.:

$$P_{12} = \alpha(E_1 - E_2) \quad [2]$$

where α depends on the oscillator parameters. This basic relationship, derived rigorously by Lyon, states that the energy flows from the oscillator of higher energy content to the one of lower energy: from this point of view, this law is analogous to thermal conductivity, so that a thermal analogy can be established. Later on, Lyon and Scharton considered an array of equal oscillators, obtaining for them the same relationship.

Power Balance Between Two Modal Groups

Starting from these results, SEA tries to extend the exact relationship between two coupled oscillators to modal groups or sets of oscillators. In this attempt,

the formulation becomes more insidious, making SEA somewhat muddled.

The extension to modal groups imposes that the energy flow between groups of oscillators is not severely affected by other modal groups in the system, a concept that is translated into the requirement of weak modal coupling between the modal subsystems, practically implying that the coupling between subsystems is much lower than the internal forces. Moreover, since a straightforward extension from two oscillators to a set of oscillators can be obtained in terms of vibration modes, in general eqn [2] is rewritten for any two sets of oscillators i and j by introducing the concepts of modal density n (number of modes per unit frequency) and modal energy (E/n), i.e.:

$$P_{ij} = \beta_{ij} \left(\frac{E_i}{n_i} - \frac{E_j}{n_j} \right) \quad [3]$$

where β_{ij} is a new constant depending on the oscillator parameters and modal densities. It is worthwhile emphasizing that, in the present context, E_i is the vibrational physical energy of the i th modal group: for example, if a flexural beam generates only a modal group of bending modes, E_i is the whole flexural energy of the beam. Eqn [3] is the basic equation of SEA, stating that, in the thermal analogy, modal energy is equivalent to temperature.

Since the energy flowing away from system i to system j is similar to a dissipated power, eqn [3] is rewritten in the following form:

$$P_{ij} = \omega E_i \eta_{ij} - \omega E_j \eta_{ji} \quad [4]$$

where the term η_{ij} is the coupling loss factor between system i and system j . By comparing eqns [3] and [4] one has the reciprocity relationship:

$$\frac{\beta_{ij}}{n_i} = \omega \eta_{ij}; \quad \frac{\beta_{ij}}{n_j} = \omega \eta_{ji} \quad \Rightarrow \quad n_i \eta_{ij} = n_j \eta_{ji} \quad [5]$$

that can be conveniently used for determining the coupling loss factor between coupled subsystems.

To derive the power balance equations, consider now the case of Figure 1 which represents two SEA subsystems, each characterized by numerous modes, with the first subsystem excited by an input power P_1^{in} , while $P_2^{in} = 0$. (In a practical situation the first system could be a flexurally excited plate and the second an acoustic room where the plate is suspended somewhere). It is assumed that the subsystems' energies (powers) are averaged in time.

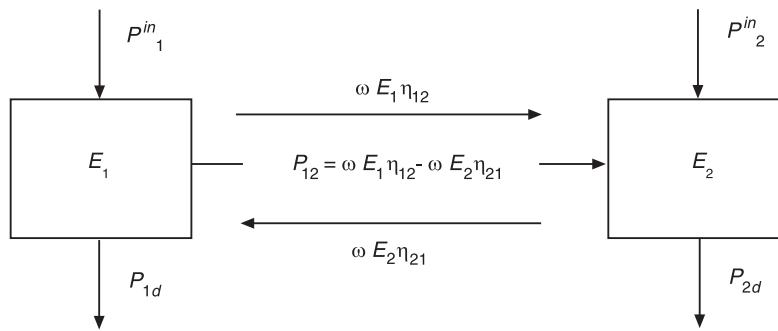

Figure 1 Energy flows between two SEA subsystems.

Using the developments of the previous section, the steady-state power balance between the two subsystems can be written as:

$$\begin{cases} P_1^{in} = \omega E_1 \eta_{d1} + \omega E_1 \eta_{12} - \omega E_2 \eta_{21} \\ 0 = \omega E_2 \eta_{d2} + \omega E_2 \eta_{21} - \omega E_1 \eta_{12} \end{cases} \quad [6]$$

This is a system with unknowns E_1 and E_2 , representing the energies stored in each subsystem. From the second equation the ratio between these energies is given by:

$$\frac{E_2}{E_1} = \frac{\eta_{12}}{\eta_{d2} + \eta_{21}}$$

Note that, if $\eta_{21} \gg \eta_{d2}$, implying that the coupling loss factor is much larger than the loss factor of the second system, from the previous relationship and from eqn [5] one can derive the equality of modal energies, i.e., $E_1/n_1 = E_2/n_2$. Although it is generally difficult to fulfill exactly this condition, the equality of modal energies provides a simple estimate (upper limit) for the response of the whole system.

Extension of the Power Balance to a Set of Oscillators

Under the assumption of weak coupling, the extension of the power balance equations to multiple oscillators is straightforward. For m group of oscillators, m balance equations can be written in the form:

$$P_i^{in} = P_{di} + \sum_{i=1, j \neq i}^m P_{ij}$$

or, in matrix form, using eqn [4]:

$$\mathbf{P} = [\mathbf{A}] \mathbf{E} \quad [7]$$

where \mathbf{P} is the vector of input powers P_i^{in} and \mathbf{E} is the vector of time-average energies E_i .

The off-diagonal and diagonal matrix elements are, respectively:

$$A_{ij} = -\omega n_i \eta_{ij} \quad A_{ii} = \omega n_i \left[n_{di} + \sum_{j=1, j \neq i}^m \eta_{ij} \right]$$

Eqn [7] can be solved for the energies \mathbf{E} to yield:

$$\mathbf{E} = [\mathbf{A}]^{-1} \mathbf{P}$$

Estimate of the Response Parameters

The balance equations provide the values of the energies stored in each modal subsystem. From them the parameters of practical interest can be determined.

For a vibrating structure, the time-average energy doubles the kinetic average energy. In fact, it is:

$$E = T + U = 2 \cdot \frac{1}{2} M \langle v^2 \rangle$$

where M is the total mass of the system and $\langle v^2 \rangle$ the time- and space-averaged mean-square velocity of the vibrating system. Then, one can write:

$$\langle v^2 \rangle = \frac{E}{M}$$

so that the mean-square velocity of the vibrating structure is determined.

For an acoustic cavity, the quantity of interest is the mean-square pressure, averaged in time and space. The energy stored in the acoustic cavity E can be linked to the energy density: $D = \langle p^2 \rangle / \rho c^2$, where ρ is air density and c the speed of sound in air. Therefore one has:

$$E = DV = \frac{<p^2>}{\rho c^2} \Rightarrow <p^2> = \frac{E}{V} \rho c^2$$

Note that the solution of any SEA problem is a unique field value for the whole modal subsystem, so that any local variable distribution along the system is lost.

In Figure 2 the measured third-octave band average sound transmitted from an engine into an automotive compartment is compared with the sound pressure level determined by SEA, together with two curves that would represent the values $\pm 2\sigma$ (σ standard deviation) of the SEA estimate.

Comments on SEA

SEA is supposed to be a statistical approach which is capable of describing the ensemble-average response of a whole population of similar systems rather than the dynamic behavior of a single case. However, it neither determines the ensemble-average response nor provides any kind of variance. Nor is any probabilistic distribution required to solve the problem in SEA terms. Actually, SEA estimates the frequency-average value of the energy response function of archetypal subsystems over frequency intervals (Fahy); the statistical elements of SEA can be recognized in: (1) the possibility of evaluating the modal densities by general descriptors such as the area (volume) of the structural (acoustic) subsystem, without the need to define the actual boundary conditions; (2) the use, as a global descriptor, of the time-average energy that is

phase-independent; and (3) the use of mean quantities averaged in space, thus smoothing away unavoidable uncertainties and space fluctuations.

In this way SEA supplies an efficient and economic tool to analyze complex coupled dynamic systems, provided that its basic assumptions are verified, which is not easy to do *a priori*. However, while the balance equations are quite simple, it can be very troublesome to determine the whole set of parameters which are necessary to solve the problem in SEA terms: loss factors, coupled loss factors, modal densities, etc. Although recent developments based on the wave approach can yield most of these quantities, it is not yet easy to determine either theoretically or experimentally the large amount of input data necessary to solve a SEA problem. Moreover, the input power is never known practically (it depends on both the input excitation and the system response) and its estimate requires the development of mobility computations on equivalent infinite systems.

Finally, SEA provides results of poor informative content, represented by a space-average value on the whole domain of interest.

Notwithstanding these limitations, SEA is today the only approach which is capable of determining the solution of complex vibroacoustic problems at high frequencies, while supplying a quantitative estimate of the energy flows among the source and each subsystem. This is of paramount importance for the control engineer to perform appropriate actions, such as structural modifications on particular transmission paths.

In Figure 3 the energy flows transmitted from the engine source to the automotive compartment through each modal subsystem are shown. It is evident that a primary action should be performed on the fire wall.

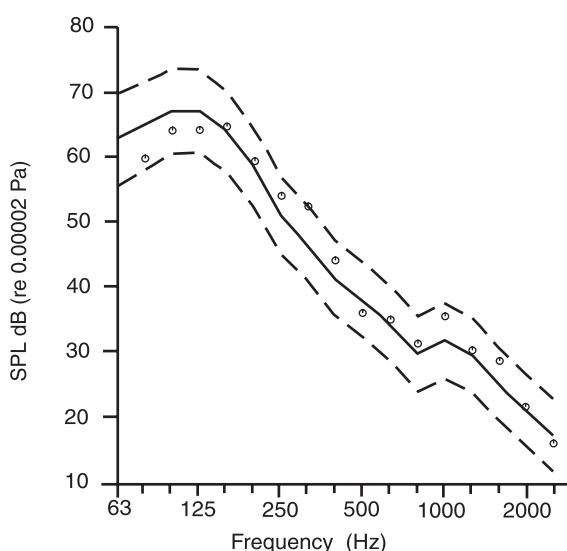

Figure 2 Sound pressure level (SPL) in an automotive compartment. Continuous line, SEA results; circles, measured results.

Alternative Methods to SEA

Although SEA dates from the early 1960s, it was a long journey to the 1990s when renewed interest pushed industrial and academic groups to cooperate to make SEA applicable to practical problems. In the meantime, new approaches were studied and new formulations proposed to provide valid explanations to the SEA assumptions, avoiding the uncertainties of SEA results, obtaining a local distribution rather than overall mean energy, covering the frequency gap between SEA and deterministic methods. This gap concerns the frequency bandwidth where the number of modes is too large for finite or boundary element methods but too low to yield accurate averages for SEA.

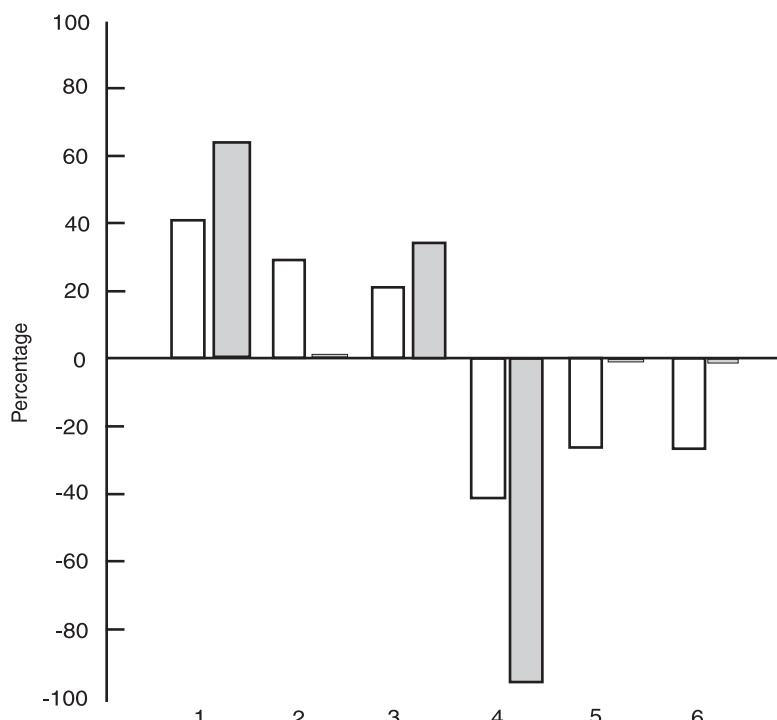

Figure 3 Energy flows into an automotive compartment. + in; – out; open columns, 63 Hz; filled columns, 2000 Hz. 1, Fire wall; 2, roof; 3, floor; 4, absorption; 5, windows; 6, other surfaces.

Among the other methods, asymptotic modal analysis (AMA) by Dowell and Kubota, wave intensity analysis (WIA) by Langley, the mean-value method by Skudrzyk, the thermal analogy methods by different groups of scientists (Nefske-Sung, Bernhard, Le Bot-Jezequel-Ichchou, etc.) and the complex envelope displacement analysis (CEDA) by Carcaterra and Sestieri deserve particular emphasis. Only some will be briefly described here.

Wave Intensity Analysis

WIA is a wave approach describing the high-frequency vibration response of elastic structures. In WIA the displacement field is regarded as a superposition of waves traveling along different directions θ , with proper amplitudes and phases. By assuming that the phase effects can be neglected, implying that the wave components are uncorrelated, the effects of resonances and anti-resonances related to the wave interactions in correspondence to in-phase and out-of-phase waves can be eliminated. From a modal point of view, this corresponds to perform modal averages on the response. When the phase dependence is eliminated, each wave is characterized by an energetic beam, corresponding to the mean energy of the traveling wave.

A power balance equation is consequently written for heading θ of each wave type j in the system that, in

principle, can be solved to yield the wave energies $E_j(\theta, \omega)$. However, in WIA the problem is solved by expanding the angular dependency of the wave energy (the energy beam) into Fourier components, whose coefficients are obtained by a Galérkin procedure. In this way an algebraic linear equation is obtained that provides the unknown energies.

Langley determines a strict relationship between WIA and SEA. In fact, if the series expansion is arrested to the first term, the energy balance exactly provides the conventional SEA equations, i.e., WIA reduces to SEA, so that WIA can be considered a generalization of SEA. Moreover, the energy balance equations of WIA can be cast in the form of conventional SEA by adding nondirect coupling loss factors to circumvent the SEA assumption of diffuse vibrational field, and this can be prevented in the presence of structural joints.

Thermal Methods

Under the name thermal analogy or heat conductivity methods, a set of similar procedures have been identified. They represent an attractive alternative to SEA, able to provide a variable distribution along the structure. The thermal methods are derived by different modal and wave approaches and lead, for steady-state problems, to a parabolic equation that is much more convenient, from a numerical point of view,

than the wave equation governing any coupled problem. In fact, while the wave equation is hyperbolic and its solution is oscillatory in space with wave number increasing with the frequency of excitation, the parabolic thermal equation admits solutions exponentially decaying from the source, without oscillations. Thus, a coarse mesh can be used for the parabolic equation while a fine mesh is required for the wave equation at high frequencies.

The formal development of the thermal method was simply an extension of the SEA algebraic balance equations, which was valid for finite subsystems equipped with modes, into differential terms. Using the same relationship proposed in SEA for the dissipated power, and assuming that elemental volumes within any vibrating elastic medium exchange energy in direct proportion to their energy levels, a local energy balance equation provides:

$$\frac{\partial e}{\partial t} = -\nabla \cdot \mathbf{q} - \Pi_d$$

where e is the energy, \mathbf{q} the intensity vector and Π_d the dissipated power. By the thermal assumption ($q = -\mu \text{grad}(e)$) and considering a stationary process harmonically excited, one obtains the equation:

$$\nabla^2 E - \beta^2 E = 0 \quad [8]$$

where E is the time-average energy.

This is analogous to the heat conductivity equation, as expected, being derived by the same SEA laws, and thus is called thermal analogy. Depending on how the problem is formulated, E is interpreted as local energy, averaged on time and on appropriate frequency bands, or as a local energy averaged in time and space.

Unlike a SEA result, the solution of this equation shows the energy variation along the system. In Figure 4 a typical result for a damped beam is presented.

In a more recent and general procedure developed by Le Bot, Jezequel, Ichchou, and others, the thermal analogy is derived by a wave approach to describe a simplified energy propagation in dynamic systems. In this development it is assumed that no correlation exists between traveling waves. This concept is analytically formulated by assessing that the wave interference among waves propagating along different directions is negligible. Particularly it is assumed that, at high frequencies, the expected value between two wave phasors, associated with two general directions of propagation, $A(\theta_i)$ and $A(\theta_j)$, are uncorrelated, i.e.:

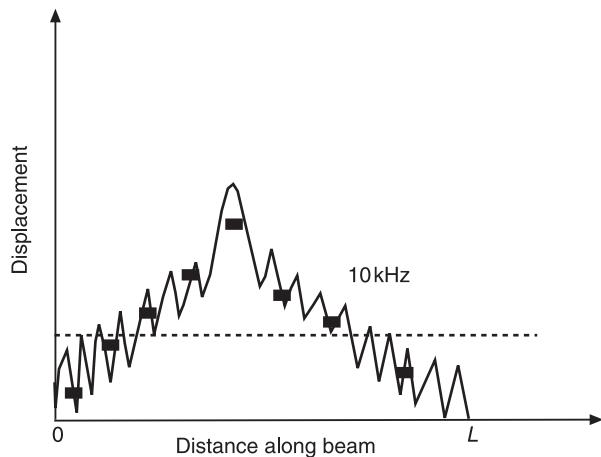

Figure 4 Comparison of a thermal analogy result (squares) with the exact (continuous line) and SEA (dashed line) solution.

$$E\{A(\theta_i)A^*(\theta_j)\} = 0$$

(E here stands for expected value). It is worthwhile pointing out that a similar assumption is introduced by Langley in developing the WIA.

Under this condition, and keeping the simplified assumptions made in the thermal analogy model, i.e.:

1. linear, elastic, dissipative system
2. steady-state conditions with harmonic excitation
3. far from singularities, evanescent waves are neglected

an energy model for symmetrical and nonsymmetrical structures is obtained. Particularly for plane waves the differential power balance equation is written as:

$$-\left(\frac{c_g^2}{\eta\omega}\right)\nabla^2 \langle E \rangle + \eta\omega \langle E \rangle = 0 \quad [9]$$

where c_g is the group velocity of the plane waves, $\langle E \rangle$ the time- and space-average of the energy density, and η the loss factor. One can simply verify that this equation is formally equivalent to the previous thermal equation and, consequently, presents the same numerical character. The solution of this equation is represented by a superposition of incident and reflected energies, whose amplitudes can be determined by boundary and joint energy conditions, involving energy flows that must be properly studied for any end and joint.

Several arguments have been developed in the recent literature to contrast the two derivations of the thermal analogy, and it is shown that both the simple extension of the SEA thermal laws or the possibility of neglecting the wave interference are not strictly correct. However, the results of the heat

conductivity approach are interesting and can be used as an approximate solution in many practical cases.

The Envelope Method

The envelope model tries to circumvent the theoretical limitations of the thermal methods, refusing the thermal analogy, while keeping the positive character of being independent of the frequency of excitation and providing a local description of the field variable. Since, for the envelope method standard procedures and successful applications were so far obtained for one-dimensional systems, we refer here to these simple systems.

The complex envelope displacement analysis can be achieved by a suitable transformation, through the action of an envelope operator \mathbf{S} on the displacement w ; that is:

$$\overleftarrow{w}(x) = \mathbf{S}[w(x)] = [w(x) + j\tilde{w}(x)] e^{-jk_0x} \quad [10]$$

where \overleftarrow{w} represents the complex envelope displacement, j is the imaginary unit, ω_0 the exciting circular frequency, $k_0 = \omega_0/c$ the carrier wave number, and \tilde{w} the Hilbert transform of the physical displacement w . The upper arrow \leftarrow indicates that the envelope variable is obtained by a shift, in the space spectrum, of the analytical signal $(w + j\tilde{w})$ to the left toward the origin of wavenumbers.

By applying the envelope operator to the physical equation of motion of a general undamped structure, described by a self-adjoint differential operator \mathbf{L} , harmonically excited with frequency ω_0 , i.e.:

$$\mathbf{L}[w(x)] + m\omega_0^2 w(x) = g(x)$$

one obtains:

$$\overleftarrow{\mathbf{L}}[\overleftarrow{w}(x)] + m\omega_0^2 \overleftarrow{w}(x) = \overleftarrow{g}(x) = [g(x) + j\tilde{g}(x)] e^{-j_0kx} \quad [11]$$

This equation provides the new governing equation for the envelope displacement, that is formally identical to the equation of motion, provided that the physical displacement, the structural operator, and the external load are substituted by the corresponding envelope terms. $\overleftarrow{\mathbf{L}}$ is the new structural envelope operator defined as $\overleftarrow{\mathbf{L}} = \mathbf{S}\mathbf{L}\mathbf{S}^{-1}$, \mathbf{S}^{-1} being the inverse envelope operator that provides the physical displacement from the complex envelope displacement, i.e.:

$$w(x) = \mathbf{S}^{-1}[\overleftarrow{w}] = \operatorname{Re}\left\{\overleftarrow{w}(x)e^{jk_0x}\right\} \quad [12]$$

Therefore, if necessary, one can recover the physical displacement, once the envelope displacement is obtained. This possibility is denied to any other method that uses the energy as field descriptor (SEA or thermal methods).

Moreover, thanks to eqn [12], the solution of the envelope equation can be obtained by using directly the boundary conditions of the physical problem. Therefore, unlike the thermal method, the boundary and joint conditions can be achieved very easily.

As an example, if one considers the equation of a longitudinal rod ($\mathbf{L} = (\partial^2/\partial x^2)$), i.e.:

$$\frac{\partial^2}{\partial x^2} w(x) + k_0^2 w(x) = g(x)$$

the second-order envelope equation is obtained:

$$\frac{\partial^2}{\partial x^2} \overleftarrow{w}(x) + 2jk_0 \frac{\partial}{\partial x} \overleftarrow{w}(x) = \overleftarrow{g}(x)$$

The envelope operator provides a convenient transformation in the wave number domain. In fact, if the physical displacement is band-limited around the carrier wave number k_0 – a condition that is typically obtained for a point load or for a general uniform load, the complex envelope displacement is band-limited around the wave numbers' origin. To understand this point, consider the wave number spectrum of the physical displacement concentrated in two regions around $\pm k_0$ (Figure 5A). The Fourier transform of the analytic displacement $\hat{w} = (w + j\tilde{w})$ is given by:

$$\hat{W}(k) = W(k) + j\tilde{W}(k) = W(k) + \operatorname{sign}(k)W(k)$$

It has a spectrum with the negative contribution of $W(k)$ deleted, while the positive one is doubled (Figure 5B). Now, by performing the Fourier transform of the complex envelope displacement, one obtains $\overleftarrow{W}(k) = \hat{W}(k + k_0)$, implying a shift of $\hat{W}(k)$ towards the origin of wave numbers (Figure 5C). This situation is very convenient from a numerical point of view. In fact, the Nyquist criterion suggests that a correct sampled signal can be obtained using a sampling frequency (wave number) that doubles, at least, the maximum frequency (wave number) of the signal. While the highest wave number of the physical displacement is $k_0 + \Delta$, the highest wave number of the envelope displacement is just Δ , so that a much lower number of samples can be used for high-frequency excitation.

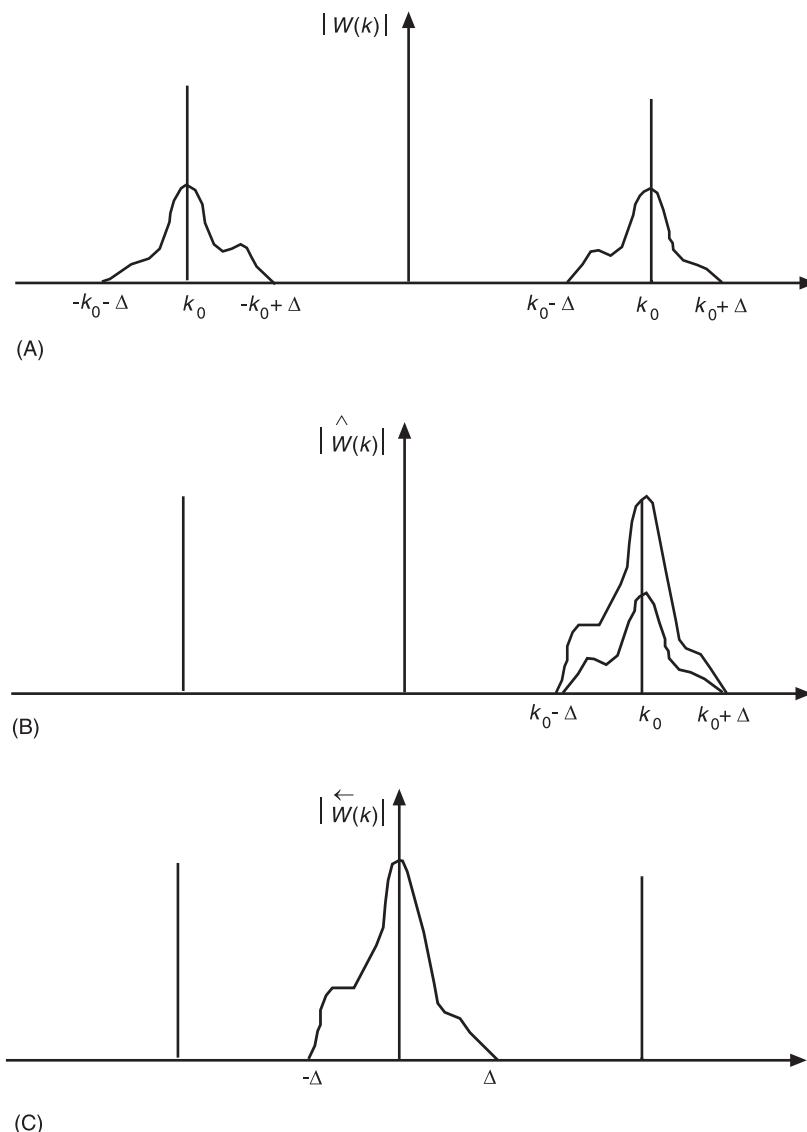

Figure 5 Fourier transform of the physical (A), analytic (B), and complex envelope displacement (C).

Therefore, the rapidly oscillating physical displacement is transformed, by the envelope operator, into a slowly oscillating solution that can be computed by a coarse number of sampled points. Moreover, due to the inverse property of the envelope operator, the physical displacement can be recovered, if required, from the envelope displacement.

Another important character of the CEDA procedure relies on the forcing term of the governing equation. Unlike in SEA or the thermal methods where the input term is the power entering the system, the input term in the envelope equation can be directly determined from the physical load, with inherent advantage.

A typical solution provided by CEDA is compared in Figure 6 with the physical solution. In Figure 7 the solutions of two flexural problems are presented. The

cases of a beam excited by a single point force and by two point forces are respectively considered and the figure shows the comparison between the analytical and CEDA solutions, after reconstruction of the physical displacements.

Nomenclature

c	speed of sound
c_g	group velocity
e	energy
g	external load
\hat{g}	analytic load $g + j\tilde{g}$
\tilde{g}	Hilbert transform of the physical load
\tilde{g}	complex envelope load
k	wave number
m	generalized mass density

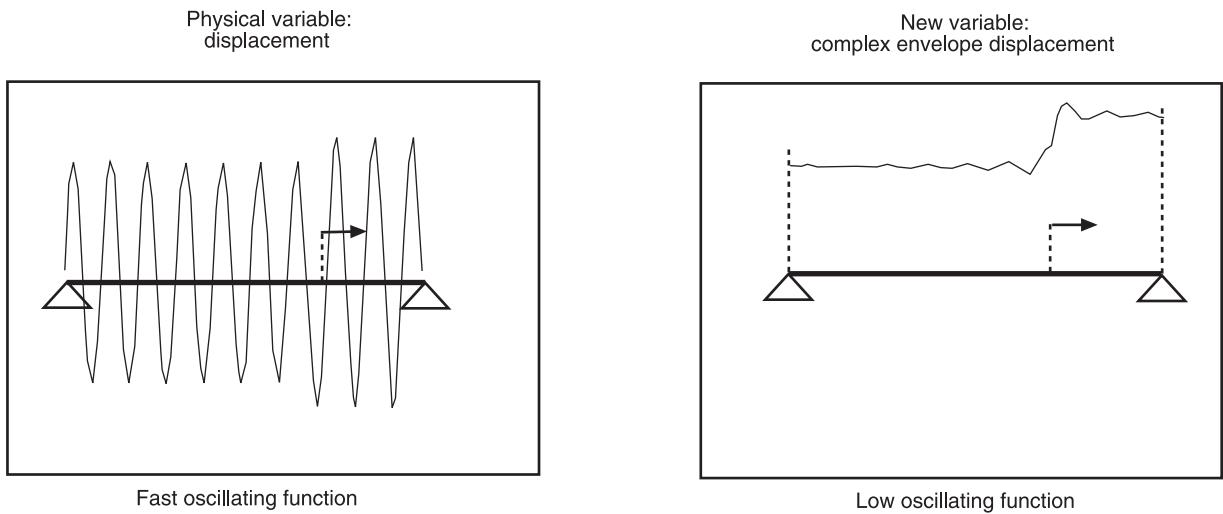

Figure 6 Physical versus CEDA solution of a wave guide.

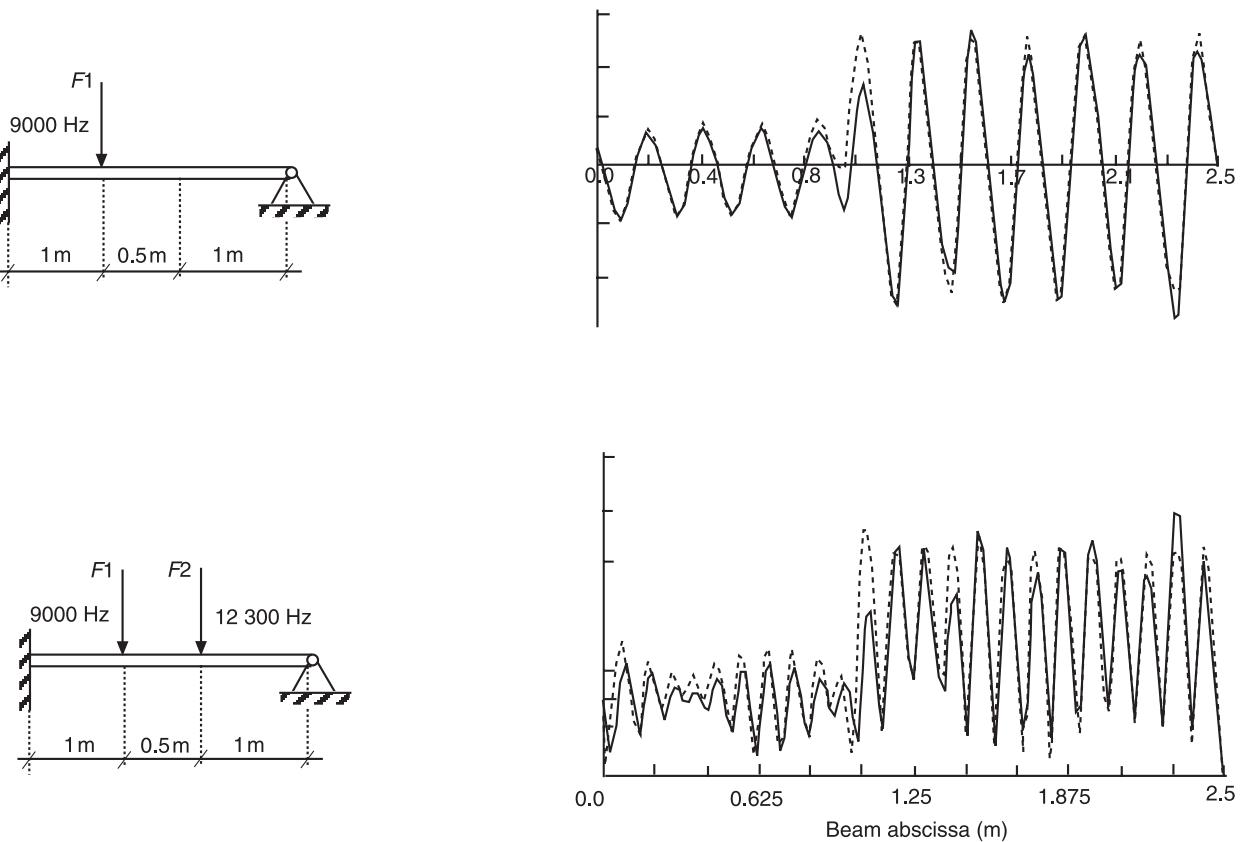

Figure 7 Comparison between the physical (solid line) and recovered solution from CEDA (dashed line) for two flexural beams.

n	modal density
p	acoustic pressure
$\langle p^2 \rangle$	time- and space-averaged mean square pressure
v	velocity
$\langle v^2 \rangle$	time- and space-averaged mean square velocity

w	displacement
\hat{w}	analytic displacement $w + j\tilde{w}$
\tilde{w}	Hilbert transform of the physical displacement
\overleftarrow{w}	complex envelope displacement
\mathbf{q}	intensity vector
D	time-average energy density

E	time-average energy
L	structural operator
\hat{L}	complex envelope of the structural operator
S	envelope operator
P^{in}	time average input power
P_d	time-average dissipated power
P_{ij}	time-average power exchanged between subsystems i and j
T	kinetic energy
U	potential energy
M	mass of the subsystem
W	Fourier transform of the physical displacement
\hat{W}	Fourier transform of the analytic displacement
\tilde{W}	Fourier transform of the Hilbert transform
\overleftarrow{W}	Fourier transform of the complex envelope displacement
η_d	loss factor
η_{ij}	coupling loss factor between subsystems i and j
ω	circular frequency
ω_0	exciting circular frequency
ρ	air density

STRUCTURE-ACOUSTIC INTERACTION, LOW FREQUENCIES

doi:10.1006/rwvb.2001.0153

An important effect of vibrations is that of producing sound, although sound can also be generated by other mechanisms such as density fluctuations of nonstationary flows (turbulence, jets, etc.) and heat. Depending on whether the sound is considered pleasant or not, it is called music or noise.

The subject of vibroacoustics is the interaction between structural motion and acoustic field. As such it involves a large range of frequencies, i.e., the bandwidth 20–20 000 Hz of human hearing. In dealing with vibroacoustics, where analytical solutions are generally not available, either an external or internal problem is considered and, for each, a low-, medium-, and high-frequency range is studied differ-

ently. The need for this subdivision relies on different approaches that are used for the numerical solution of each problem: the external problem is related to an infinite medium, typically characterized by fluid wave propagation, while the internal one is commonly described by acoustic eigenmodes or stationary waves. The numerical solution of an external problem is generally more demanding than an internal one if a traditional discretization of the acoustic medium is used, because it is necessary to discretize the whole region between the source and the receiver. The internal problem, especially when related to transportation vehicles, concerns relatively small cavities and, thus, a more limited number of degrees of freedom than the external problem.

With respect to frequencies, the low region involves large wavelengths ($\lambda = c/f$, where λ is the wavelength, c the speed of sound in the medium, and f the frequency considered), while the opposite is

expected for high frequencies. From a numerical point of view, large wavelengths imply a coarse discretization while short wavelengths demand fine meshes. Evidently a strict border among low, medium, and high frequencies does not exist, in that these regions are related to the ratio between the dimensions of the acoustic domain and the involved structural-acoustic wavelengths.

In this article the low-frequency problem is considered, while the companion article **Structure-acoustic interaction, high frequencies** describes the high-frequency case.

The wave and modal approaches to the problem are developed here, together with the most common numerical techniques related to them, i.e., the finite element method and the boundary integral methods. The ray approach is not considered because it cannot account for the interaction between vibrating structures and fluid, while it is frequently used for the design of large rooms, such as auditoriums and concert halls.

Acoustic Waves

The linearized wave equation, describing the propagation of small perturbations in a homogeneous, inviscid, and compressible fluid, is obtained by combining together the continuity equation, the momentum equation, and the elastic properties of the fluid. They are, respectively:

$$\begin{aligned}\frac{\partial p}{\partial t} + \rho_0 \operatorname{div} \mathbf{u} &= 0 \\ \rho_0 \frac{\partial \mathbf{u}}{\partial t} + \operatorname{grad} p &= 0 \\ \frac{\partial p}{\partial \rho} &= c^2\end{aligned}$$

the last being valid for an adiabatic transformation, ρ is the fluid density (ρ_0 undisturbed), \mathbf{u} the vector of components u_x , u_y , and u_z , representing the fluid particle velocity, p the acoustic pressure (varying with respect to the undisturbed pressure) and c , the speed of sound.

By combining together these equations one obtains the three-dimensional wave equation:

$$\nabla^2 p - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0$$

When dealing with steady-state problems, the Helmholtz equation is obtained from this by considering a harmonic time dependence of p , i.e.:

$$\nabla^2 p + k^2 p = 0 \quad [1]$$

where $p = p(x, y, z, w)$ and $k = \omega/c$ is the fluid wave number.

The solution of the Helmholtz equation can be specified for different problems, by imposing appropriate boundary conditions. Assuming harmonic motion, the momentum equation provides directly a relationship between the pressure gradient and the fluid particle velocities: in particular the normal velocity of a vibrating surface determines the pressure gradient on the surface, due to the compatibility condition of normal velocities at the fluid-structure interface. For example, assuming the surface on the plane xz vibrating with velocity u_y , one has:

$$\left. \frac{\partial p}{\partial y} \right|_{y=0} = -j\omega\rho_0 u_y \Big|_{y=0}$$

This is the type of condition used in problems of sound radiation to describe vibrating, reflecting, or absorbing surfaces. In particular, by indicating with \mathbf{n} the unit normal vector outward to the surface, one has:

1. for rigid surfaces (totally reflecting):

$$\frac{\partial p}{\partial n} = 0$$

2. for vibrating surfaces with velocity v (displacement w):

$$\frac{\partial p}{\partial n} = -j\omega\rho_0 v = \rho_0\omega^2 w$$

3. for absorbing surfaces:

$$\frac{\partial p}{\partial n} = -\frac{j\omega\rho_0 p}{Z_A}$$

where Z_A is the specific acoustic impedance of the absorbing material (which is known).

Note that \mathbf{n} has a different orientation depending on whether an internal or external acoustic problem is considered (see Figure 1)

Interaction Between Sound Waves and Vibrating Structures

While fluids can only sustain compressional waves, solids can store energy in shear and compression.

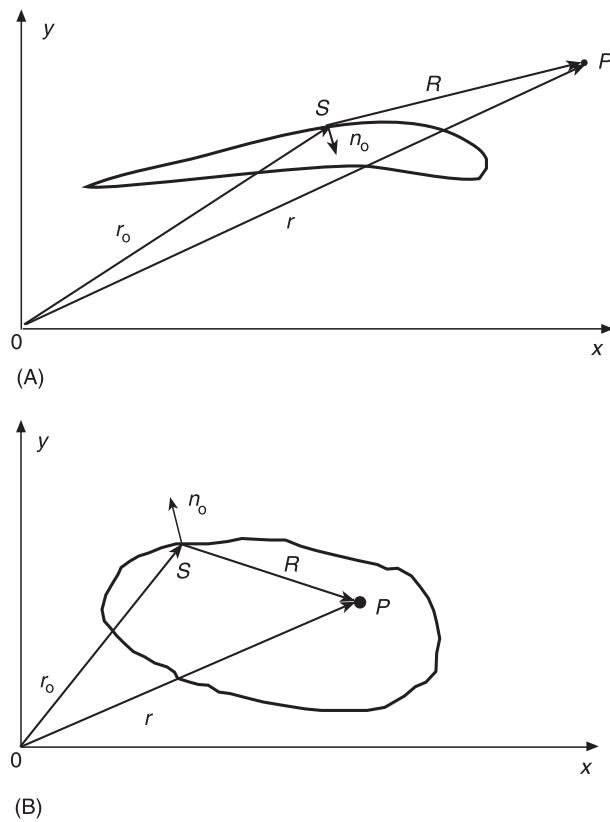

Figure 1 Source and observation points in (A) the external and (B) internal problem.

However, an effective exchange of energy between structure and fluid is only generated from structural flexural waves, because it is only in this case that the structural particle velocities are orthogonal to the direction of the fluid wave propagation.

In general, the fluid-structure interaction implies the contemporary solution of the equations governing both the structural and acoustic phenomena. In fact the (flexural) vibrating structure generates fluctuating pressures in the fluid, so that the Helmholtz equation must be solved with suitable boundary conditions specifying the motion of the vibrating surfaces. On the other hand, especially if the fluid is a liquid, the pressure produced in the fluid can significantly affect the structural motion and, in this case, a full coupled analysis is necessary, i.e., one should load the structure with the external exciting pressure and the acoustic pressure generated in the fluid.

However, if the fluid is air, as in most of structural-acoustic interaction problems, this requirement is not compulsory because the acoustic pressure is not sufficient to modify the structural motion. In this case only the effect of the vibrating surface on the acoustic medium must be considered, disregarding fluid-load-ing effects: therefore, first the structural problem

excited by the external load is solved and then the structural solution is used as a boundary condition for the acoustic problem.

Numerical Solution of Vibroacoustic Problems

The great advantage of an analytical solution is the possibility of having a direct dependence of the solution on the physical parameters. On the other hand, in most cases an analytical solution is not available due to the complexity of geometrical, kinematic, and dynamic conditions.

The problems of practical interest in vibroacoustics can be divided into two main categories:

1. analysis of free and forced vibration of the fluid in a cavity
2. analysis of the acoustic field in an infinite medium, induced by vibrating surfaces

In any numerical analysis, the field variables that are continuous in the region of the elastic medium are represented by their values at discrete points in space (discretization), together with shape functions, providing an interpolation of the field parameters among these points.

The numerical analysis of sound fields in closed spaces (internal problem) at low frequencies is generally developed by the finite element method, as in the case of the structural problem.

For infinite regions, and often even for internal problems, the finite element method is not appropriate, and it is convenient to develop a boundary formulation that, from the Helmholtz differential equation, produces an integral equation. This equation is then solved numerically by the boundary element method or by Succi's method.

The Finite Element Method

The finite element method can be applied to any physical problem described by partial differential equations. This approach is widely described in other sections (**Finite element methods**; **Object oriented programming in FE analysis**; **Damping in FE models**). Consequently, only a brief summary will be presented here with some notes on the acoustic problem.

In the finite element method the space is divided into contiguous finite elements of appropriate shape, whose dimensions must be lower than the wavelength of the involved wave at the highest frequency of interest. At the element nodes suitable degrees of freedom are defined. They are the values of the field

variables at the nodes and, when they are needed to define the problem fully, their spatial derivatives, as in the case of the flexural vibrations of beams, where at each node both displacement and rotation must be considered.

For the analysis of structural or fluid vibrations, as well as for their interaction, the Lagrange equations are used. The potential and kinetic energies associated with each element can be expressed in terms of the nodal variables, provided that the distribution of the field variables among the nodal points is appropriately assumed. The spatial distribution of the field variables (shape functions) must be defined in a way that is simple, yet capable of satisfying continuity conditions at the nodes. Depending on the problem considered, an appropriate function is associated with each degree of freedom and put in a vector $\mathbf{f}(\mathbf{x})$ of shape functions.

For a general structure excited by a distributed load \bar{g} , the independent variables at each node of an element are defined and put in an element vector \mathbf{q}_e , so that, by means of the shape functions, one can write the general field variable (e.g., $w(\mathbf{x})$) as:

$$w(\mathbf{x}) = \mathbf{f}(\mathbf{x})^T \mathbf{q}_e \quad [2]$$

where $\mathbf{x} = xi + yj + zk$.

The potential and kinetic energies of each element of the general structure are given by:

$$U_e = \frac{1}{2} \int_D \boldsymbol{\sigma}^T \boldsymbol{\varepsilon} dD \quad T_e = \frac{1}{2} \int_D m(\mathbf{x}) \dot{w}^2 dD$$

where $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are the stress and strain tensors, respectively, m is the mass per unit volume of the structure and D the structural domain. Both $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ can be expressed in terms of the nodal variables by using the strain and elasticity matrices:

$$\boldsymbol{\varepsilon} = \mathbf{B} \mathbf{q}_e \quad \boldsymbol{\sigma} = \mathbf{D} \boldsymbol{\varepsilon} = \mathbf{D} \mathbf{B} \mathbf{q}_e$$

where \mathbf{B} depends on the shape functions. This permits the energies and the generalized force vector to be expressed in terms of the assumed degrees of freedom, i.e.:

$$U_e = \frac{1}{2} \mathbf{q}_e^T \mathbf{K}_e \mathbf{q}_e \quad T_e = \frac{1}{2} \dot{\mathbf{q}}_e^T \mathbf{M}_e \dot{\mathbf{q}}_e \quad \mathbf{F}_e = - \int_D \mathbf{f}^T \bar{g} dD$$

where:

$$\mathbf{K}_e = \int_D \mathbf{B}^T \mathbf{D} \mathbf{B} dD \quad \mathbf{M}_e = \int_D m(\mathbf{x}) \mathbf{f} \mathbf{f}^T dD$$

are the symmetric stiffness and mass matrices of the element, respectively. By means of the element matrices, the matrices of the assembled system can be determined by sum, after the definition of a dummy matrix linking together the degrees of freedom \mathbf{q}_e of each element with the degrees of freedom \mathbf{q}_s of the whole system, i.e.:

$$\mathbf{q}_e = \mathbf{C}_e \mathbf{q}_s$$

Therefore the potential and kinetic energies of the whole system can be written as:

$$U = \frac{1}{2} \mathbf{q}_s^T \mathbf{K} \mathbf{q}_s \quad T = \frac{1}{2} \dot{\mathbf{q}}_s^T \mathbf{M} \dot{\mathbf{q}}_s$$

where \mathbf{K} and \mathbf{M} are the stiffness and mass matrices of the assembled system. They are respectively:

$$\mathbf{K} = \sum_{e=1}^n \mathbf{C}_e^T \mathbf{K}_e \mathbf{C}_e \quad \mathbf{M} = \sum_{e=1}^n \mathbf{C}_e^T \mathbf{M}_e \mathbf{C}_e$$

By applying the Lagrange equation, the discretized equation of motion is obtained:

$$\mathbf{M} \ddot{\mathbf{q}}_s + \mathbf{K} \mathbf{q}_s = \mathbf{F} \quad [3]$$

where \mathbf{F} is the generalized force vector ($= \sum_e \mathbf{F}_e$). Finally, the geometrical boundary conditions must be imposed. Now the discrete problem can be solved by a classical modal analysis or numerical integration.

The extension of the finite element method to the acoustic (internal) problem is straightforward.

The potential and kinetic energies of an acoustic field element V_e are given by:

$$U_e = \frac{1}{2} \int_{V_e} p^2 / \rho c^2 dV_e \quad [4]$$

$$T_e = \frac{1}{2} \rho_0 \int_{V_e} |\mathbf{u}|^2 dV_e$$

where p is the acoustic pressure, $p^2 / \rho c^2$ the energy density, c the speed of sound, and $\mathbf{u} = u_x \mathbf{i} + u_y \mathbf{j} + u_z \mathbf{k}$ the velocity of the air particles. It is convenient to rewrite both of these energies in terms of the same field variable (either pressure or velocity). Pressure is the most suitable because it is a

scalar. Therefore, by considering a harmonic problem, T can be transformed by means of the momentum equation to yield:

$$T_e = \frac{1}{2\rho_0\omega^2} \int_{V_e} \left[\left(\frac{\partial p}{\partial x} \right)^2 + \left(\frac{\partial p}{\partial y} \right)^2 + \left(\frac{\partial p}{\partial z} \right)^2 \right] dV_e$$

From this point on, the finite element formulation of the acoustic problem follows the steps shown for the structure, leading to an equation analogous to eqn [3].

For a coupled structural-acoustic problem, the energies can be written as the sum of the energies of the whole dynamic system. However, since a full coupling is usually not necessary, the structural problem is separated from the acoustic one; the result of the structural problem is used as boundary condition for the acoustic field.

Boundary Integral Formulation for the Structural-Acoustic Problem

The Helmholtz differential equation can be transformed into an integral equation (Kirchoff-Helmholtz), with inherent advantages in solving the coupled problem.

To pass from the differential to the integral form, the Green function must be used. First we will speak about the free-space Green function leading to the boundary element formulation and then the cavity Green function leading to the Succi method.

The free-space Green function $G_\infty(r/r_0)$ for the Helmholtz equation is the solution of the equation:

$$\begin{aligned} \nabla^2 G_\infty(r/r_0) + k^2 G_\infty(r/r_0) \\ = -\delta(r - r_0) \end{aligned} \quad [5]$$

satisfying the Sommerfeld condition at infinity that prevents reflected waves, because of the lack of reflecting surfaces at infinity. r and r_0 are the distances, from the origin of a reference frame, of the observer P and the source S , respectively (Figure 1). δ is Dirac's delta function, representing a point source in the space, located in r_0 . In practice, Green's function is a particular solution of the Helmholtz equation forced by a point source. It can be demonstrated that the free-space Green function for the three-dimensional Helmholtz problem is:

$$G_\infty = \frac{1}{4\pi R} e^{-jkR} \quad [6]$$

where $R = |r - r_0|$ is the distance between source and receiver. Note that G_∞ and $\delta(r - r_0)$ are symmetric when source (r_0) and receiver (r) are interchanged.

To show the utility of the Green function, consider the Helmholtz eqn [1]. By multiplying eqn [5] by p and eqn [1] by $G_\infty(r/r_0)$, and subtracting, one obtains:

$$\begin{aligned} G_\infty(r/r_0) \nabla^2 p(r) - p(r) \nabla^2 G_\infty(r/r_0) \\ = p(r) \delta(r - r_0) \end{aligned}$$

By integrating on the fluid medium V , exchanging r and r_0 , and recalling the symmetry property of G and δ , one has:

$$\begin{aligned} \int_V [G_\infty(r/r_0) \nabla_0^2 p(r_0) - p(r_0) \nabla_0^2 G_\infty(r/r_0)] dV \\ = \int_V p(r_0) \delta(r - r_0) dV \end{aligned}$$

where the subscript 0 denotes derivation with respect to the coordinates x_0, y_0 and z_0 of the source. Using Green's theorem, the first integral on the volume becomes an integral over the boundary surface of the fluid, thus:

$$\begin{aligned} p(r) = \int_{S_0} \left[G_\infty(r/r_0) \frac{\partial}{\partial n_0} p(r_0) \right. \\ \left. - p(r_0) \frac{\partial}{\partial n_0} G_\infty(r/r_0) \right] dS_0 \end{aligned} \quad [7]$$

where $r_0 \in S_0, r \in V$. Any possible condition on the surfaces can be stated by imposing the boundary conditions through $\partial p / \partial n$. This integral equation provides the value of the pressure $p(r)$ in any point of the fluid medium, as a function of the pressure $p(r_0)$ on the surface. n_0 is the normal outward to the surface at the source point (Figure 1). Since $G_\infty(r/r_0)$ is the pressure value in r produced by a point source in r_0 , eqn [7] states that the pressure field in r is just the sum of the pressures produced by all the elementary sources located on the vibrating surface.

Unfortunately, the problem cannot be solved in this form because neither the surface pressure $p(r_0)$ nor the pressure at the observation point $p(r)$ is known.

To circumvent this drawback, let the observation point P tend to the surface, so that this point becomes a point on the surface. Then the problem has a single unknown, the pressure distribution on the surface $p(r_0)$, and the integral equation can be solved.

However it must be stressed that, when r tends to the surface, the integrals in eqn [7] become singular for $r \equiv r_0$. It is then necessary to determine the limit of the integrals computed on a surface that excludes a small area around the singular point. This can be done by means of the Gauss integral, and it can be shown that this yields the new equation:

$$\frac{1}{2}p(r_0) = - \int_S \left[p(r_0) \frac{\partial}{\partial n_0} \left(\frac{e^{-jkR}}{4\pi R} \right) - \frac{e^{-jkR}}{4\pi R} \frac{\partial p}{\partial n_0} \right] dS_0 \quad [8]$$

where the explicit expression [6] of the free-space Green function is written instead of G_∞ .

In general, the constant that multiplies $p(r_0)$ on the left-hand side is $\beta(r_0)/4\pi$, where β is the solid angle at the point r_0 . If the tangent plane exists in r_0 , $\beta = 2\pi$ and the constant is just $\frac{1}{2}$ as in the considered equation.

Eqn [8] is the fundamental equation of the integral formulation. It can be solved after having determined the vibrating velocity on the surface. Once $p(r_0)$ is known, eqn [7] can be used to determine the pressure at any point of the external field, by the simple solution of an algebraic problem.

Solution of the External Problem: The Boundary Element Method

For an external problem – the case of a vibrating surface in an infinite medium – the free-space Green function must be used and eqn [8] must be solved with the boundary conditions expressed by $\partial p / \partial n = -j\omega\rho_0 v_n(r_0)$, where $v_n(r_0)$ is the normal velocity at any point of the surface, determined, for example, by a finite element method.

It is obvious that, in general, the integral eqn [8] can be tackled only numerically: the corresponding approach is called boundary element method. To this aim the vibrating surface is subdivided into surface elements of suitable dimensions, depending on the maximum frequency of analysis, as in the finite element method. The field variables can be described by appropriate shape functions: however, for the acoustic problem, a zeroth-order approximation can be used, i.e., the field variables (pressure and velocity) can be assumed constant on each element, thus obtaining a piecewise constant variation of the variables along the surface elements.

By dividing the vibrating surface in such a way, the integral equation can be substituted by the following algebraic problem:

$$\begin{aligned} p_k + \frac{1}{2\pi} \sum_{i=1}^n p_i \int_{S_i} \frac{\partial}{\partial n_{0_i}} \left(\frac{e^{-jkR_i}}{R_i} \right) dS_i \\ = -\frac{1}{2\pi} \sum_{i=1}^n j\omega\rho_0 v_{n_i} \int_{S_i} \frac{e^{-jkR_i}}{R_i} dS_i \quad k = 1, 2, \dots, n \end{aligned} \quad [9]$$

where the right-hand side term is known. S_i is the surface of the i th boundary element, n_{0_i} is the normal outward to the i th surface element and R_i is the distance between the k th element and any other element i of the surface (k observation point). This is now an algebraic system $n \times n$, n being the number of boundary elements, that provides the pressure value on each boundary element. This equation can be written in matrix form as follows:

$$\mathbf{p}(\omega) + \mathbf{T}(\omega)\mathbf{p}(\omega) = \mathbf{f}(\omega)$$

i.e.:

$$[\mathbf{I} + \mathbf{T}(\omega)]\mathbf{p}(\omega) = \mathbf{f}(\omega)$$

with the symbols having obvious meaning. Note that both the matrix \mathbf{T} (i.e., the coefficient matrix accounting for the integrals on the left-hand side) and the vector \mathbf{f} (expliciting the integrals on the right-hand side) depend on ω , which implies a recomputation of the integrals in eqn [9] every time ω changes, and this is rather time-consuming.

Solution of the Internal Problem

The internal problem implies the computation of the acoustic pressure in a cavity in which some (or all) surfaces vibrate and radiate sound inward. Only the internal field is considered. Here two different numerical approaches are possible.

The Boundary Element Method

The formulation is analogous to the external problem, and the same free-space Green function G_∞ can be used, because reflecting waves are superimposed on the outgoing waves by making explicit the corresponding boundary conditions of the cavity's surfaces. First, the problem is solved on the cavity's surface, then, the acoustic pressure in the cavity is determined as a function of the surface pressures.

However, for the internal problem, instead of using the free-space Green function, it is more convenient to use the real part of G_∞ , i.e.:

$$G_R(r/r_0) = \frac{1}{4\pi R} \cos kR$$

In fact, for the internal problem the imaginary part of G_∞ is not influential, i.e., no information derives from its contribution to the integral formulation. The main advantage of this form of Green function is the following: when using G_R , the harmonic parts of G_R and its derivative:

$$\begin{aligned}\frac{\partial G_R}{\partial n} = & -\frac{1}{4\pi R^2} \cos kR \cdot \cos n\widehat{R} \\ & -\frac{1}{4\pi R} \sin kR \cdot \cos n\widehat{R}\end{aligned}$$

do not change appreciably in the integrals of eqn [9] with varying ω : therefore it is possible to carry out the harmonic parts from the integrals and compute the integrals only once. In this way, the time computation can be noticeably reduced. This choice cannot be used for G_∞ because the phases of the resulting pressure are greatly affected by this approximation.

The Succi Method

For the internal problem the possibility exists of using another form of Green function, the cavity Green function, that is obtained from eqn [3] with the boundary conditions on the cavity surfaces.

The most important difference between the acoustic pressure in a cavity and in an infinite medium is the existence, for the closed space, of acoustic modes associated with natural frequencies, as in the case of structures. They are the effect of interference between propagation waves that give rise to stationary waves. Therefore, the fluid in a cavity exhibits a resonant behavior, whose effect is that of producing a large response in correspondence to the natural acoustic frequencies.

The cavity Green function can be expressed in terms of the acoustic modes and natural frequencies (or natural wave numbers), as follows:

$$G_c(r/r_0) = \sum_n \frac{\Psi_n(r)\Psi_n(r_0)}{\Lambda_n(k_n^2 - k^2)} \quad [10]$$

where n is the number of acoustic modes $\Psi_n(r)$, $k = \omega/c$, $k_n = \omega_n/c$ are the natural wave numbers, and Λ_n is a normalization factor for the acoustic eigenfunctions, i.e.:

$$\int_V \Psi_m(r)\Psi_n(r) dV = \delta_{mn}\Lambda_n \quad [11]$$

where δ_{mn} is the Kronecker delta ($\delta_{mn} = 1$ for $m = n$, $\delta_{mn} = 0$ for $m \neq n$).

If, for a cavity of any shape, we know the acoustic modes and natural wave numbers, the problem would be immediately solved because p could be obtained by series expansion of the known eigenfunctions. Unfortunately, for any complex cavity, the computation of its eigenparameters can only be achieved numerically.

Therefore, in Succi's method, the given cavity (e.g., an automobile compartment) is enclosed in a simpler

cavity whose eigenfunctions are known, e.g., a rectangular volume with rigid surfaces (Figure 2).

The eigenfunctions of this cavity are given by:

$$\begin{aligned}\Psi_i(x, y, z) &= \Psi_{nmp}(x, y, z) \\ &= \cos \frac{n\pi x}{a} \cos \frac{m\pi y}{b} \cos \frac{p\pi z}{c}\end{aligned}$$

where Ψ_i replaces Ψ_{nmp} for the sake of simplicity.

By using the expansion theorem, we can express approximately the acoustic pressure of the automobile cabin by the eigenfunctions of the rectangular volume, i.e.:

$$p(r) = \sum_n b_n \Psi_n(r) \quad [12]$$

Of course, depending on the shape of the cavity, the number of eigenfunctions used is generally higher (or much higher) than those which are strictly necessary if the true eigenfunctions of the cavity are used.

By this approximation, both the eigenvalue problem of the unknown cavity and the forced problem can be solved.

In practice, Succi's method is a Rayleigh–Ritz-type method where particularly simple admissible functions are used.

Eigenvalue problem for determining the eigenparameters of the complex cavity Starting from the integral eqn [7] with G_c written instead of G_∞ , we wish to determine the eigenvalues and eigenfunctions of the cabin with rigid surfaces. In such a case, since $\partial p / \partial n = 0$, eqn [7] becomes:

$$p(r) = - \int_{S_0} p(r_0) \frac{\partial G_c(r/r_0)}{\partial n_0} dS_0$$

where S_0 is the automotive surface.

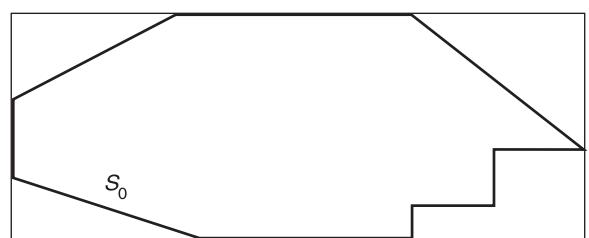

Figure 2 Automobile cabin enclosed in a rectangular volume.

By the approximation [12], this equation is transformed into the following form:

$$\sum_n b_n \Psi_n(r) = - \int_{S_0} \sum_m b_m \Psi_m(r_0) \sum_n \frac{\Psi_n(r)(\partial\Psi_n(r_0)/\partial n_0)}{\Lambda_n(k_n^2 - k^2)} dS_0$$

Since r is not on the surface, $\Psi_n(r)$ can be carried out from the integral:

$$\sum_n b_n \Psi_n(r) = \sum_m \sum_n \frac{b_m \Psi_n(r)}{\Lambda_n(k^2 - k_n^2)} \int_{S_0} \Psi_m(r_0) \frac{\partial\Psi_n(r_0)}{\partial n_0} dS_0$$

By computing the integral on the right-hand side (that can be put in a matrix whose elements are P_{mn}), remembering the normalization condition for the eigenmodes of the rectangular volume [11], and multiplying the previous equation by $\Psi_i(r)$ ($i = 1, 2, \dots, n$), one obtains, after integrating over the volume V of the rectangular cavity:

$$\Lambda_n(k^2 - k_n^2) b_n = \sum_m b_m P_{mn}$$

or, in matrix form:

$$[P_{mn} + \Lambda_m(k_m^2 - k^2) \delta_{mn}] \mathbf{b} = 0 \quad [13]$$

In this equation the k_m are known, being the eigenvalues of the rectangular volume. k are the natural wave numbers of the automotive cabin, while \mathbf{b} are the corresponding eigenvectors. Therefore, by solving this problem, the acoustic natural frequencies and the acoustic modes of the cavity are easily determined.

Forced problem In the forced problem, we assume that the cavity surface S_0 has a surface S_v harmonically vibrating with circular frequency ω , and an absorbing surface S_a (Figure 3). Under these conditions, eqn [7] reads:

$$p(r) = - \int_{S_0} p(r_0) \frac{\partial G_c}{\partial n_0} dS - \int_{S_v} (j\omega\rho_0 v_n) G_c dS_v - \int_{S_a} \frac{j\omega\rho p}{Z_A} p(r_0) G_c dS_a$$

By using the approximation [12], one has:

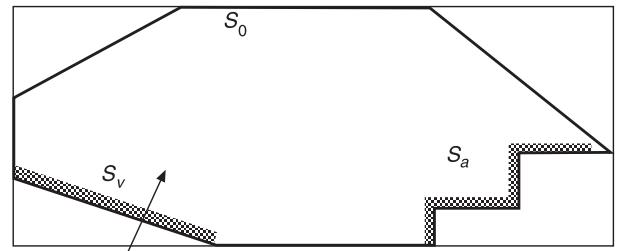

Figure 3 Automobile cabin with vibrating, absorbing, and rigid surfaces.

$$\begin{aligned} & \sum_n b_n \Psi_n(r) \\ &= - \int_{S_0} \sum_m b_m \Psi_m(r_0) \sum_n \frac{\Psi_n(r)(\partial\Psi_n(r_0)/\partial n_0)}{\Lambda_n(k_n^2 - k^2)} dS \\ &\quad - \int_{S_v} \sum_m \frac{\Psi_m(r)\Psi_m(r_0)}{\Lambda_m(k_m^2 - k^2)} (j\omega\rho_0 v_n) dS_v \\ &\quad - \int_{S_a} \frac{j\omega\rho_0}{Z_A} \sum_m b_m \Psi_m(r_0) \sum_n \frac{\Psi_n(r)\Psi_n(r_0)}{\Lambda_n(k_n^2 - k^2)} dS_a \end{aligned}$$

i.e.:

$$\begin{aligned} \sum_n b_n \Psi_n(r) &= \sum_m \sum_n \frac{b_m \Psi_n(r)}{\Lambda_n(k^2 - k_n^2)} \\ &\quad \times \left[\int_{S_0} \Psi_m(r_0) \frac{\partial\Psi_n(r_0)}{\partial n_0} dS \right. \\ &\quad \left. - \int_{S_a} \frac{j\omega\rho_0}{Z} \Psi_m(r_0) \Psi_n(r_0) dS_a \right] \\ &\quad - \sum_m \frac{\Psi_m(r)}{\Lambda_m(k^2 - k_m^2)} \int_{S_v} j\omega\rho_0 v_n \Psi_m(r_0) dS \end{aligned}$$

By computing the integrals and calling them, respectively, P_{mn} , F_{mn} , and v_m , multiplying the previous equation by $\Psi_i(r)$ ($i = 1, 2, \dots, n$), and integrating on the volume V of the rectangular cavity, one obtains:

$$[P_{mn} - F_{mn} + \Lambda_m(k_m^2 - k^2) \delta_{mn}] \mathbf{b} = \mathbf{v} \quad [14]$$

In this equation k_m are the natural wave numbers of the rectangular volume and are known, as well as $k = \omega/c$, the matrices \mathbf{P} and \mathbf{F} , and the vector \mathbf{v} on the right-hand side. The only unknown is vector \mathbf{b} , and this can be solved by inverting the equation.

When b is determined, the acoustic pressure p in the automobile cabin can be immediately computed using eqn [12].

Comments on the Different Numerical Approaches

In the boundary integral formulation associated with the boundary element method solution, the unknown field (the acoustic pressure in the medium) becomes the field variable in correspondence with the vibrating surface. It is obvious that, for the external problem, this yields a significantly reduced computational burden, because the number of degrees of freedom must be defined only on the surface, i.e., it is not necessary to discretize the whole fluid region, but only the vibrating surface (nonlocal discretization). In some cases, the internal problem can also be solved advantageously by this procedure: in the medium-frequency range or for large cavities, the number of degrees of freedom necessary to solve the acoustic field can become very large with respect to the structural degrees of freedom. This happens when the number of acoustic modes which are equivalent, for a cavity, to the structural modes, becomes very large.

Therefore, it can be stressed that the boundary integral formulation is convenient for external problems and for the internal case, when either the dimensions of the fluid region or the frequency of interest are quite large, that is, when the involved acoustic wavelengths ($\lambda = c/f$) become significantly smaller than the dimensions of the considered region.

However, one should always consider that the finite element formulation leads to block diagonal matrices that are very convenient to decompose, while the boundary element method introduces sparse matrices that are much more cumbersome from a numerical point of view.

With reference to the internal problem, both the boundary element method and Succi's method originate from the integral formulation. However, while the boundary element method is actually a direct method of solving integral equations (the acoustic pressure is the unknown in the integrals), Succi's method transforms the unknown pressure distribution in the integral equation into a series of known functions. From a numerical point of view this is a relevant advantage, and in most cases the computation time is noticeably reduced.

Figure 4 shows an automobile cabin, and **Figure 5** shows a comparison between a finite element method solution and Succi's method, which is presented in the bandwidth 0–200 Hz. In the same frequency range the ratio between the computer time demanded by a

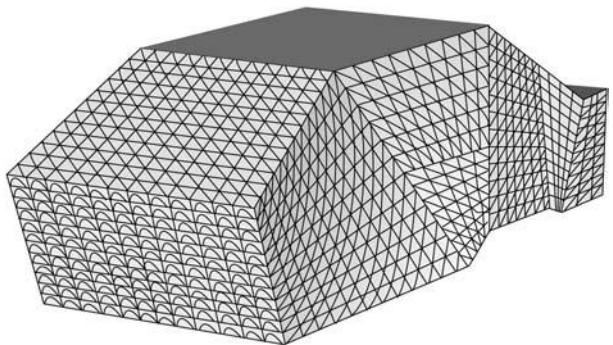

Figure 4 Automobile cabin.

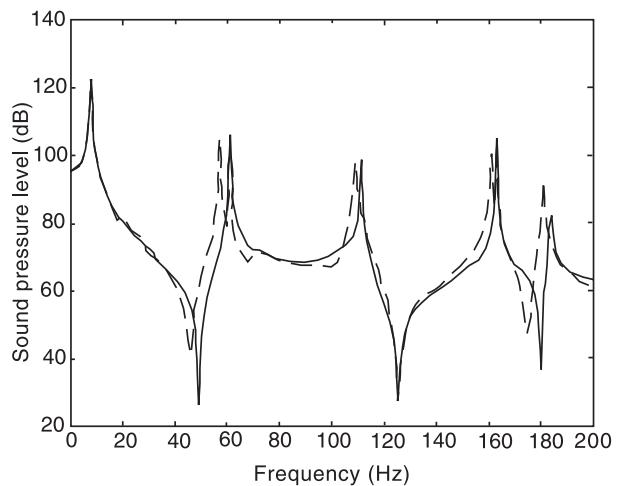

Figure 5 Sound pressure levels: comparison between finite element (continuous line) and Succi's results (dashed line).

boundary element method solution obtained by commercial software and that required for Succi's method proved to be of the order of 6.

Another advantage of Succi's method with respect to the boundary element method is represented by the possibility of determining directly, by the solution of an eigenvalue problem, the natural frequencies and acoustic eigenfunctions of a cavity.

However, it is worthwhile pointing out that the accuracy of Succi's method worsens as the cavity's shape becomes more and more dissimilar to the rectangular volume. In this case, the eigenfunctions of the rectangular volume cannot be considered an accurate basis for the solution of the cavity, and even using a high number of modes, some accuracy is lost.

Nomenclature

c	speed of sound
k	wave number
k_n	natural wavenumber
p	acoustic pressure
\mathbf{n}	outward unit vector normal to the surface

u	fluid particle velocity
v	velocity of a surface point
w	displacement of a surface point
\mathbf{q}	vector of coordinates
r	distance of the observer from the origin
r_0	distance of the source from the origin
G	Green function
G_∞	free-space Green function
G_c	cavity Green function
G_R	real part of the free-space Green function
K	stiffness matrix
M	mass matrix
R	distance between source and observer
T	kinetic energy
U	potential energy
M	mass of the subsystem
δ	Dirac function
δ_{mn}	Kronecker delta
ω	circular frequency
ω_n	natural acoustic frequency
ρ	fluid density
Ψ_i	ordered acoustic mode of order i corresponding to indices mnp

Λ_n normalization factor

doi:10.1006/rwvb.2001.0040

Introduction

Vibration testing of a system is usually undertaken for the purpose of parameter or system identification. If the object is linear, a great deal of information can be obtained from such tests. This is discussed elsewhere in the encyclopedia. However, when the system is nonlinear the general identification procedure is much more complicated and detailed models are often impossible to obtain. Nevertheless, it is still important to ascertain what operating conditions may lead to an unacceptable type of response. The purpose of this article is to present guidelines for testing systems that may be nonlinear and thus behave in unpredictable ways, i.e., unlike a linear system. Before embarking on this, it is important to appreciate some of the different responses that can arise on account of nonlinearities. These are presented in the next section, followed by recommendations for specific testing techniques that should be employed to guarantee that all types of responses have been found. Throughout, harmonic inputs are assumed unless otherwise stated.

Linear versus Nonlinear Response

The following subsections briefly describe some of the unusual phenomena that occur on account of

nonlinearities. More details can be found in the texts cited at the end of this article.

Resonance Frequency

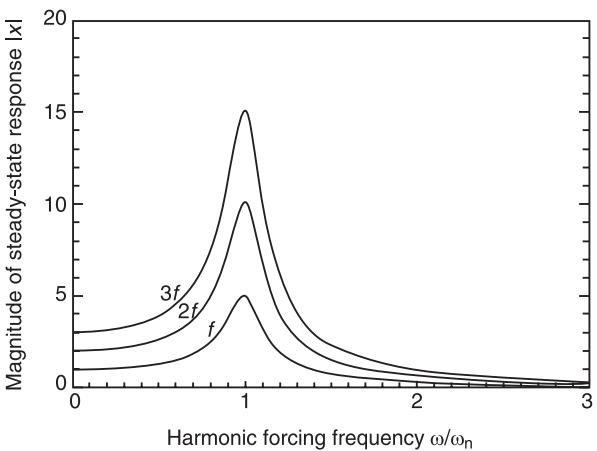

One of the most fundamental differences between linear and nonlinear systems is the dependence of the resonant frequency on the level of the response. Alternatively, this can be viewed as a dependence on the magnitude of the excitation since, normally, as the level of the excitation is increased, so is the level of the response. This behavior is represented in **Figure 1**.

Figure 1A shows a typical linear response of a one-degree-of-freedom system (1 DOF) where the steady-state response, $|x|$, linearly increases with the level of the force, f . The resonant frequency, ω_p , is essentially independent of f and is very close to the natural frequency, ω_n . In contrast, **Figure 1B** shows how a typical* nonlinear system might respond. Depending on the level of the force, the maximum response occurs at different forcing frequencies, i.e., the resonant frequency becomes a function of the level of the response.

Multiple Steady States

This type of behavior gives rise to a great deal of problems while testing nonlinear systems. In linear systems, solutions are unique, i.e., given some system that is described by linear differential equations then the solution set due to a given input term is unique.

* For this example a ‘hardening’ nonlinearity is shown. The description hardening refers to the stiffness term that increases or hardens as the amplitude increases. This leads to an increase in the natural frequency as the response increases.

(A)

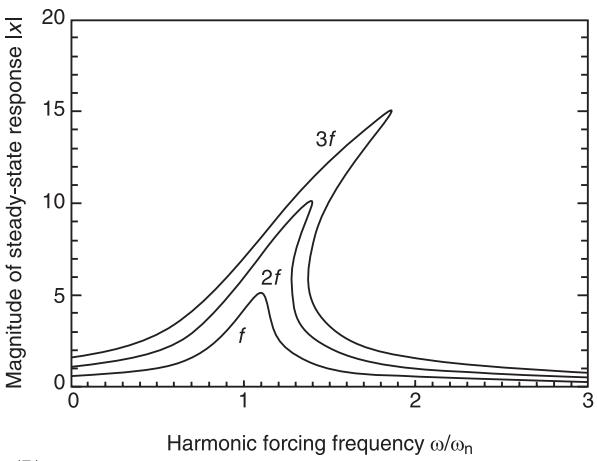

Figure 1 Frequency response for three different levels of force f . (A) Linear case; (B) typical nonlinear case.

However, this need not be the case in nonlinear systems. This may be more clearly understood if Figure 1B is redrawn for a single, constant level of force. This is shown in Figure 2. For any value of forcing frequency, ω , such that $\omega_a < \omega < \omega_b$, there are three possible steady-state responses. The one that is adopted is dependent on the phase relationship between the response and the force. Alternatively, this may be viewed as a dependence on the initial conditions of the problem. In addition, the midvalued solution (shown as a dashed line in Figure 2) is unstable and cannot be observed in practice.

Nonharmonic Response

In harmonically excited linear systems the steady-state response will always be of the same frequency

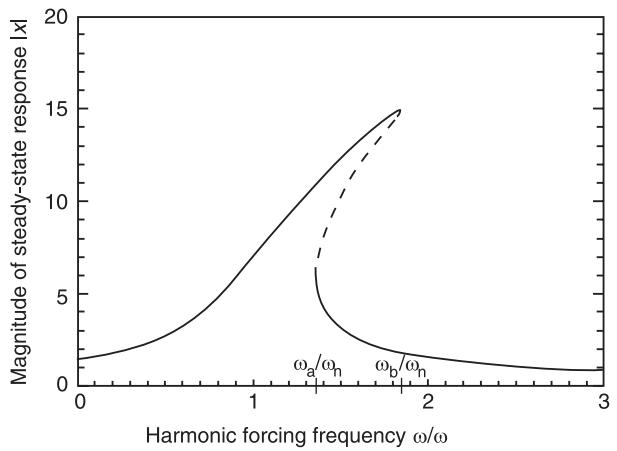

Figure 2 Typical nonlinear frequency response function. Continuous line, stable; dashed line, unstable.

as the input[†]. This may be almost true in some nonlinear systems where only small harmonic distortions are present, but on occasion it is quite possible to observe frequencies that are vastly different from the input term. As a general rule, if even-order nonlinearities are present they will generate even harmonics, whereas odd-order nonlinearities tend to generate odd harmonics. Moreover, the response may not be periodic at all but instead quasiperiodic or even chaotic responses may be observed. To complicate the picture further, these responses usually take a large number of forcing cycles to develop fully and are dependent on initial conditions.

Lack of Superposition

This is perhaps the key distinguishing factor between linear and nonlinear systems. Being aware of this is of great practical importance because we can no longer predict the cumulative response of a system by considering the individual components of the forcing terms. For example, 1 DOF cases exist where a two-harmonic forcing term, $f(t) = f_1 \sin \omega_1 t + f_2 \sin \omega_2 t$, can give rise to a resonant response (at the natural frequency of the system) even when ω_1 and ω_2 are well removed from that natural frequency. This is known as a combination resonance and is only one example of the type of misleading response that can occur because superposition is not valid.

Modal Interaction

Moving to systems of more than 1 DOF, additional problems are encountered when dealing with nonlinear systems. Unlike their linear counterparts where a standard eigenvalue/vector analysis can usually be used to uncouple modes, nonlinear systems typically

[†] Strictly, this is limited to systems that have constant coefficients and have some damping such that transient motions decay.

cannot be fully uncoupled. The practical implication of this is that modes can interact and energy can flow from one mode to others. The final response of the system might be very different from its initial behavior. The frequency content of the response can evolve in time and its final content might be vastly different from the forcing frequency. Steady-state solutions might never be attainable, with a continuing exchange of energy occurring between the modes. This is particularly true if the linear natural frequencies are, or almost are, commensurate. This condition is known as internal tuning.

Miscellaneous

Details of all of the above phenomena can be found in the texts listed in the Further Reading section at the end of this article, as can more specialized types of nonlinear behavior. Examples of this would include systems with gaps (e.g., causing rattles and chatter); friction-induced instabilities (e.g., causing brake squeal), and frequency entrainment (often observed in the run-up of rotating systems). Resonances may also arise due to time-dependent coefficients in a system's governing equation (so-called parametric resonances) and there are vast arrays of systems that exhibit chaotic responses.

While the testing procedures outlined in the next section may not give insight into why a particular response is occurring, they will uncover most of the types of the behavior listed above. Regions in the parameter space can then be mapped out indicating where resonances and other complex responses occur.

Testing Procedures

Having briefly reviewed some of the more fundamental differences between linear and nonlinear system responses we shall now detail how to modify the standard vibration-testing procedures to ensure that the true nonlinear behavior of the object is captured. In general, a slow frequency and/or force sweep is the preferred method of testing. Alternatives such as impact testing and random excitation are less desirable due to the superposition principle being inherently invalid in nonlinear systems. However, low-level impact and random inputs can be of use to determine quickly the approximate values of the (linear) natural frequencies.

The test set-up is no different whether the system is linear or nonlinear. A source of excitation, e.g., an electrodynamic shaker, is attached to the test piece by a stinger, a compliant mount, or such like. The response due to this excitation is also measured by, for example, an accelerometer, strain gauge, etc. This

is shown schematically in Figure 3. The input and the output should be continuously monitored taking care to minimize the amount of signal preprocessing. Of course, antialiasing filters should be used if digital devices are employed, but be aware that one should sample a wide frequency bandwidth encompassing harmonics and subharmonics of the forcing frequency. This will ensure that the complete response of the system is being captured because, as previously explained, nonlinear systems often generate frequencies that are very different from the forcing frequency.

Another characteristic of nonlinear systems is that their behavior often takes a great deal of time to develop and thus, being able to observe any precursor to a change in the underlying behavior is desirable. Hence, analysis of the signals should be carried out in real time, i.e., as the test is being run. One can watch for the appearance and disappearance of harmonics and/or phase changes as they are sensitive indicators of ongoing changes and that the test needs to be continued. A two-channel fast Fourier transform (FFT) analyzer can be used for this, with displays set to show the evolution of the frequency content (akin to short-time Fourier transforms or spectrograms) or to show an orbit plot of input versus output signal. The latter is particularly useful to detect sudden changes in the phase relationship between the two signals. Some more complex types of analyses and displays can be used. For example, for very low dimensional systems Poincaré sections can be developed and for systems that contain a very wide range of frequencies and have inherent impulsive events, a wavelet-based analysis may be of use. Dimensional calculations can also be made, but all of these involve more complex processing that often has to be done offline. They give specialized information about the system, whose description is beyond the scope of this article.

We will now discuss specific test procedures that can be used to uncover a variety of nonlinear characteristics that a system may possess.

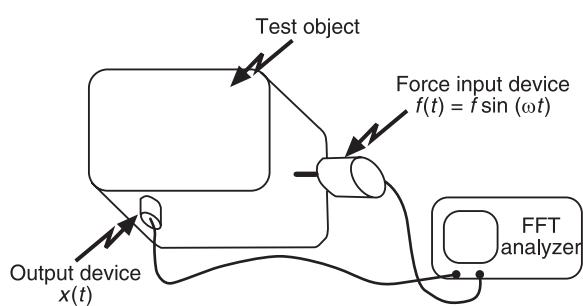

Figure 3 Typical experimental set-up.

Parameter Sweep Through Resonances

The main purpose of this test is to map out the combination of f and ω that gives rise to the largest responses in the neighborhood of a natural frequency. Closely related to this is to find regions where multiple steady states might exist and therefore jumps between different operating conditions could be observed.

One first finds the approximate values of the natural frequencies by, for example, a standard impact test, taking care to impart only a low level of excitation. One then completes a sweep of the forcing frequency, ω , by starting close to but below one of the natural frequencies and very slowly increasing ω . With reference to Figure 2, when ω is increased slightly above a value of ω_b , the solution will pass through a transient response and then settle to a much smaller-amplitude solution. The procedure is then reversed, starting above the natural frequency and slowly sweeping downwards. A transition, or jump, to a higher level will occur close to ω_a .

There are a number of issues one must be aware of when completing this task. Firstly, we have assumed that the nonlinearity is hardening, i.e., the peak response occurs at a forcing frequency above the linear natural frequency. The opposite may be true and so care should be taken to sweep the forcing frequency slowly in both directions from the natural frequency.

Secondly, the system may be behaving linearly and so the peak response could be exceedingly close to the linear natural frequency (see the curve labeled f in Figure 1B for an example of this). One can always check this by increasing the level of force, f , and see if there is a corresponding linear increase in the response. In either case, the best practice is often simultaneously to alter f and ω and carefully monitor the response for sudden changes in its behavior (also see the subsection on accelerated testing, below). If this is found, a more systematic parameter search can then be undertaken in that region.

Depending on the final application, the experimental results can be presented in a variety of ways. It is often desirable to consider the $f-\omega$ plan and divide it into regions indicating where jumps occur, where nonharmonic responses occur, etc. Results from the test to follow can also be summarized this way, quickly allowing design engineers to perceive potentially dangerous operating conditions.

Tests for Sub- and Superharmonic Resonances

In addition to testing in the neighborhood of the natural frequencies, one should also sweep through forcing frequencies that are close integer multiples

and submultiples of the natural frequencies[‡]. Resonances that exist in these regions are potentially very dangerous because using conventional (linear) thinking, one only has to avoid forcing close to a natural frequency to avoid large responses. Impact and random excitation tests are unlikely to uncover these resonances since the responses take a high number of forcing cycles to develop and their domain of attraction may be small (also see the subsection on Dependence on Initial Conditions, below).

Accelerated Testing

Although it is important to sweep a parameter relatively slowly to ensure that adequate time is given for a response to develop, this can take a considerable amount of time. Moreover, many types of response may never be observed if their domain of attraction is not entered by the particular set of initial conditions that exist as the test is being run. The testing time can be accelerated by increasing the level of force above typical operating conditions and then sweeping the frequency faster. As the sweep continues there will usually be some sign of a response developing (recall that the input and output should be analyzed in real time). When this is seen, the level of force can be reduced to a more realistic level and then a detailed investigation of the existence of that solution can be made.

There is a fine art to doing this, and simultaneous changes in f and in ω may have to be made. The key is to watch for some early sign of a response growing (see the introduction to Testing Procedures, above) and then let it continue to develop while slowly reducing the level of the force. Care must be taken not to lose the response on account of changing the force level too quickly. The aim is to reduce the level of the force and simultaneously to change the forcing frequency up or down, in order to follow the solution. Of course, there is always the possibility that the response may cease to exist at the lower levels of force, regardless of the value of ω .

Different initial conditions should be tested to explore the region thoroughly for possible solutions. This is discussed in the next subsection.

Dependence on Initial Conditions

Recall that for a fixed forcing function, multiple solutions may exist. This nonuniqueness of solutions is potentially very problematic when testing, for one

[‡] I.e., $\omega \approx p\omega_n$ and ω_n/p for small integer values of p . Such responses are called subharmonic and superharmonic resonances. Related to these are forcing frequencies that are linear combinations of natural frequencies in multiple DOF systems.

can never be sure that all possible solutions have been found. However, there are some general techniques that can help. If the device is small enough, one can simply hold and then release it and see if the same response returns. This should be repeated a number of times in an attempt to enter domains that will attract to different solutions. The device does not have to be brought to rest each time since the requirement is to change the phase between the forcing term and the response(s). An alternative to this is to impact the object while it is being harmonically forced and again observe if the response returns to the pre-impact level. Different levels of impact and different locations should be tested.

Mode Interaction

Modal interaction can occur when there is a simple relationship between the linear natural frequencies of a system, ω_{n_i} , $i = 1, 2, 3, \dots$ where i denotes the i th natural frequency. Therefore, the first step in this test is to obtain a good estimate of all the linear natural frequencies. It is important to include even those lying beyond the input frequency bandwidth of interest, since energy can be transferred to modes well removed from the excitation frequency. As recommended previously, a low-level impact test is often adequate to find the natural frequencies. Once found, check for internal tuning relationships, such as $\omega_{n_i} \approx p\omega_{n_j}$ for low integer values of p ($i = 1, 2, 3, \dots \neq j$ and $j = 1, 2, 3, \dots \neq i$). For example, say that $\omega_{n3} \approx 2\omega_{n1}$, then a slow-frequency sweep test should be completed in the neighborhood of ω_{n3} , taking care to observe for a response growing with a frequency close to ω_{n1} . The opposite case should also be tested, i.e., sweeping through ω_{n1} and looking for a response with a frequency of ω_{n3} . One must be aware of all the previously discussed points, regarding initial conditions, sweep directions, etc. in the search for modal interaction. The procedures outlined in the subsection on Accelerated Testing can also be employed to ensure that an exhaustive search has been made. It should be noted that the responses may take many forcing cycles to develop.

The situation can readily become very complex as the number of degrees of freedom increases. The number of internal tuning conditions can quickly rise, necessitating running many tests and there may be many modes involved in a chain, or cascading effect. For example, say that $\omega_{n3} \approx 2\omega_{n1}$ and that $\omega_{n1} \approx \omega_{n4} - \omega_{n2}$, then it is possible that an excitation close to ω_{n3} will eventually cause mode 1 to grow, which in turn will eventually cause modes 4 and 2 to respond.

Concluding Remarks

Nonlinear systems are inherently difficult to test and to interpret the results correctly. Great care must be taken to avoid preconceived ideas of how the system is likely to respond, for often this would influence the type of test being run and the processing techniques employed. Time must be given for complex responses to develop and a wide range of different force, frequency, and sweep directions must be covered to ensure that all possible input regimes have been explored. Likewise, preconceived ideas about the expected type of response can lead to the introduction of inappropriate conditioning of the response signals and thus mask behaviors that may lead to incorrect classification or understanding of the system. Often commercially based testing apparatus assumes a system's linearity and thus the results generated are invalid for nonlinear systems. If one has to use a commercial test package it is good practice to check that all results are reproducible under different conditions such as sweep directions, level of excitation, and initial conditions.

Nomenclature

f	force
$ x $	steady-state response
ω_p	resonant frequency

THEORY OF VIBRATION

Fundamentals

B Yang, University of Southern California, Los Angeles, CA, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0112

Vibrations are the oscillating motion of an object or a dynamic system about an equilibrium position. This oscillating motion can be either periodic, or nonperiodic and transient. Examples of vibrations are diverse, including the back-and-forth motion of an engine piston, the oscillations of a violin string, the fluctuations of a highway bridge with passing vehicles, and the rolling of a ship under the influence of ocean waves.

For vibrations to occur, two elements are essential: a mass or inertia element that stores kinetic energy; and a spring or elastic element that stores potential energy. The spring element provides a restoring force that continually pulls the mass toward its equilibrium position, and thus causes the oscillations of the mass. During vibrations, potential energy and kinetic energy are converted to each other as they are stored in and released from the two elements, respectively.

Vibrations of a system are initiated when energy is imparted to it. A free vibration occurs when external excitations are absent, but kinetic energy or potential energy is present initially in the system. Free vibrations of many systems are harmonic motion with periods or natural frequencies that are inherently dependent upon inertia and elastic properties. A forced vibration occurs with the application of external forces to the system. Forced vibrations can be periodic, nonperiodic, or random. Under a harmonic (sinusoidal) excitation, the response of a system becomes increasingly large if the excitation frequency is close to one of the natural frequencies of the system. This phenomenon is called resonance. Control of resonant vibrations is one important issue in design of structures and machines.

For any real vibrating system, there always exists energy dissipation in motion, which is termed damping. Damping occurs as a result of friction among moving objects, or interactions of moving objects with their surrounding environments (e.g., rough

surface, air, fluids, and electromagnetic fields). Damping converts the mechanical energy in a vibrating system to other forms of energy such as heat and acoustic energy. This energy conversion process in general is irreversible. The presence of damping causes the amplitude of free vibrations to decay, and leads to the reduction in amplitude of forced vibrations. In addition, damping can be purposely introduced to suppress resonant vibrations.

Inertia, elasticity, and damping are inherent properties of vibrating systems.

Vibrations can degrade the performance and reliability of structures and machines, cause property damage, and in worst cases result in loss of human lives. Hence, vibration control is essential for proper operation of many systems. On the other hand, vibration phenomena are useful in certain devices such as musical instruments, shakers, and cardiac pacemakers. In either way, it is essential to model and analyze the behaviors of vibrating systems.

Any study of vibrations inevitably turns to dynamics, as vibration involves motion (displacement, velocity, and acceleration), forces, and inertia. Kinematics, the study of geometry of motion without reference to forces and inertia, is part of dynamics. In this article, the fundamentals of vibration theory are presented under the following headings: classification of vibrating systems; equations of motion; free vibration; forced vibration; and modal analysis. For the sake of simplicity, linear lumped systems will be mainly considered.

Classification of Vibrating Systems

There are several ways to classify vibrating systems, depending on different perspectives. In view of the distributions of inertia and elastic parameters, there are distributed parameter systems such as structures composed of flexible beams and plates, and lumped parameter systems such as systems of lumped masses, and rigid bodies. Vibrations of distributed parameter systems are described by partial differential equations, while vibrations of lumped parameters are described by ordinary differential equations. Because exact solutions of partial differential equations are difficult to obtain, distributed parameter systems are often approximated by lumped parameter models, through a procedure called discretization. In engineering practice, discretization via the finite element method is widely adopted.

From the viewpoint of energy conversion, vibrating systems are divided into two kinds: (1) conservative systems which have no damping, and no energy exchange with the surrounding environments; and (2) nonconservative systems which exchange energy with the surrounding environments via damping, gyroscopic, and circulatory forces, magnetoelectromechanical interactions, or other means. One important feature of conservative systems is the existence of normal modes of vibration, which are composed of real natural frequencies (eigenvalues) and real orthogonal mode shapes (eigenvectors). The concept of normal modes has an important position in vibration theory, and lays a foundation for the development of a useful vibration analysis technique called modal analysis.

Vibrating systems can also be categorized as linear systems whose motion is described by linear differential equations; and nonlinear systems whose motion is governed by nonlinear differential equations, due to nonlinear material and/or geometric properties of the systems. For linear systems, many well-developed methods of vibration analysis are available, as the superposition principle is valid. In the study of small oscillations, a nonlinear system can be treated as a linear one by proper linearization. However, nonlinearities must be considered when large oscillations are of concern. Physically, nonlinear systems have certain unique characteristics that linear systems lack, such as subharmonic and superharmonic resonances, parametrically excited vibrations, limit cycles, self-excited oscillations, and chaotic motion. Analysis of nonlinear vibrations is much more difficult, and still needs further development.

Vibrations become random when there are uncertainties in motion. The cause of uncertain motion may be the unpredictability of excitations, or the lack of accurate information about the physical properties of the system. Buildings under earthquake excitations and large space structures with uncertain elastic and damping parameters are two examples. Random vibrations are usually studied based on the theory of stochastic processes. Thus, vibrating systems are also classified as deterministic systems and stochastic systems.

Equations of Motion

Mathematically, the motion of a vibrating system is described by time-dependent coordinates or generalized displacements. These coordinates are governed by differential equations of motion, which are derived from basic laws of physics, like Newton's laws. Vibrating systems can be classified by the number of degrees of freedom (DOF) of motion. The number

of degrees of freedom is the number of independent coordinates needed to describe motion completely.

Systems with One Degree of Freedom

The simplest vibrating system is shown in Figure 1, where $x(t)$ is the horizontal displacement of the mass, measured from the equilibrium position at which the spring is unstretched, and $f(t)$ is an external force. The mass does not move vertically, due to the constraint of the frictionless surface. The system has one DOF as the coordinate $x(t)$ completely describes the motion. According to Newton's second law, the motion of the spring–mass system is governed by:

$$m\ddot{x}(t) = f(t) - f_s(t) \quad [1]$$

where $\ddot{x} = d^2x/dt^2$ is the acceleration of the mass, and f_s is the spring force which always pulls the mass towards the equilibrium position. For small oscillations, the spring force can be assumed to be proportional to the mass displacement; that is, $f_s(t) = kx$ where k is a spring coefficient or stiffness. It follows that the motion of the spring–mass system is described by the linear differential equation:

$$m\ddot{x}(t) + kx(t) = f(t) \quad [2]$$

For large oscillations, however, the spring force may become a nonlinear function of the displacement, say $f_{NL}(x)$, which results in a nonlinear equation of motion:

$$m\ddot{x}(t) + f_{NL}(x) = f(t) \quad [3]$$

Eqns [2] and [3] are generic of 1-DOF vibrating systems. For instance, the angular displacement θ of the shaft–disk system in Figure 2A is governed by the differential equation:

$$J\ddot{\theta}(t) + K\theta(t) = M_0(t) \quad [4]$$

where M_0 is an external torque; and the swaying motion of a simple pendulum in Figure 2B is described by:

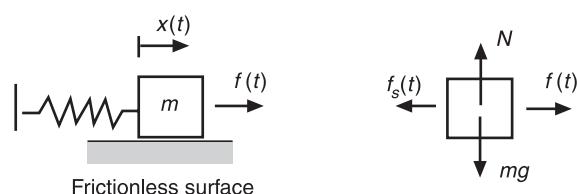

Figure 1 A spring–mass system.

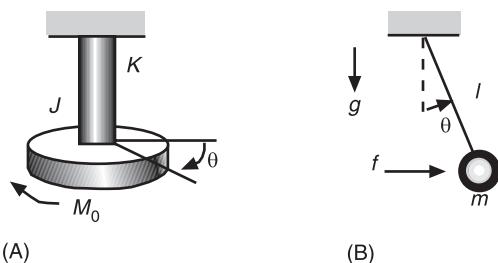

Figure 2 (A) Shaft-disk system: J , polar moment of inertia of the disk; K , torsional stiffness of the shaft. (B) Simple pendulum: g , gravitational acceleration.

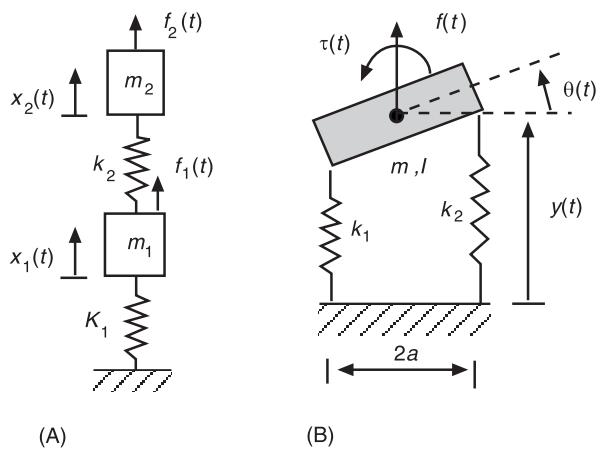

Figure 3 Two-DOF systems.

Systems with Multiple Degrees of Freedom

Many vibrating systems either have more than one mass element, or have a single mass that is in multi-dimensional motion. These systems are called multi-DOF systems because the complete description of their motion requires more than one coordinate. The motion of multi-DOF systems is governed by a set of simultaneous differential equations. As two examples, the equations of motion of the two-mass system in Figure 3A are of the matrix form:

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{pmatrix} \ddot{x}_1(t) \\ \ddot{x}_2(t) \end{pmatrix} + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix} \begin{pmatrix} x_1(t) \\ x_2(t) \end{pmatrix} = \begin{pmatrix} f_1(t) \\ f_2(t) \end{pmatrix} \quad [6]$$

while the spring-supported rigid body in Figure 3B, whose motion involves both vertical translation $y(t)$ and rotation $\theta(t)$, is described by:

$$\begin{bmatrix} m & 0 \\ 0 & I \end{bmatrix} \begin{pmatrix} \ddot{y}(t) \\ \ddot{\theta}(t) \end{pmatrix} + \begin{bmatrix} k_1 + k_2 & a(k_2 - k_1) \\ a(k_2 - k_1) & a^2(k_1 + k_2) \end{bmatrix} \begin{pmatrix} y(t) \\ \theta(t) \end{pmatrix} = \begin{pmatrix} f(t) \\ \tau(t) \end{pmatrix} \quad [7]$$

In general, the motion of an n -DOF linear vibrating system can be described by the matrix differential equation:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{Kx}(t) = \mathbf{f}(t) \quad [8]$$

where \mathbf{M} and \mathbf{K} are n -by- n mass and stiffness matrices, respectively, $\mathbf{x}(t)$ is a vector of n coordinates or

generalized displacements, and $\mathbf{f}(t)$ is a vector of external forces. Eqn [8] can be derived by either Newton's laws or energy methods.

Distributed Parameter Systems

Eqn [8] represents lumped parameter models of vibrating systems because their mass and spring elements are concentrated at a finite number of points. For a distributed parameter system, like a flexible structure, its mass is distributed over the entire body which it occupies in space, and so are its elastic elements. Distributed parameter systems are also called infinite-dimensional systems because complete description of motion requires an infinite number of coordinates (degrees of freedom). The motion of a distributed parameter system is governed by partial differential equations like:

$$M[w_{,tt}(x, t)] + K[w(x, t)] = f(x, t) \quad [9]$$

where \mathbf{M} and \mathbf{K} are mass and stiffness differential operators, respectively, x represents a point in space, $w(x, t)$ is the generalized displacement, $w_{,tt} = \partial^2 w / \partial t^2$, and $f(x, t)$ is the distribution of external forces applied to the distributed system. One example is the tensioned uniform string shown in Figure 4A. The transverse displacement w of the string, under a transverse load $f(x, t)$, is governed by the partial differential eqn [9] with the mass and stiffness operators given by:

$$M = \rho, \quad K = -T \partial^2 / \partial x^2 \quad [10]$$

where ρ and T are the linear density (mass per unit length) and tension of the string, respectively.

Eqn [9] represents a distributed model of vibrating systems. Because exact solutions of partial differential

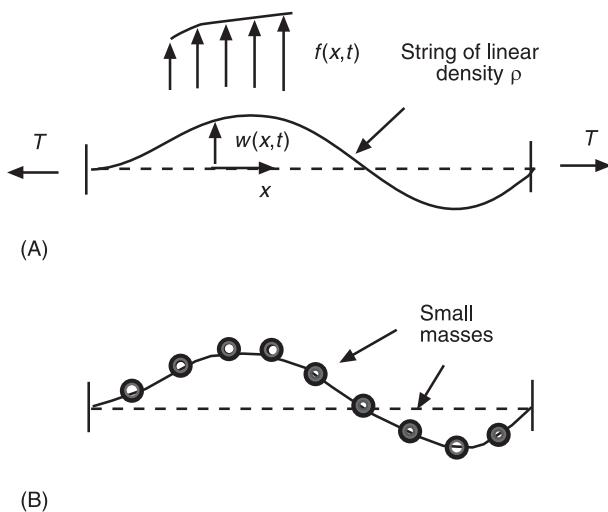

Figure 4 A string in transverse vibration: (A) distributed parameter model; (B) lumped parameter model.

equations are only available for a few simple systems, distributed vibrating systems are often approximated by lumped-parameter models. In such approximations, a vibrating continuum is treated as a finite number of elastically interconnected lumped masses (see **Figure 4B**, for instance). By certain mathematical algorithms such as the Rayleigh–Ritz method and the finite element method, the partial differential equation of motion is reduced to a set of ordinary differential equations like eqn [8]. This process is called discretization.

Besides equations of motion, a description of the vibrating systems also needs to assign initial conditions, and boundary conditions (for distributed parameter systems). A fundamental issue in vibration theory is to solve initial-boundary value problems associated with differential equations.

Free Vibration

Free vibration occurs without externally applied forces; it arises when kinetic energy or potential energy is present initially in the vibrating system. The energy input is due to initial displacements and velocities, which are also called initial disturbances.

Harmonic Motion

Free vibrations of an undamped 1-DOF system are described by the differential equation:

$$m\ddot{x}(t) + kx(t) = 0 \quad [11]$$

with the initial conditions $x(0) = x_0$ and $\dot{x}(0) = v_0$, where x_0 and v_0 are initial displacement and velocity,

respectively. The displacement is assumed as $x(t) = Ae^{\lambda t}$, which, according to eqn [11], results in the characteristic equation:

$$m\lambda^2 + k = 0 \quad [12]$$

The roots or eigenvalues of the characteristic equation are $\lambda_1 = i\omega_n$, and $\lambda_2 = -i\omega_n$, $i = \sqrt{-1}$. The parameter ω_n is given by:

$$\omega_n = \sqrt{\frac{k}{m}} \quad [13]$$

which is called the natural circular frequency of the vibrating system, of which the units are radians per second. The natural frequency depends on inertia and elastic properties of the system. The free vibration is of the form:

$$x(t) = A \sin \omega_n t + B \cos \omega_n t \quad [14]$$

which, by the initial conditions, is determined as:

$$\begin{aligned} x(t) &= x_0 \cos \omega_n t + \frac{v_0}{\omega_n} \sin \omega_n t \\ &= A_m \sin(\omega_n t + \phi) \end{aligned} \quad [15]$$

where the amplitude and phase angle are:

$$A_m = \sqrt{x_0^2 + \frac{v_0^2}{\omega_n^2}}, \quad \phi = \tan^{-1}\left(\frac{\omega_n x_0}{v_0}\right) \quad [16]$$

The displacement in eqn [15] is sinusoidal, and hence is called simple harmonic motion. The period of harmonic motion (the time needed to complete a cycle of motion) is:

$$T = \frac{2\pi}{\omega_n} = \frac{1}{f_n} \quad [17]$$

where $f_n = \omega_n/(2\pi)$ is the natural frequency of the vibrating system, in hertz (Hz). **Figure 5** shows that the harmonic motion can be viewed as the projection of a rotating vector OP of amplitude A_m and rotation speed ω_n on the vertical axis OX . Natural frequency, amplitude, and the phase angle are three major parameters of harmonic motion.

Modes of Vibration

The free vibration of an undamped multi-DOF system is described by:

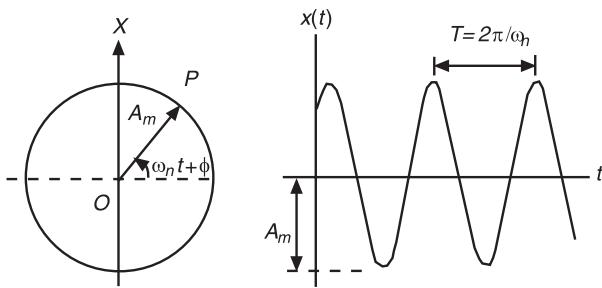

Figure 5 Simple harmonic motion.

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = 0 \quad [18]$$

$$\mathbf{x}(0) = \mathbf{x}_0 \quad \text{and} \quad \dot{\mathbf{x}}(0) = \mathbf{v}_0 \quad [19]$$

where the vectors \mathbf{x}_0 and \mathbf{v}_0 contain initial displacements and velocities, respectively. Extending the concept of harmonic motion, assume $x(t) = \mathbf{u}e^{i\omega t}$. According to this, eqn [18] leads to the eigenvalue problem:

$$\omega^2 \mathbf{M}\mathbf{u} = \mathbf{K}\mathbf{u} \quad [20]$$

There are n eigenvalues, $\omega_1^2, \omega_2^2 \dots \omega_n^2$, which are the roots of the characteristic equation:

$$\det(-\omega^2 \mathbf{M} + \mathbf{K}) = 0 \quad [21]$$

The ω_k are called the natural frequencies of the system. Corresponding to ω_k , the eigenvector \mathbf{u}_k describes a specific distribution of displacements, and is called mode shape. The pair (ω_k, \mathbf{u}_k) defines the k th mode of vibration of the system by:

$$\mathbf{x}_k(t) = (A_k \sin \omega_k t + B_k \cos \omega_k t) \mathbf{u}_k \quad [22]$$

For free vibration analysis, the solution of eqn [18], is represented by a linear combination of all modes:

$$\begin{aligned} \mathbf{x}(t) &= \sum_{l=1}^n \mathbf{x}_l(t) \\ &= \sum_{l=1}^n (A_l \sin \omega_l t + B_l \cos \omega_l t) \mathbf{u}_l \end{aligned} \quad [23]$$

where A_l and B_l are determined by the initial conditions.

The concept of modes of vibration is extremely important in the theory of vibration, and will be explained further later on.

Effects of Viscous Damping

Among the available damping models, viscous damping is most commonly used. Figure 6 shows a viscously damped 1-DOF system, where viscous damping is indicated by a dashpot or damper. The damping force is proportional to the velocity of the mass, but opposite to the motion of the mass, i.e., $f_c(t) = -c\dot{x}(t)$, where c is the damping coefficient, in kg s^{-1} . The equation of motion of the damped system is:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = f(t) \quad [24]$$

The characteristic equation of the damped system, obtained by assuming $x(t) = Ae^{i\omega t}$ and $f(t) = 0$ in eqn [24], is:

$$m\lambda^2 + c\lambda + k = 0 \quad [25]$$

The roots of the characteristic equation are:

$$\lambda_{1,2} = -\xi\omega_n \pm i\sqrt{1 - \xi^2}\omega_n, \quad i = \sqrt{-1} \quad [26]$$

where $\omega_n = \sqrt{k/m}$ is called the undamped natural frequency, and $\xi = C/(2m\omega_n)$ the damping ratio.

When $0 < \xi < 1$, the roots are complex, and the free response is:

$$x(t) = e^{-\xi\omega_n t} (A \sin \omega_d t + B \cos \omega_d t) \quad [27]$$

where $\omega_d = \sqrt{1 - \xi^2}\omega_n$ is called the damped natural frequency, and A and B are determined by the initial conditions. This motion, which is oscillatory with decaying amplitude, is called underdamped vibration. In Figure 7 the dotted curves indicate the decay in the amplitude of free vibration, which is controlled by the damping ratio ξ . This type of response is commonly seen in many vibrating systems.

When $\xi > 1$, the characteristic roots are both real and negative, and the system response is called over-damped vibration. In this case, the amplitude of free vibrations decays, without oscillatory motion:

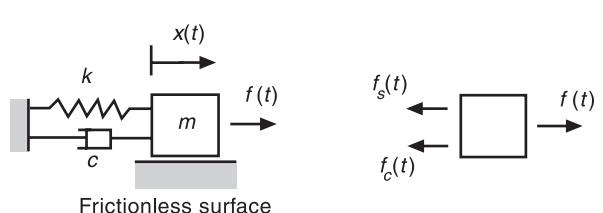

Figure 6 A 1-DOF system with viscous damping.

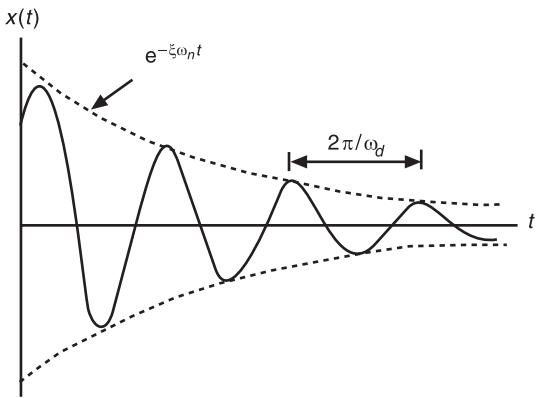

Figure 7 Free vibration of an underdamped system.

$$\begin{aligned}x(t) &= e^{-\xi\omega_n t} (Ae^{-\beta t} + Be^{\beta t}), \\ \beta &= \omega_n \sqrt{\xi^2 - 1}\end{aligned}\quad [28]$$

When $\xi = 1$, there are two repeated roots, $\lambda_1 = \lambda_2 = -\omega_n$, and the system response is:

$$x(t) = e^{-\omega_n t} (A + Bt) \quad [29]$$

which decays without oscillation. This motion is called critically damped vibration as it is the case which separates oscillation ($0 < \xi < 1$) from non-oscillation ($\xi > 1$).

Besides decay in vibration amplitude, the effects of damping are also seen from decay in mechanical energy. The rate of change of total mechanical energy (sum of kinetic energy and potential energy) is:

$$\frac{d}{dt} \left(\frac{1}{2} mx^2 + \frac{1}{2} kx^2 \right) = -cx^2 \quad [30]$$

which is negative most of the time. (It is only zero at those discrete times when the displacement peaks.) Thus, the damping renders the mechanical energy decreasing continuously. If damping is absent ($c = 0$), the mechanical energy is conserved as its rate of change is zero all the time.

For a multi-DOF system with viscous damping, its motion can be described by the matrix differential equation:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{f}(t) \quad [31]$$

where \mathbf{C} is the damping matrix consisting of the coefficients of dampers. The concepts of free vibrations and modes of vibration presented previously can be extended here.

Forced Vibration

The motion of a vibrating system that results from externally applied forces is called forced vibration. A forced vibration often consists of two parts: transient response, which is the motion that disappears after a period of time; and steady-state response, which is the motion that remains after the transient response has disappeared.

Harmonic Excitation

Consider the motion of a damped 1-DOF system subject to a harmonically varying force:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = F_0 \sin \omega t \quad [32]$$

where ω is the excitation frequency or forcing frequency. The steady-state response $x_{ss}(t)$ of the system is assumed to be sinusoidal with the same frequency, i.e.:

$$x_{ss}(t) = X_0 \sin (\omega t + \phi) \quad [33]$$

Substitute eqn [33] into eqn [32], to find the amplitude and phase angle:

$$\begin{aligned}X_0 &= \frac{F_0}{k} \frac{1}{\sqrt{(1-r^2)^2 + 4\xi^2 r^2}}, \\ \phi &= \tan^{-1} \left(\frac{2\xi r}{1-r^2} \right)\end{aligned}\quad [34]$$

where r is the frequency ratio $r = \omega/\omega_n$, and ω_n and ξ are the undamped natural frequency and damping ratio introduced in eqn [26]. As shown in Figure 8 and eqn [34], the amplitude of the steady-state response depends on the excitation frequency and damping ratio. For light damping, say $\xi \leq 0.1$, the amplitude approaches a maximum value as the excitation is near the undamped natural frequency ω_n . Moreover, the smaller the damping ratio, the higher the peak.

The steady-state response $x_{ss}(t)$ is a particular solution. The total solution of eqn [32] is the sum of a particular solution and the solution of the corresponding homogeneous equation. For the under-damped case ($0 < \xi < 1$) this becomes:

$$\begin{aligned}x(t) &= e^{-\xi\omega_n t} (A \sin \omega_d t + B \cos \omega_d t) \\ &\quad + X_0 \sin (\omega t + \phi)\end{aligned}\quad [35]$$

where A and B are determined by the initial conditions. The first term in eqn [35] is the transient response because it approaches zero for large values of t .

The response of multi-DOF systems subject to harmonic excitations can be similarly determined. To this end, consider:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{F}_0 \sin \omega t \quad [36]$$

By complex analysis, the excitation is the imaginary part of the exponential form $\mathbf{F}_0 e^{i\omega t}$, $i = \sqrt{-1}$. Thus, the steady-state response can be written as:

$$\mathbf{x}(t) = \text{Im}(\mathbf{X}_0 e^{i\omega t}) \quad [37]$$

where the complex vector \mathbf{X}_0 by eqn [36] is determined as:

$$\mathbf{X}_0 = (-\omega^2 \mathbf{M} + i\omega \mathbf{C} + \mathbf{K})^{-1} \mathbf{F}_0 \quad [38]$$

The amplitudes and phase angles of the displacement parameters can be evaluated from eqns [37] and [38]. As in Figure 8, the amplitude can be plotted versus the excitation frequency. The difference is that the amplitude–frequency curves have multiple peaks, because there are n undamped natural frequencies from the characteristic eqn [21].

Resonance

Without damping ($\xi = 0$), the amplitude given in eqn [34] becomes infinite as the excitation frequency approaches the undamped natural frequency; see also Figure 8. This phenomenon of unbounded response is called resonance and $\omega = \omega_n$ is called the resonance condition. The expression given in eqn [33], however, is unable to describe the gradual growth of the amplitude. The resonant response

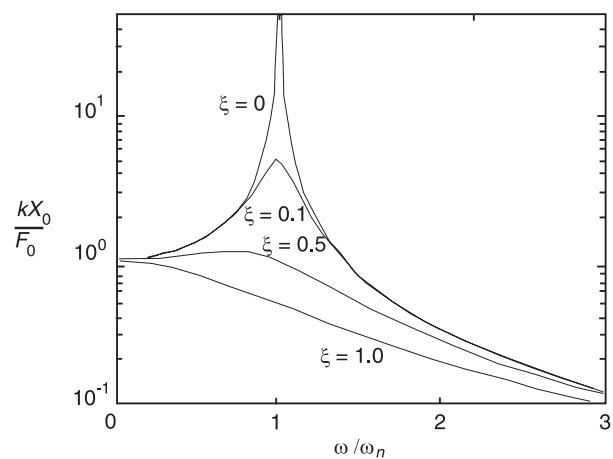

Figure 8 Amplitude of steady-state response versus frequency ratio.

under the harmonic excitation $F_0 \sin \omega_n t$, according to the theory of differential equations, is:

$$x(t) = \frac{F_0}{2m\omega_n} t \sin \omega_n t \quad [39]$$

A plot of the resonant response given in Figure 9 shows the unbounded growth of the vibration amplitude. Physically, the amplitude cannot keep growing, as the spring would be already broken.

The phenomenon of resonance is seen in general vibrating systems. Control of resonant vibrations is critical in many engineering applications. Three commonly used techniques for resonance control, among others, are: (1) passive or active damping, which reduces resonance peaks (see Figure 8); (2) frequency tuning, which shifts the natural frequencies away from the excitation frequencies; and (3) dynamic vibration absorption, which confines the vibration energy within an added vibrating subsystem, called vibration absorber.

Periodic Excitation

Response to arbitrary periodic excitations can be determined by extending the approach given in eqn [33]. In Figure 10, a general periodic forcing function $F(t)$ repeats itself in a fixed time period T (the period), such that $F(t + T) = F(t)$ for all values of t . A sinusoidal function is a periodic function, but the reverse may not be true. A periodic forcing function can be expanded in an infinite series of sinusoidal functions, called the Fourier series:

$$F(t) = \frac{a_0}{2} + \sum_{n=1}^{\infty} (a_n \cos n\omega t + b_n \sin n\omega t) \quad [40]$$

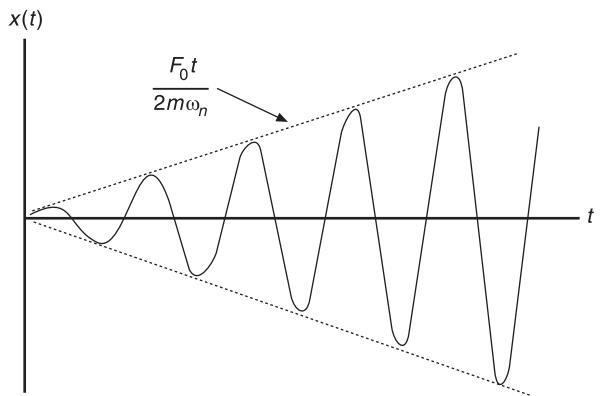

Figure 9 Resonant vibration of an undamped 1-DOF system.

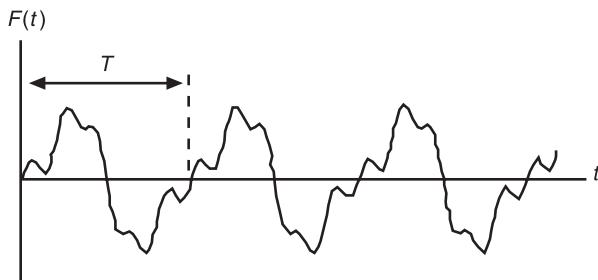

Figure 10 A periodic forcing function.

where $\omega = 2\pi/T$, and the Fourier coefficients a_n and b_n are calculated by the formulas:

$$a_n = \frac{2}{T} \int_0^T F(t) \cos n\omega t dt, \quad n = 0, 1, 2, \dots \quad [41]$$

$$b_n = \frac{2}{T} \int_0^T F(t) \sin n\omega t dt, \quad n = 1, 2, 3, \dots \quad [42]$$

Following the superposition principle, the response to a periodic excitation is the sum of the contributions of all individual harmonic components. For instance, a particular solution of eqn [24] to a periodic force can be written as:

$$x_p(t) = X_0 + \sum_{n=1}^{\infty} X_n \sin(n\omega t + \phi_n) \quad [43]$$

It can be shown that $X_0 = a_0/(2k)$, and $X_n \sin(n\omega t + \phi_n)$ is the solution of:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = a_n \cos n\omega t + b_n \sin n\omega t \quad [44]$$

which can be obtained by following eqns [33] and [34]. The total response of the system is the sum of the particular solution and the homogeneous solution accounting for the initial conditions.

The harmonic analysis given above is also applicable to multi-DOF systems. It should be pointed out that, under periodic excitations, resonance occurs if one of the natural frequencies is identical to $n\omega$ for any integer n .

Impulse Response

A common source of vibrations is the sudden application of large-magnitude, short-duration forces, such

as shock and impact loads. The time history of an impact or shock load in general is difficult to measure. However, its temporal effect can be quantified. For instance, consider a damped 1-DOF system subject to an impulsive force with the time history shown in Figure 11, where the duration ε is arbitrarily small, i.e., $\varepsilon = 0^+$. By the impulse-momentum principle deduced from Newton's second law:

$$\begin{aligned} I_0 &= \int_0^\varepsilon F(t) dt \\ &= m\dot{x}(\varepsilon) - m\dot{x}(0) \\ &= m\dot{x}(0^+) - mv_0 \end{aligned} \quad [45]$$

where I_0 is the impulse of the force. This indicates that the impulsive force causes a jump in the initial velocity, $\Delta\dot{x} = \dot{x}(0^+) - \dot{x}(0) = I_0/m$. Note that $F(t) = 0$ for $t > 0^+$. Thus, the impulse-excited motion is equivalent to the free vibration problem:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = 0, \quad t > 0^+ \quad [46]$$

$$x(0^+) = x_0, \quad \dot{x}(0^+) = v_0 + I_0/m \quad [47]$$

For an underdamped system ($0 < \xi < 1$) initially at rest i.e., x_0 and v_0 , its impulse response is:

$$x(t) = \frac{I_0}{m\omega_d} e^{-\xi\omega_d t} \sin \omega_d t \quad [48]$$

The above analysis is also applicable to multi-DOF systems.

Response to Arbitrary Forces

There are many solution methods for the response to arbitrary external forces, among which are convolution integral, Laplace and Fourier transforms, and modal analysis. In addition, numerical methods, such

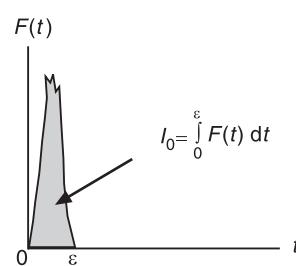

Figure 11 An impulsive force, $\varepsilon = 0^+$.

as finite difference methods and numerical integration, are often used for complex vibrating systems. For demonstrative purposes, a Laplace transform-Green's function approach is briefly discussed here.

Consider the motion of a damped multi-DOF system subject to arbitrary external and initial disturbances:

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) &= \mathbf{f}(t) \\ \mathbf{x}(0) = \mathbf{x}_0, \quad \dot{\mathbf{x}}(0) &= \mathbf{v}_0 \end{aligned} \quad [49]$$

Laplace transformation of eqn [49] with respect to t yields:

$$\hat{\mathbf{x}}(s) = H(s) \left\{ \mathbf{M}\mathbf{v}_0 + \mathbf{C}\mathbf{x}_0 + s\mathbf{M}\mathbf{x}_0 + \hat{\mathbf{f}}(s) \right\} \quad [50]$$

where $\hat{\mathbf{x}}(s)$ and $\hat{\mathbf{f}}(s)$ are the Laplace transforms of $\mathbf{x}(t)$ and $\mathbf{f}(t)$, respectively, s is the complex Laplace transform parameter, and $H(s) = (s^2\mathbf{M} + s\mathbf{C} + \mathbf{K})^{-1}$ is called the transfer function of the system. Inverse Laplace transform of eqn [50] gives the total response:

$$\begin{aligned} \mathbf{x}(t) &= G(t)(\mathbf{M}\mathbf{v}_0 + \mathbf{C}\mathbf{x}_0) \\ &+ \frac{d}{dt} G(t)\mathbf{M}\mathbf{v}_0 + \int_0^t G(t-\tau)\mathbf{f}(\tau) d\tau \end{aligned} \quad [51]$$

where $G(t)$, the inverse Laplace transform of the transfer function $H(s)$, is called the impulse response function or Green's function of the system. Physically, the first two terms of eqn [51] represent vibration due to initial disturbances; the last term represents vibration due to external forces.

Modal Analysis

Modal analysis is a useful technique of analysis and solution for general vibrating systems. Its use depends on the existence of certain orthogonality relations among system eigenvectors (mode shapes). Orthogonality relations are used to decouple the original equations of vibration into a set of independent differential equations. The solution of those decoupled equations yields the response in a series of system eigenvectors. Solution by this technique is usually called modal expansion or eigenfunction expansion. The basic concept of modal analysis is detailed as follows.

First, consider undamped systems modeled by eqn [8]. Under the condition of symmetric mass and stiffness matrices, and the condition of distinct eigenvalues, the eigenvectors defined in eqn [20] share the orthogonality relations:

$$\mathbf{u}_k^T \mathbf{M} \mathbf{u}_l = 0, \quad \mathbf{u}_k^T \mathbf{K} \mathbf{u}_l = 0 \quad \text{for } k \neq l \quad [52]$$

Eigenvectors satisfying the above relations are usually called orthogonal or normal modes. The eigenvectors can be scaled or normalized such that:

$$\mathbf{u}_k^T \mathbf{M} \mathbf{u}_k = 1 \quad [53]$$

The orthogonality relations provide a convenient way of determining a dynamic response to arbitrary excitations. As an example, let the solution be expressed by a series of system eigenvectors:

$$\mathbf{x}(t) = \sum_{k=1}^n q_k(t) \{ \mathbf{u}_k \} \quad [54]$$

where the unknown time-dependent coefficients $q_k(t)$ are called modal coordinates. Eqn [54] represents a real transformation from physical coordinates to modal coordinates. Substitution of the expression [54] into eqn [8], and use of the orthogonality relations [52] and normalization condition [53], leads to n independent second-order differential equations:

$$\ddot{q}_k(t) + \omega_k^2 q_k(t) = \mathbf{u}_k^T \mathbf{f}(t), \quad k = 1, 2, \dots, n \quad [55]$$

which can be easily solved by many methods. With the determined $q_k(t)$, a closed-form modal expansion of the total response is given by eqn [54]. Furthermore, having solved eqn [55], the Green's function in eqn [51] is found to be:

$$G(t) = \sum_{k=1}^n \frac{1}{\omega_k} \sin \omega_k t \cdot \mathbf{u}_k^T \mathbf{u}_k \quad [56]$$

Next, consider the damped systems described by eqn [49]. A system is called proportionally damped if the condition:

$$\mathbf{K} \mathbf{M}^{-1} \mathbf{C} = \mathbf{C} \mathbf{M}^{-1} \mathbf{K} \quad [57]$$

holds. Under this condition, the eigenvalues are complex, but the eigenvectors are real. More importantly, the eigenvectors are the same as those of the corresponding undamped system. Consequently, the eigenvectors enjoy the orthogonality relations given in eqn

[52]. In addition, they also satisfy:

$$\mathbf{u}_k^T \mathbf{C} \mathbf{u}_l = 0 \quad \text{for } k \neq l \quad [58]$$

It follows that the modal expansion, eqn [54], can be directly used to decouple eqn [49] into:

$$\ddot{q}_k(t) + 2\xi_k\omega_k\dot{q}_k(t) + \omega_k^2 q_k(t) = \mathbf{u}_k^T \mathbf{f}(t) \quad [59]$$

for $k = 1, 2 \dots n$, where ξ_k is called the modal damping ratio. The response of the damped system can be obtained in closed form.

If the condition, eqn [57], is not met, the eigenvalues and eigenvectors are both complex. The system is then called nonproportionally damped. Besides nonproportional damping, complex modes are also caused by other effects such as gyroscopic forces induced by mass transport or Coriolis acceleration, and circulatory forces. These complex modes of vibration in general are not orthogonal in the sense of eqns [52] and [58]. As a result, the conventional modal expansion fails to decouple the equations of motion. In this case, complex modal analysis can be adopted. In a complex modal analysis, the original equations of vibration are cast in to a first-order state-space form with the state-space vector $\mathbf{z}(t)$ containing displacements and velocities:

$$\mathbf{z}(t) = \begin{pmatrix} \mathbf{x}(t) \\ \dot{\mathbf{x}}(t) \end{pmatrix} \quad [60]$$

In this form, the orthogonality relations among state-space eigenvectors can be established. Consequently, the state equation is decoupled into a set of independent first-order differential equations, and the modal expansion of the state-space vector is obtained.

Nomenclature

f_s	spring force
g	gravitational acceleration
I_0	impulse of the force
k	spring coefficient or stiffness
K	stiffness differential operator
M	mass differential operator
M_0	external torque
r	frequency ratio
T	tension of the string
v_0	initial velocity
x_0	initial displacement
\ddot{x}	acceleration of the mass
ρ	linear density
ξ_k	modal damping ratio

Introduction

Linear system models are very important in vibration analysis. Linear models enable the designer to obtain a basic understanding of the component interactions in a system. Although nonlinearity exists in real systems, linear modeling and analysis are essential in most cases as they yield simpler mathematical formulation. The principle of superposition plays an extremely important role in mechanical vibrations and dynamic analysis of linear systems.

It is known generally that all physical systems are nonlinear. However, assumptions and approximations are made such that the mathematical model and the resulting equations are linear. This is done for important reasons: the solution of linear problem is feasible and provides a good insight into the system behavior. Also, the results obtained using the linear approximation are often sufficient for many engineering applications. The importance of the principle of linear superposition to vibration analysis is seen by observing some of the following ramifications of the nonvalidity of the superposition to nonlinear systems.

1. Two linearly independent solutions cannot be linearly combined to obtain the solution of a nonlinear second-order differential equation.
2. The general solution to a nonlinear system equation cannot be obtained by a summation of the free vibration and forced vibration responses. This is because of the interaction between the free and forced vibration responses.
3. The development of a convolution integral approach based on the impulse response is not valid for nonlinear systems.
4. Superposition of modes will not be valid for nonlinear systems. This is due to mode coupling.
5. The mathematical techniques, such as Fourier series and Laplace transform, cannot be used to obtain responses of nonlinear systems under combination of excitations.

Thus, it is seen that the superposition is an extremely important part of linear vibration analysis. It enables

a solution of linear system models to a variety of excitations such as periodic functions, transients, modal excitations, etc. In the following section, the applications of the principle of linear superposition to wave addition, system response, convolution integral, and modal superposition are presented. It is to be noted that, although the principle of superposition is quite simple in its statement and application, it has a profound impact on all types of linear systems modeling and analysis.

Linearity and Superposition

Figure 1 shows a linear lumped system model of a single-degree-of-freedom system with mass m , spring stiffness k and viscous damping coefficient c . **Figure 2** shows a black-box model of the single-degree-of-freedom system with a harmonic input, $f(t)$, and solution, $x(t)$. The system equation is given by:

$$m(d^2x/dt^2) + c(dx/dt) + kx = f(t) \quad [1]$$

The principle of superposition says that the harmonic motions can be combined linearly to obtain the total motion. In reference to system analysis, the total response of a linear system can be obtained by the linear combination or addition of the individual responses of the system for the corresponding individual excitations. In other words, for the linear black-box model of **Figure 2**, if $x_1(t)$ and $x_2(t)$ are the harmonic solutions, for the harmonic inputs are $f_1(t)$ and $f_2(t)$ respectively, then the total solution, as shown in **Figure 3**, is given by:

$$x(t) = x_1(t) + x_2(t) \quad [2]$$

It is seen that, whenever linearity holds, the powerful principle of superposition can be applied effectively. Thus, superposition can also be described as that, whenever many waves pass through the same given region, their effects are simply additive. The total solution is obtained by superposition.

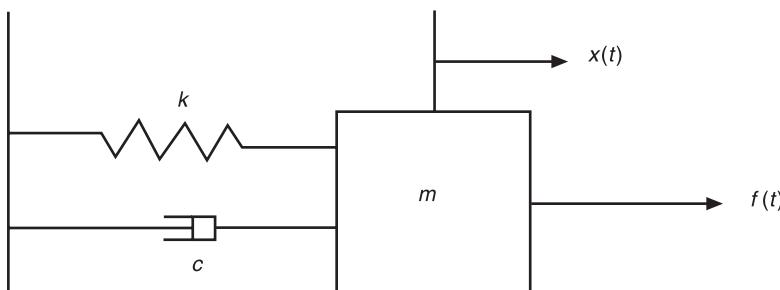

Figure 1 A single-degree-of-freedom system model.

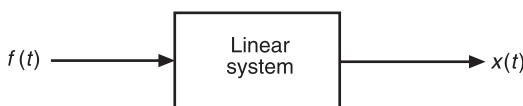

Figure 2 An input–output model of a system.

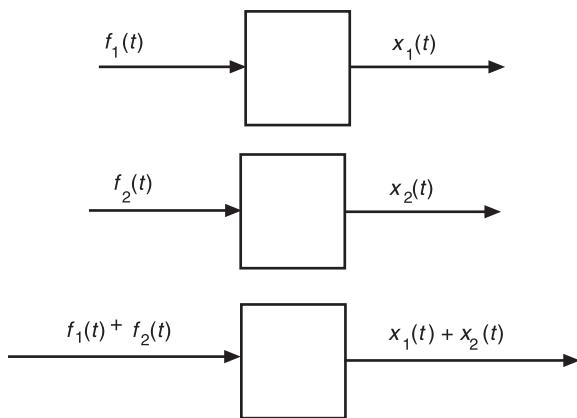

Figure 3 Principle of superposition.

To illustrate the importance of the principle of superposition, let the system shown in Figure 3 have a nonlinear spring in place of a linear spring. Let the nonlinear spring term be $k(x + ex^2)$, where e is the nonlinearity factor. The system equation is given by:

$$m(d^2x/dt^2) + c(dx/dt) + k(x + ex^2) = f(t) \quad [3]$$

By introducing the solutions x_1 and x_2 we get:

$$m(d^2x_1/dt^2) + c(dx_1/dt) + k(x_1 + ex_1^2) = f_1(t) \quad [4]$$

$$m(d^2x_2/dt^2) + c(dx_2/dt) + k(x_2 + ex_2^2) = f_2(t) \quad [5]$$

By adding eqns [4] and [5] and then comparing them with eqn [1] we can see that the following inequality exists due to nonlinearity:

$$(x_1 + x_2)^2 \neq (x_1^2 + x_2^2) \quad [6]$$

Thus solutions x_1 and x_2 for forcing functions f_1 and f_2 respectively, cannot be added to obtain the total solutions.

Applications of Superposition

Addition of Simple Harmonic Waves

In many situations, there is a need to combine the effects of individual vibrations to obtain the superposition effect. Generally, the presence of one vibration does not alter the medium significantly such that the characteristics of the other vibrations are disturbed. Thus the total vibration is obtained by a linear superposition of individual vibrations.

Given that the two displacements have same angular frequency:

$$x_1(t) = A_1 e^{j(\omega t + \phi_1)} \quad \text{and} \quad x_2(t) = A_2 e^{j(\omega t + \phi_2)}$$

The linear superposition from eqn [2] gives:

$$A e^{j(\omega t + \phi)} = (A_1 e^{j\phi_1} + A_2 e^{j\phi_2}) e^{j\omega t} \quad [7]$$

Using phasor representation, the combined effect is shown in Figure 4. The real displacement is given by:

$$x(t) = A \cos (\omega t + \phi) \quad [8]$$

where:

$$A^2 = A_x^2 + A_y^2 \quad \text{and} \quad \phi = \tan^{-1}(A_y/A_x)$$

$$A_x = A_1 \cos \phi_1 + A_2 \cos \phi_2$$

$$A_y = A_1 \sin \phi_1 + A_2 \sin \phi_2$$

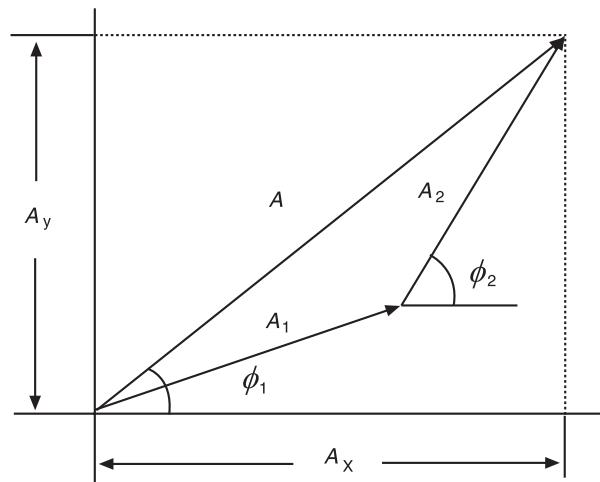

Figure 4 Superposition of two waves of same frequency.

Thus, the linear superposition of two simple harmonic vibrations of the same frequency yields another simple harmonic vibrations of the same frequency. Further, the superposition can be extended to the case where there are n number of simple harmonic vibrations of the same frequency:

$$A = \left[\left(\sum_n A_n \cos \phi_n \right)^2 + \left(\sum_n A_n \sin \phi_n \right)^2 \right]^{1/2} \quad [9]$$

$$\phi = \tan^{-1} \left(\sum_n A_n \sin \phi_n / \sum_n A_n \cos \phi_n \right) \quad [10]$$

When the frequencies of the waves are not identical, then the linear superposition yields a combined solution which is dependent on the ratio of the two frequencies. If the ratio is close to unity, then the well-known beating phenomenon occurs. If the ratio is very large, then a nonperiodic solution results.

System Response

The linear equation of motion of a single-degree-of-freedom system as shown in Figure 1 is given by:

$$m (d^2x/dt^2) + c (dx/dt) + kx = f(t) \quad [11]$$

The total response of the system eqn [6] is given by combining the solutions of the homogeneous part with $f(t) = 0$ and of the nonhomogeneous part with $f(t)$ as a given excitation function. Using the principle of superposition, the total response of the system is given by:

$$x(t) = x_c(t) + x_p(t) \quad [12]$$

where $x_c(t)$ is the complementary solution or free response and $x_p(t)$ is the particular solution or the forced response. It is to be noted that the free response $x_c(t)$ depends on the initial conditions whereas the forced response is dependent on the given particular forcing function $f(t)$.

In addition it is noted that, for given different forcing functions, $f(t)$, the corresponding particular solutions, $x_p(t)$, can be obtained and the total response is given by:

$$x(t) = x_c(t) + x_{p1}(t) + x_{p2}(t) + x_{p3}(t) + \dots \quad [13]$$

In the case of $f(t)$ being a periodic forcing function, the Fourier series approach is used to express the

periodic forcing function in terms of harmonic components. Then by the application of the superposition principle the total response is obtained using the individual responses for the corresponding component of the periodic forcing function.

Superposition Integral

Another important application of the superposition principle is in the case of a linear system under arbitrary excitation. When an undamped linear system is excited by a unit impulse function, then the unit impulse response is given by:

$$h(t) = (1/(m\omega_n)) \sin(\omega_n t) \quad [14]$$

Any arbitrary excitation can be considered to be a series of impulse excitations, as shown in Figure 5. Using an elapsed time variable, $(t - \xi)$, the unit impulse response at time $t = \xi$ is given by $h(t - \xi)$. Then the superposition principle can be used to combine these contributions for the varying amplitudes as per the given function. The response is given by:

$$x(t) = \int_0^t f(\xi) h(t - \xi) d\xi \quad [15]$$

Eqn [15] is the convolution integral and is also referred to as the superposition integral.

Modal Superposition

In dealing with the linear vibrations of a continuous system, the superposition principle is very useful in evaluating the response of the system. The general solution of a wave equation is obtained by the superposition of various normal modes. A property of the normal modes is that they are linearly independent of each other. As an illustration in the case of a transverse vibration of a string, the wave equation is given by (Figure 6):

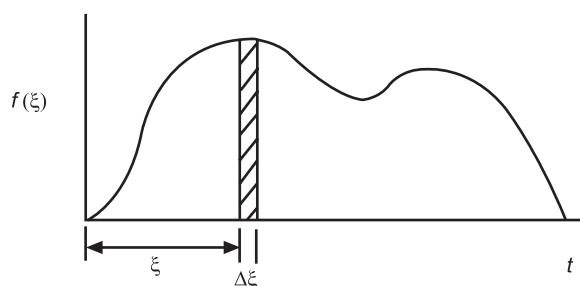

Figure 5 An arbitrary excitation.

$$c^2(\frac{d^2y}{dx^2}) = (\frac{d^2y}{dt^2}) \quad [16]$$

Then, for a prescribed boundary condition such as both ends fixed, the transverse displacements, y , at both ends are zero. Using the superposition principle, the total solution is given by:

$$y(x, t) = \sum_m y_m(x, t) \quad [17]$$

$$y(x, t) = \sum_m \sin(m\pi x/l) \times [C_n \cos(mc\pi t/L) + D_n \sin(mc\pi t/L)] \quad [18]$$

where L is the length of the string, m is the mode number, c is the wave speed, and C_n and D_n are the constants dependent on the initial conditions. Thus

the principle of superposition has resulted in the total solution $y(x, t)$. Figure 6 shows the first three modes and their superposition, which represents the net vibration of the string.

This modal superposition is based on the summation of harmonic motions that is also seen in Fourier series representation of periodic functions. To illustrate the additive effects in superposition, the following example of a square wave is presented. A square wave, $f(t)$, is given by:

$$f(t) = \begin{cases} +1 & 0 < t < T/2 \\ -1 & T/2 < t < T \end{cases} \quad [19]$$

where T is the period of the wave.

It can easily be shown that this wave is represented using the Fourier series as:

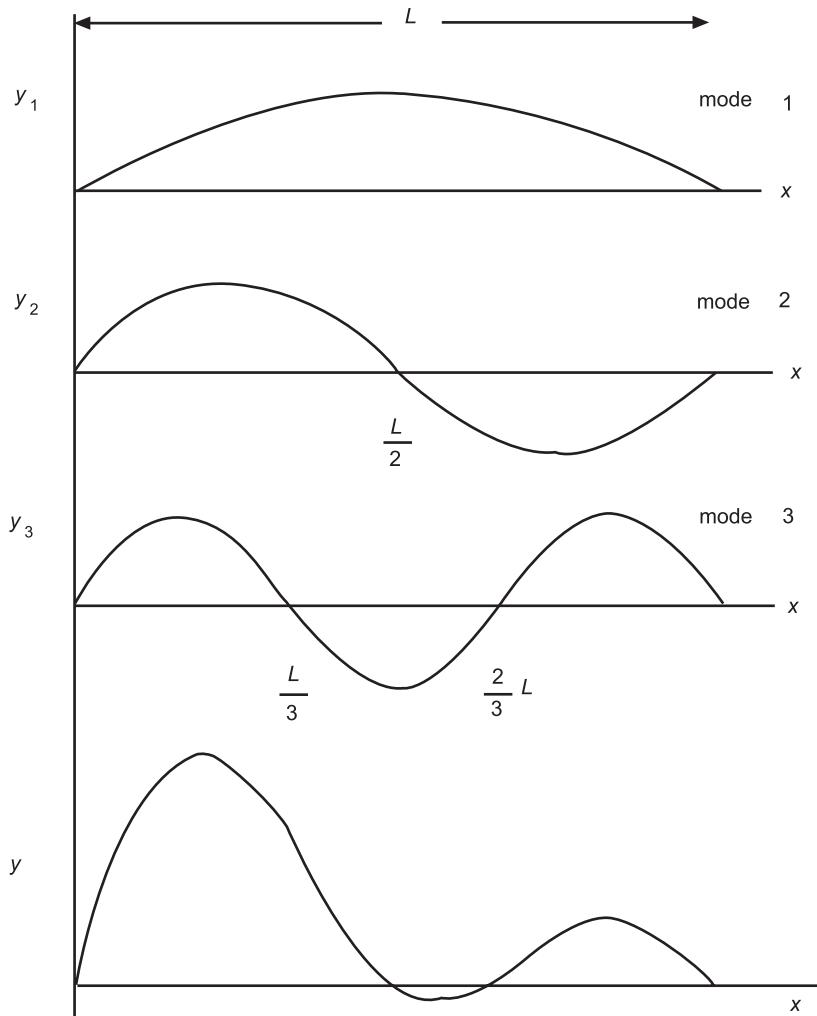

Figure 6 Three normal modes of a vibrating string.

$$f(t) = \frac{4}{\pi} \left(\sin \omega t + \frac{1}{3} \sin 3\omega t + \frac{1}{5} \sin 5\omega t + \dots \right) \quad [20]$$

The superposition of these motions can be seen in Figure 7. The linear addition effect of the superposition is clearly seen as the fundamental wave transforms into a square wave. Thus, the principle of superposition can be used in both ways. This means that sinusoidal waves can be added to obtain the total

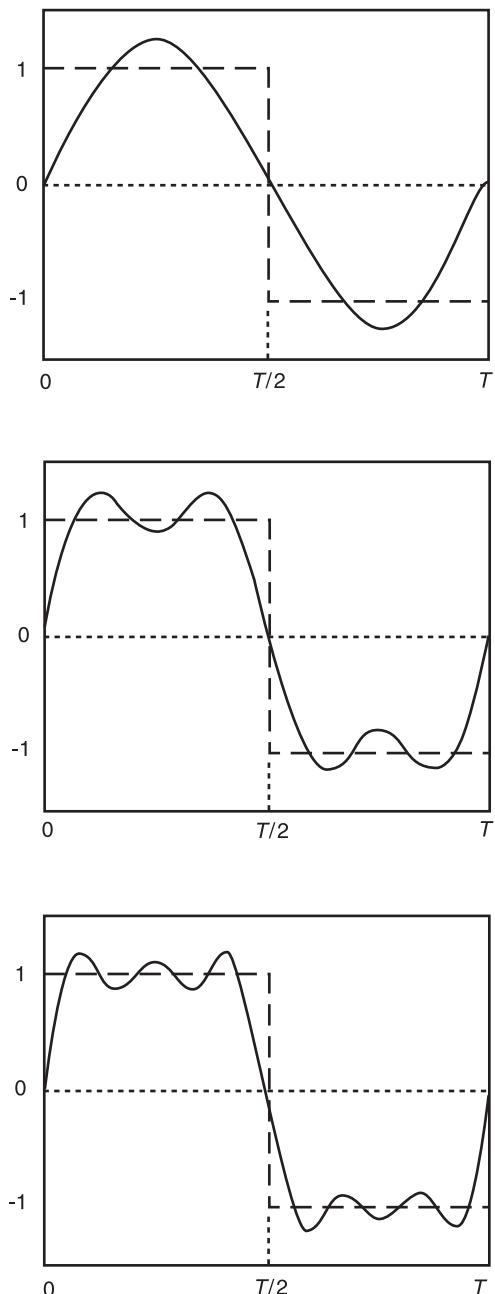

Figure 7 Summation of first three sinusoidal waves.

solution and a periodic wave can also be represented as a summation of sinusoidal waves.

Conclusion

The importance of principle of superposition is seen through its many applications in linear system analysis. An understanding of the application of the principle of superposition is essential in vibration analysis of linear systems. Although most systems are nonlinear in nature, the linearization of the systems gives an insight into the system performance. Such linear analysis of systems in the presence of complex forcing functions is possible mainly due to the principle of linear superposition.

Nomenclature

<i>c</i>	wave speed
<i>e</i>	nonlinearity factor
<i>f(t)</i>	periodic forcing function
<i>L</i>	length of string
<i>m</i>	mode number
<i>T</i>	period of wave

Duhamel's Principle and Convolution

G Rosenhouse, Technion - Israel Institute of Technology, Haifa, Israel

doi:10.1006/rwvb.2001.0113

Duhamel's principle or convolution expresses the solution for a problem as a superposition of a set of solutions of the homogeneous wave equation and certain initial conditions. In problems that involve mechanical vibrations a force-time function that excites a system is replaced by a sequence of pulses that are represented by initial conditions at each segment of time. Now, decreasing the intervals into infinitesimal ones converts the sums into integrals, which are a special case of Duhamel's integral. This procedure allows us to obtain the aforementioned set of solutions. Finally, the total solution is obtained by superposition at any time of interest. Duhamel's principle is useful for either deterministic or random vibrations. For example, it is frequently applied in seismic analysis of structures.

About Duhamel

Jean-Marie Duhamel (1797–1872) studied at the Ecole Polytechnique. He was considered to be a remarkable teacher of mathematics. He was a professor there since 1830 for 39 years, and was elected to the Académie des Sciences in Paris in 1840. He was director of studies at the Ecole Polytechnique for the period 1848–51. In 1851 he took the chair in analysis and also became a professor at the Faculty des Science, Paris.

Duhamel worked on partial differential equations and applied his methods to acoustics, physics of harmonic overtones, rational mechanics, and heat. His acoustical studies involved vibrating strings and vibration of air in cylindrical and conical pipes. He developed a heat theory that is mathematically similar to the work of Fresnel in optics. Duhamel based his theory on the transmission of heat in crystal structures on the works of Fourier and Poisson. Duhamel's principle in partial differential equations was a consequence of his research on the distribution of heat in a solid with a variable boundary temperature.

Duhamel's Theorem: Definitions

The solution $v(x, y, z, t)$ of the boundary value problem with variable source and surface conditions is given in terms of the solution $\phi(x, y, z, t, t')$ of the boundary value problem with constant source and surface conditions by the formula:

$$v(x, y, z, t) = \frac{\partial}{\partial t} \left[\int_0^t \phi(x, y, z, t - t', t') dt' \right] dt \quad [1]$$

where (x, y, z) represents the radius vector of the point of interest in the Cartesian orthogonal spatial

system of coordinates. Other equivalent coordinates systems can also be used.

A very important version of Duhamel's principle is defined as convolution. The convolution of two functions f and g is defined by $f * g$ and is given as:

$$f * g = \int_{-\infty}^{\infty} f(\tau)g(t - \tau) d\tau \quad [2]$$

If the integrals involved with the convolution exist, then it is a linear operation that satisfies:

$$\begin{aligned} (f + h) * g &= f * g + h * g \\ f * (g + h) &= f * g + f * h \end{aligned} \quad [3]$$

The convolution is also commutative:

$$f * g = g * f \quad [4]$$

There are other forms of Duhamel's principle that suit the solution of problems of mechanical and electrical vibrations.

Derivation of the Convolution Theorem from Fourier Transforms

The Fourier transforms of $f(t)$, $g(t)$ and $h(t)$ are, respectively, $F(\omega)$; $G(\omega)$, and $H(\omega)$, with ω as the radian frequency of the signals. We assume the relation $H(\omega) = F(\omega)G(\omega)$, and the aim is to find the time domain relation between the signals $f(t)$, $g(t)$, and $h(t)$. By definition, the use of the Fourier transform yields:

$$\begin{aligned} h(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} (H(\omega)e^{i\omega t}) d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} (F(\omega)G(\omega)e^{-i\omega t}) d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) \left[\int_{-\infty}^{\infty} g(\tau)e^{i\omega t} d\tau \right] e^{-i\omega t} d\omega \end{aligned} \quad [5]$$

Now, by changing the order of integration we have:

$$h(t) = \int_{-\infty}^{\infty} g(\tau) \left[\frac{1}{2\pi} \int_{-\infty}^{\infty} f(\omega)e^{i\omega(t-\tau)} d\omega \right] dt \quad [6]$$

Which, in turn, results in the convolution theorem:

$$\begin{aligned} b(t) &= \int_{-\infty}^{\infty} g(\tau)f(t-\tau) d\tau \\ &= \int_{-\infty}^{\infty} f(\tau)g(t-\tau) d\tau = f(t) * g(t) \end{aligned} \quad [7]$$

Because of its symmetry, a frequency domain convolution can be obtained. Using eqn [7] for the time domain, we obtain:

$$\begin{aligned} H(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t) \left[\int_{-\infty}^{\infty} G(\Omega) e^{i\Omega t} d\Omega \right] e^{-i\omega t} dt \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} G(\Omega) \left[\int_{-\infty}^{\infty} f(t) e^{i(\omega-\Omega)t} dt \right] d\Omega \end{aligned} \quad [8]$$

or:

$$\begin{aligned} H(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} G(\Omega) F(\omega - \Omega) d\Omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\Omega) G(\omega - \Omega) d\Omega \end{aligned} \quad [9]$$

Thus:

$$H(\omega) = \frac{1}{2\pi} F(\omega) * G(\omega) \quad [10]$$

Since Ω is generally complex, $H(\omega)$ is called the complex convolution theorem.

The Engineering Approach

The response of a mechanical system to a step function excitation or to a unit impulse can serve as a tool in the analysis of the response of a linear system to an excitation by an arbitrary function of time. This method is based on the principle of superposition that can be applied to any linear system that can be simulated by a set of linear differential equations. Figure 1A provides a simple illustration where a mass-spring system, with m as the mass and k as the spring constant, is vibrating in the x -direction due to an arbitrary force, $f(\tau)$. If the coefficients of the differential equations of the system are constant, it is assumed that a unit step function or a unit impulse applied at the time τ , as shown in Figures 1B and 1C, respectively, yields a response $x(t)$ as a function of the elapsed time $t - \tau$ only. However, if the coefficients are functions of time this assumption is, in general, not satisfied.

The applied force $f(\tau)$ at the time τ can be split along the time axis into a sequence of step functions Δf , at each time step $\Delta\tau$, as illustrated in Figure 1B, by application of steps at $0, \Delta\tau, 2\Delta\tau, \dots$. This procedure yields a finite difference approximation. A unit step function that begins at τ results in the displacement $\Phi(t - \tau)$ which depends on the properties of the system, and is defined as the indicial admittance of the system. The total displacement $x(t)$ becomes:

$$x(t) = \sum_{\tau=0}^{N(\tau=t)} \Delta f(n\Delta\tau) \Phi(t - n\Delta\tau) \quad [11]$$

If we write $\Delta f = (\Delta f / \Delta\tau)\Delta\tau$, and $n\Delta\tau = \tau$, then:

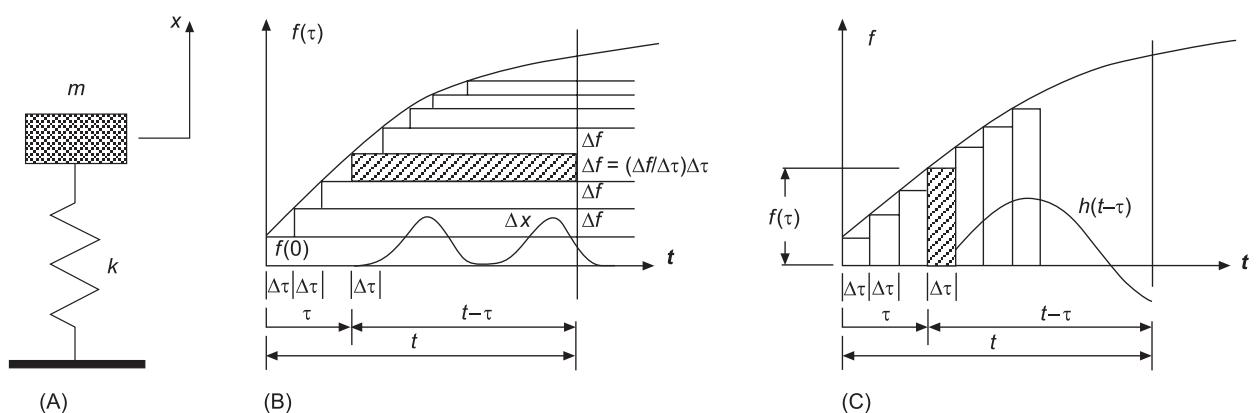

Figure 1 Schemes illustrating Duhamel's principle.

$$x(t) = \sum_{\tau=0}^{\tau=1} \frac{\Delta f}{\Delta \tau} \Phi(t - \tau) \Delta \tau \quad [12]$$

and, in the limit:

$$x(t) = \lim_{\Delta \tau \rightarrow 0} \{x(t)\} = \int_0^t \frac{\Delta f}{\Delta \tau} \Phi(t - \tau) d\tau \quad [13]$$

Eqn [13] has the form of Duhamel's integral that we have met before. By integrating by parts of eqn [13] another version of Duhamel's integral can be obtained:

$$x(t) = \int_0^t f(\tau) \Phi'(t - \tau) d\tau \quad [14]$$

$\Phi'(t - \tau) = h(t - \tau)$. $h(t - \tau)$ is the impulse response function (the response at t to a unit impulse at τ). This result leads to another form of solution, which collects the contributions of discrete impulses $f(\tau)\Delta\tau$, that exist in the interval $\tau = 0$ to $\tau = t$ as shown in Figure 1C, on the displacement $x(t)$:

$$x(t) = \sum_{\tau=0}^{\tau=t} [f(\tau)h(t - \tau)\Delta\tau] \quad [15]$$

In the limit $\Delta\tau \rightarrow 0$, Duhamel's integral or the convolution is obtained:

$$x(t) = \int_0^t f(\tau)h(t - \tau) d\tau \quad [16]$$

An important feature of this approach is that the solution can be expressed in terms of the initial conditions of each step or contribution. If from Figures 1A and 1C we take the impulse at τ and calculate its contribution at the time t , then from the multiplication of the impulsive force $f(\tau)$ by the increment of time Δt , we obtain the impulse $f(\tau)\Delta\tau$. The impulse equals the resulting momentum, $m dx/d\tau$. The initial conditions for the single impulse at τ are: $x(\tau) = 0$, and $dx/d\tau = v(\tau)$. Hence, $v(\tau) = f(\tau)\Delta\tau/m$. We remain with the homogeneous equation of motion of the mass-spring for the incremental contribution Δx of the impulse at τ to the displacement at t :

$$m \frac{d^2 \Delta x(t - \tau)}{d(t - \tau)^2} + k \Delta x(t - \tau) = 0 \quad [17]$$

and the last boundary conditions. Solving eqn [17] and substituting the initial conditions to find the solution constants yields:

$$\Delta x(t - \tau) = \frac{f(\tau)\Delta\tau}{m\omega_0} \sin(\omega_0(t - \tau)) \quad \omega_0 = \sqrt{\left(\frac{k}{m}\right)} \quad [18]$$

Following eqn [16], the whole displacement of the specific problem, at t becomes:

$$\begin{aligned} x(t) &= \int_0^t f(\tau)h(t - \tau) d\tau \\ &= \frac{1}{m\omega_0} \int_0^t f(\tau) \sin(\omega_0(t - \tau)) d\tau \end{aligned} \quad [19]$$

The solution of the contribution $\Delta x(t - \tau)$ for the step function that begins at τ is:

$$\Delta x(t - \tau) = \frac{\Delta f(\tau)}{k} [1 - \cos(\omega_0(t - \tau))] \quad \omega_0 = \sqrt{\left(\frac{k}{m}\right)} \quad [20]$$

and the whole displacement at t becomes:

$$x(t) = \frac{1}{k} \int_0^t \frac{df(\tau)}{d\tau} [1 - \cos(\omega_0(t - \tau))] d\tau \quad [21]$$

Obviously eqns [19] and [21] should lead to the same result. Further development of this formulation includes the addition of damping, etc. These extensions enable us to solve more complicated problems.

In the case of a damped single-degree-of-freedom (SDOF) system, a dashpot is used where a viscous damping coefficient c , is added in parallel to the spring. The equation of motion for an impulse at τ becomes:

$$\begin{aligned} \frac{d^2 \Delta x(t - \tau)}{d(t - \tau)^2} + 2\beta \frac{d\Delta x(t - \tau)}{d(t - \tau)} + \omega_0^2 \Delta x(t - \tau) \\ = \frac{f(\tau)\delta(t - \tau)}{m} \quad \beta = \frac{c}{2m}, \quad \omega_0 = \sqrt{\left(\frac{k}{m}\right)} \end{aligned} \quad [22]$$

and the initial conditions for the single impulse at τ are: $x(\tau) = 0$, and $dx/d\tau = v(\tau)$. Hence,

$v(\tau) = f(\tau)\Delta\tau/m$. Hence, for a damped SDOF system, Duhamel's integral becomes:

$$\begin{aligned} x(t) &= \int_0^t f(\tau)b(t-\tau) d\tau \\ &= \frac{1}{m\omega} \int_0^t f(\tau) \exp[-\beta(t-\tau)] \sin(\omega(t-\tau)) d\tau \\ \omega &= \sqrt{(\omega_0^2 - \beta^2)} = \omega_0 \sqrt{1 - \zeta^2}, \quad \zeta = \beta/\omega_0 \end{aligned} \quad [23]$$

Eqn [16] has some other variants. For example, since all values of $f(\tau)$ at $\tau < 0$ are zero, and the integral from $\tau = -\infty$ to $\tau = t$ is zero, the limits of the integral can be extended to this range. Moreover, since the response function $b(t-\tau)$ for $\tau < t$ is zero (these impulses do not exist so far), the time limits can be extended to the interval $(-\infty, \infty)$ without changing the result of eqn [16]:

$$x(t) = \int_{-\infty}^{\infty} f(\tau)b(t-\tau) d\tau = f * b \quad t \in R \quad [24]$$

The Discrete Time Convolution

Whenever the right-hand side of eqn [17] exists, the discrete time convolution of the discrete time signals becomes:

$$\{f * h\}(t) = \sum_{m=-\infty}^{\infty} f[m]h[n-m] \quad n \in Z \quad [25]$$

Hence, a discrete time convolution is an operator acting on a pair of discrete time signals f and h , resulting in a discrete time signal $f * h$, the value of which at the time n is $\{f * h\}[n]$.

The circular convolution of a finite duration discrete time signal, $\{x[n], y[n]; 0 \leq n \leq N-1\}$, is:

$$\begin{aligned} \{f \otimes h\}[n] \\ = \sum_{m=0}^{N-1} f[m]h[(n-m) \bmod N] \quad 0 \leq n \leq N-1 \end{aligned} \quad [26]$$

This is an operator acting on a pair of N -dimensional vectors f and h , which yields an N -dimensional vector $f \otimes h$, and its n th component is $\{f \otimes h\}[n]$.

Energy Methods

S S Rao, University of Miami, Coral Gables, FL, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0115

Introduction

Energy methods can be used to find the solution of solid mechanics problems without having to solve the governing differential equations. The foundations of energy methods can be traced to the concepts of work, potential energy, and kinetic energy that were introduced by Huygens, Leibniz, Bernoulli, and Lagrange. The energy principles of mechanics are sufficiently general to allow Newton's second law to be deduced from them. The principle of virtual work, first presented by Jean Bernoulli, leads to the principle of minimum potential energy. The principle of complementary energy can be derived from the principle of virtual work by means of Legendre transformation. The principle of minimum complementary energy can be considered as the generalization of Castigliano's theorem. The principle of virtual work, coupled with the concept of inertia force, as presented by D'Alembert, can be used to derive the Hamilton's principle. Lagrange equations of motion can be obtained directly from the Hamilton's principle.

Newton's second law of motion, Lagrange equations, or Hamilton's principle can be used to derive the equations governing the dynamics of rigid bodies as well as vibrating systems. For the solution of equations of motion of a vibrating system, exact methods of solving ordinary and partial differential equations can be used. These methods can only be used for simple systems with simple boundary and initial conditions. Useful approximate solution methods, based on variational principles and energy methods, were devised by Rayleigh, Ritz, Galerkin, and

Plate 51 Shape Memory Alloys. Memory metal. Close-up view of a wire of memory metal being 'educated' by being bent around a spindle. Memory metals are alloys of nickel, titanium and aluminium or copper. Once manufactured in a certain shape the metal may be deformed with little effort, but will regain its shape upon gentle heating. The heat makes the metal plastic, allowing it to return to the structural arrangement in which it was made (its minimum energy configuration). Repeated bending of the metal, each time to the same position, alters the original structure permanently and 'educates' it to a new shape. (With permission from Science Photo Library).

others. Approximate solutions, based on numerical analysis, such as finite difference and finite element methods have also been developed. This article deals with the approximate methods based on energy principles. These methods include the Rayleigh's method and the Rayleigh–Ritz method.

Rayleigh's Method for Discrete Systems

The Rayleigh's method is useful to find an approximate value of the fundamental natural frequency of a vibrating system. The method makes use of energy expression and does not require either the differential equation of motion of the system or its solution. Rayleigh's method can be stated as follows:

The frequency of vibration of a conservative system vibrating about an equilibrium position has a stationary value in the neighborhood of a natural mode. This stationary value, in fact, is a minimum value in the neighborhood of the fundamental natural mode.

Although Rayleigh's method is more useful for continuous than for discrete systems, the method is described for both in this article.

To derive an expression for the approximate value of the first natural frequency of a multi-degree-of-freedom (discrete) system according to Rayleigh's method, let the displacement $x_i(t)$ of mass m_i be of the form:

$$x_i(t) = X_i \sin \omega t \quad [1]$$

where X_i is the amplitude and ω is the frequency. The displacements of all the n masses of the system can be expressed as a vector as:

$$\bar{x}(t) = \bar{X} \sin \omega t \quad [2]$$

where:

$$\bar{x}(t) = \begin{Bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_n(t) \end{Bmatrix} \quad \text{and} \quad \bar{X} = \begin{Bmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{Bmatrix}$$

The kinetic energy of the system can be written as:

$$T(t) = \frac{1}{2} \dot{\bar{x}}(t)^T \bar{M} \dot{\bar{x}}(t) \quad [3]$$

and the potential (strain) energy in the form:

$$U(t) = \frac{1}{2} \bar{x}(t)^T \bar{K} \bar{x}(t) \quad [4]$$

where $\dot{\bar{x}}(t) = (d/dx)(\bar{x}(t))$ is the vector of velocities of the masses:

$$\dot{\bar{x}}(t) = \begin{Bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \\ \vdots \\ \dot{x}_n(t) \end{Bmatrix}$$

\bar{M} is the mass matrix and \bar{K} is the stiffness matrix of the system. Using eqn [2], the kinetic and potential energies can be expressed as:

$$T(t) = \frac{1}{2} \bar{X}^T \bar{M} \bar{X} \omega^2 \cos^2 \omega t \quad [5]$$

$$U(t) = \frac{1}{2} \bar{X}^T \bar{K} \bar{X} \sin^2 \omega t \quad [6]$$

When the system is conservative, the maximum kinetic energy is equal to the maximum potential energy:

$$T_{\max} = U_{\max} \quad [7]$$

Using eqns [5] and [6], eqn [7] can be rewritten as:

$$\frac{1}{2} \bar{X}^T \bar{M} \bar{X} \omega^2 = \frac{1}{2} \bar{X}^T \bar{K} \bar{X} \quad [8]$$

which yields the frequency of vibration as:

$$R = \omega^2 = \frac{\bar{X}^T \bar{K} \bar{X}}{\bar{X}^T \bar{M} \bar{X}} \quad [9]$$

The expression on the right-hand side of eqn [9] is known as Rayleigh's quotient or Rayleigh's function.

Eqn [9] can be used to find an approximate value of the fundamental natural frequency of a system. The procedure involves selecting an arbitrary trial vector \bar{X} to represent the fundamental natural mode. The substitution of the trial vector into eqn [9] yields an approximate value of the fundamental natural frequency. Because of the stationary property of the Rayleigh's quotient, a very good estimate of the fundamental natural frequency can be found even when the trial vector deviates greatly from the exact mode (eigenvector). Naturally, a better value of the fundamental natural frequency can be obtained when the trial vector resembles the first eigenvector more closely.

Stationarity of Rayleigh's quotient

The Rayleigh's quotient is stationary when the vector \mathbf{X} is in the neighborhood of an eigenvector $\mathbf{X}^{(r)}$. To prove this, let the arbitrary vector \mathbf{X} be expressed as a linear combination of the normal modes of the system, $\mathbf{X}^{(i)}$, as:

$$\mathbf{X} = a_1 \mathbf{X}^{(1)} + a_2 \mathbf{X}^{(2)} + \dots \quad [10]$$

where $a_1, a_2 \dots$ are constants. Using eqn [10], the numerator and denominator of the Rayleigh's quotient can be expressed as:

$$\mathbf{X}^T \mathbf{K} \mathbf{X} = a_1^2 \mathbf{X}^{(1)T} \mathbf{K} \mathbf{X}^{(1)} + a_2^2 \mathbf{X}^{(2)T} \mathbf{K} \mathbf{X}^{(2)} + \dots \quad [11]$$

$$\mathbf{X}^T \mathbf{M} \mathbf{X} = a_1^2 \mathbf{X}^{(1)T} \mathbf{M} \mathbf{X}^{(1)} + a_2^2 \mathbf{X}^{(2)T} \mathbf{M} \mathbf{X}^{(2)} + \dots \quad [12]$$

Note that the mixed terms of the form $a_i a_j \mathbf{X}^{(i)T} \mathbf{K} \mathbf{X}^{(j)}$ and $a_i a_j \mathbf{X}^{(i)T} \mathbf{M} \mathbf{X}^{(j)}$, are zero due to the orthogonality property of eigenvectors. The eigenvectors also satisfy the relation:

$$\mathbf{X}^{(i)T} \mathbf{K} \mathbf{X}^{(i)} = \omega_i^2 \mathbf{X}^{(i)T} \mathbf{M} \mathbf{X}^{(i)} \quad [13]$$

Using eqns [11]–[13], eqn [9] can be written as:

$$\begin{aligned} R(\mathbf{X}) &= \omega^2 \\ &= \frac{a_1^2 \omega_1^2 \mathbf{X}^{(1)T} \mathbf{M} \mathbf{X}^{(1)} + a_2^2 \omega_2^2 \mathbf{X}^{(2)T} \mathbf{M} \mathbf{X}^{(2)} + \dots}{a_1^2 \mathbf{X}^{(1)T} \mathbf{M} \mathbf{X}^{(1)} + a_2^2 \mathbf{X}^{(2)T} \mathbf{M} \mathbf{X}^{(2)} + \dots} \end{aligned} \quad [14]$$

If the eigenvectors are M-orthogonalized;

$$\mathbf{X}^{(i)T} \mathbf{M} \mathbf{X}^{(j)} = 1 \quad [15]$$

and eqn [14] reduces to:

$$R(\mathbf{X}) = \omega^2 = \frac{a_1^2 \omega_1^2 + a_2^2 \omega_2^2 + \dots}{a_1^2 + a_2^2 + \dots} \quad [16]$$

If \mathbf{X} differs from the eigenvector $\mathbf{X}^{(r)}$ by a small amount, the constant a_r , will be much larger than all other constants $a_i (i \neq r)$. Hence eqn [16] can be expressed as:

$$R(\mathbf{X}) = \frac{a_r^2 \omega_r^2 + a_r^2 \sum_{\substack{i=1,2,\dots \\ i \neq r}} (a_i/a_r)^2 \omega_i^2}{a_r^2 + a_r^2 \sum_{\substack{i=1,2,\dots \\ i \neq r}} (a_i/a_r)^2} \quad [17]$$

Since $|a_i/a_r| = \varepsilon_i \leq 1$ where ε_i , is a small number for all $i \neq r$, eqn [17] yields:

$$R(\mathbf{X}) = \omega_r^2 \{1 + O(\varepsilon^2)\} \quad [18]$$

with $O(\varepsilon^2)$ denoting a function of ε of the second order. Eqn [18] implies that if the arbitrary vector \mathbf{X} differs from the true eigenvector $\mathbf{X}^{(r)}$ by a small quantity of the first order, $R(\mathbf{X})$ differs from the eigenvalue ω_r^2 by a small quantity of the second order. This shows that the Rayleigh's quotient is stationary in the neighborhood of an eigenvector.

Minimum Value of $R(\mathbf{X})$

The stationary value can be shown to be a minimum in the neighborhood of the fundamental mode, $\mathbf{X}^{(1)}$. To investigate this property, rewrite eqn [17] with $r = 1$:

$$\begin{aligned} R(\mathbf{X}) &= \frac{\omega_1^2 + \sum_{i=2,3,\dots} (a_i/a_1)^2 \omega_i^2}{1 + \sum_{i=2,3,\dots} (a_i/a_1)^2} \\ &\cong \omega_1^2 + \sum_{i=2,3,\dots} (\omega_i^2 - \omega_1^2) \varepsilon_i^2 \end{aligned} \quad [19]$$

In view of the fact that $\omega_i^2 < \omega_1^2$ for $i = 2, 3, \dots$, eqn [19] leads to:

$$R(\mathbf{X}) \geq \omega_1^2 \quad [20]$$

which indicates that Rayleigh's quotient is never lower than the first eigenvalue, ω_1^2 .

Application – Free Vibration of a Rod Carrying an End Mass

The natural frequency of longitudinal vibration of a rod carrying an end mass (Figure 1) is considered. The axial displacement of the cross-section of the rod (under a static load) is assumed to vary linearly along the length of the rod, as shown in Figure 1B. The amplitude of vibration is also assumed to vary linearly, as shown in Figure 1B. If x_0 denotes the amplitude of the rod at $z = L$, the amplitude of vibration (x) of the cross-section at z can be expressed as:

$$x = \frac{x_0 z}{L} \quad [a]$$

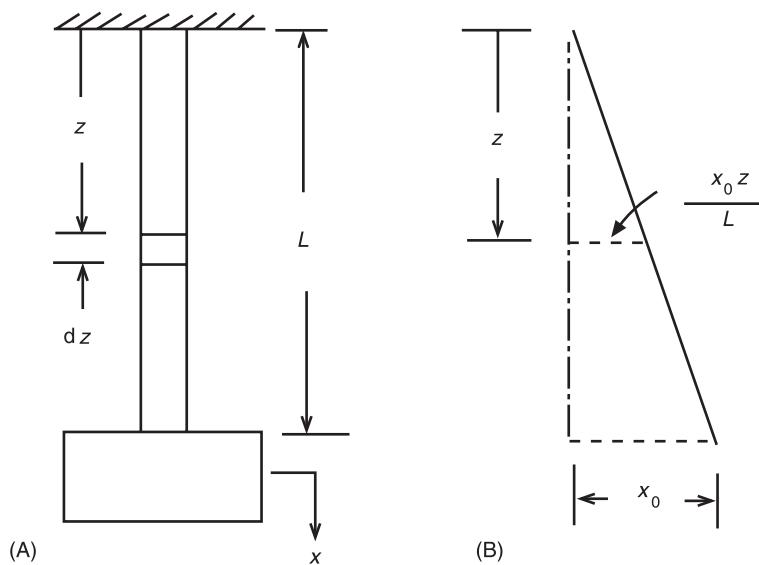

Figure 1 A rod carrying an end mass. (A) System; (B) variation of axial displacement.

When the natural frequency of vibration is ω_n , the maximum velocity of the cross-section is given by:

$$x\omega_n = \frac{x_0z}{L}\omega_n \quad [b]$$

The maximum kinetic energy of an element of the rod of length dz can be expressed as:

$$dT = \frac{1}{2}(\rho dz)\left(\frac{x_0z\omega_n}{L}\right)^2 \quad [c]$$

where ρ is the mass of rod per unit length and ρdz is the mass of the element of length dz . The maximum kinetic energy of the system (rod and the end mass) can be determined as:

$$\begin{aligned} T_{\max} &= \frac{1}{2}M(x_0\omega_n)^2 + \frac{1}{2}\int_0^L \rho\left(\frac{x_0z}{L}\right)^2\omega_n^2 dz \\ &= \frac{1}{2}\left(M + \frac{m_0}{3}\right)x_0^2\omega_n^2 \end{aligned} \quad [d]$$

where $m_0 = \rho L$ is the mass of the rod. The maximum strain energy of the system can be expressed as:

$$U_{\max} = \frac{1}{2}kx_0^2 \quad [e]$$

where $k = (AE)/L$ is the axial stiffness, A = cross-sectional area, and E = Young's modulus of the rod. Equating T_{\max} and U_{\max} , we find that the natural frequency of vibration of the system is:

$$\begin{aligned} \omega_n &= \left(\frac{k}{m_{\text{eq}}}\right)^{1/2} = \left[\frac{k}{M + (m_0/3)}\right]^{1/2} \\ &= \left\{\frac{AE}{L(M + (m_0/3))}\right\}^{1/2} \end{aligned} \quad [f]$$

where $m_{\text{eq}} = M + (m_0/3)$ is the equivalent mass of the system. Eqn [f] shows that one-third of the mass of the rod is to be added to the attached mass to find the equivalent mass of the system.

Application – Natural Frequency of Vibration of a Three-Degree-of-Freedom System

The natural frequency of vibration of the three degree-of-freedom spring-mass system shown in Figure 2 is considered. The strain energy of the system can be expressed as:

$$\begin{aligned} U &= \frac{1}{2}k_1x_1^2 + \frac{1}{2}k_2(x_2 - x_1)^2 + \frac{1}{2}k_3(x_3 - x_2)^2 \\ &= \frac{k}{2}(3x_1^2 + 5x_2^2 + 3x_3^2 - 4x_1x_2 - 6x_2x_3) \end{aligned} \quad [a]$$

The kinetic energy of the system is given by:

$$\begin{aligned} T &= \frac{1}{2}m_1\dot{x}_1^2 + \frac{1}{2}m_2\dot{x}_2^2 + \frac{1}{2}m_3\dot{x}_3^2 \\ &= \frac{m}{2}(\dot{x}_1^2 + 2\dot{x}_2^2 + 3\dot{x}_3^2) \end{aligned} \quad [b]$$

For free vibration, harmonic motion at frequency ω_n , is assumed as:

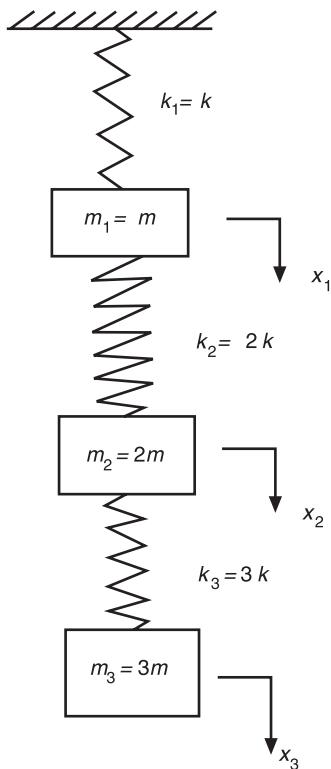

Figure 2 A three-degree-of-freedom spring-mass system.

$$U_{\max} = \frac{k}{2} (3X_1^2 + 5X_2^2 + 3X_3^2 - 4X_1X_2 - 6X_2X_3) \quad [g]$$

$$T_{\max} = \frac{m\omega_n^2}{2} (X_1^2 + 2X_2^2 + 3X_3^2) \quad [h]$$

By assuming the mode shape as:

$$\begin{Bmatrix} X_1 \\ X_2 \\ X_3 \end{Bmatrix} = \begin{Bmatrix} 1 \\ 2 \\ 3 \end{Bmatrix} X_1 \quad [i]$$

where X_1 is the amplitude of vibration of the first mass, the maximum potential and kinetic energies can be expressed as:

$$U_{\max} = 3kX_1^2, \quad T_{\max} = 18mX_1^2\omega_n^2 \quad [j]$$

By setting $T_{\max} = U_{\max}$, the natural frequency of vibration can be found as:

$$\omega_n^2 = \frac{k}{6m} = 0.166667 \frac{k}{m} \quad [k]$$

The exact value of the natural frequency is given by:

$$x_i(t) = X_i \cos \omega_n t, \quad i = 1, 2, 3 \quad [c]$$

$$\omega_n^2 = 0.113992 \frac{k}{m} \quad [l]$$

so that:

$$\dot{x}_i = -\omega_n X_i \sin \omega_n t, \quad i = 1, 2, 3 \quad [d]$$

Substituting eqns [c] and [d] into eqns [a] and [b] yields:

$$U = \frac{k}{2} (3X_1^2 + 5X_2^2 + 3X_3^2 - 4X_1X_2 - 6X_2X_3) \cos^2 \omega_n t \quad [e]$$

$$T = \frac{m\omega_n^2}{2} (X_1^2 + 2X_2^2 + 3X_3^2) \sin^2 \omega_n t \quad [f]$$

Thus, the maximum potential energy (equal to maximum strain energy in the absence of external forces) and maximum kinetic energy are given by:

Rayleigh's Method for Continuous Systems

The eigenvalue problem of a continuous (distributed) system can be expressed, in general terms, as:

$$L(\phi) = \lambda M(\phi) \quad [21]$$

where $L(\phi)$ and $M(\phi)$ are linear homogeneous differential operators of orders p and q , respectively, with $p < q$ and p and q even numbers, λ is the eigenvalue and ϕ is the field variable such as displacement. Eqn [21] is to be satisfied over the domain of the system (D) and $\phi(D)$ denotes the distribution of ϕ over D . If λ_r represents an eigenvalue and ϕ_r the corresponding eigenfunction is:

$$L(\phi_r) = \lambda_r M(\phi_r) \quad [22]$$

The multiplication of eqn [22] by ϕ_r and integration over the domain D gives:

$$\lambda_r = \frac{\int_D \phi_r L(\phi_r) dD}{\int_D \phi_r M(\phi_r) dD} = \frac{\bar{N}(\phi_r)}{\bar{D}(\phi_r)} \quad [23]$$

$$\int_0^L [EA\phi'_r(x)]' \phi_r(x) dx = -\omega_r^2 \int_0^L \rho A(x) \phi_r^2(x) dx \quad [28]$$

where the numerator, $\bar{N}(\phi_r)$, can be shown to be proportional to the strain energy of mode r and the denominator, $\bar{D}(\phi_r)$ can be shown to be proportional to the kinetic energy of mode r . Both $\bar{N}(\phi_r)$ and $\bar{D}(\phi_r)$ are functions of the eigenfunction ϕ_r , and are positive for a positive definite system. Eqn [23] is called the Rayleigh's quotient. The explicit expressions for the Rayleigh's quotient are given below for a few simple cases.

Longitudinal Vibration of a Thin Bar

The equation of motion governing the longitudinal vibration of a thin bar is given by:

$$\frac{\partial}{\partial x} \left(EA \frac{\partial u}{\partial x} \right) = \rho A \frac{\partial^2 u}{\partial t^2} \quad [24]$$

where E = Young's modulus, $A(x)$ = area of cross-section, ρ = density, and $u(x, t)$ = longitudinal displacement. For harmonic motion:

$$u(x, t) = \phi(x) \sin \omega t \quad [25]$$

and eqn [24] becomes:

$$\frac{d}{dx} \left(EA \frac{d\phi}{dx} \right) = -\rho A \omega^2 \phi$$

or:

$$[EA\phi'(x)]' = -\rho A \omega^2 \phi(x) \quad [26]$$

where a prime denotes differentiation with respect to x .

For r th mode, eqn [26] gives:

$$[EA\phi'_r(x)]' = -\rho A \omega_r^2 \phi_r(x) \quad [27]$$

Multiplying eqn [27] by $\phi_r(x)$ and integrating over the length of the bar (L) leads to:

Integrating the left-hand side integral of eqn [28] by parts results in:

$$\begin{aligned} & EA\phi'_r(x)\phi_r(x)|_0^L - \int_0^L EA[\phi'_r(x)] dx \\ &= -\omega_r^2 \int_0^L \rho A[\phi_r(x)]^2 dx \end{aligned} \quad [29]$$

Eqn [29] can be rewritten as:

$$R = \omega_r^2 = \frac{\int_0^L EA[\phi'_r(x)]^2 dx - EA\phi_r(x)\phi'_r(x)|_0^L}{\int_0^L \rho A[\phi_r(x)]^2 dx} \quad [30]$$

For simple boundary conditions such as free ends ($\phi'_r = 0$) and fixed ends ($\phi_r = 0$), eqn [30] reduces to:

$$R = \omega_r^2 = \frac{\int_0^L EA[\phi'_r(x)]^2 dx}{\int_0^L \rho A[\phi_r(x)]^2 dx} \quad [31]$$

The expressions on the right-hand side of eqns [30] and [31] denote Rayleigh's quotients.

Note that eqn [31] can also be derived from potential and kinetic energy expressions. The potential or strain energy of a bar is given by:

$$U(t) = \frac{1}{2} \int_0^L EA \left[\frac{\partial u(x, t)}{\partial x} \right]^2 dx \quad [32]$$

and the kinetic energy by:

$$T(t) = \frac{1}{2} \int_0^L \rho A \left[\frac{\partial u(x, t)}{\partial t} \right]^2 dx \quad [33]$$

Using $u(x, t) = \phi(x) \sin \omega t$, eqns [32] and [33] can be expressed as:

$$U(t) = \frac{1}{2} \sin^2 \omega t \int_0^L EA \left[\frac{d\phi(x)}{dx} \right]^2 dx \quad [34]$$

$$T(t) = \frac{1}{2} \omega^2 \cos^2 \omega t \int_0^L \rho A [\phi(x)]^2 dx \quad [35]$$

Equation U_{\max} to T_{\max} results in eqn [31].

Application – Longitudinal Vibration of a Tapered Rod

Consider the longitudinal vibration of a linearly tapered fixed-free rod shown in Figure 3. The area of cross-section of the rod is given by:

$$A(x) = A_0 \left(1 - \frac{x}{L}\right) \quad [a]$$

where A_0 denotes the area at the root ($x = 0$). The maximum strain energy of the rod can be expressed as:

$$U_{\max} = \frac{1}{2} \int_0^L EA(x) [\phi'_r(x)]^2 dx \quad [b]$$

where $\phi_r(x)$ is the deflection (mode) shape that satisfies the fixed boundary condition. Let $\phi_r(x)$ be assumed as:

$$\phi_r(x) = \sin \frac{\pi x}{2L} \quad [c]$$

so that:

$$\phi'_r(x) = \frac{\pi}{2L} \cos \frac{\pi x}{2L} \quad [d]$$

and:

$$\begin{aligned} U_{\max} &= \frac{1}{2} \int_0^L EA_0 \left(1 - \frac{x}{L}\right) \left(\frac{\pi}{2L}\right)^2 \cos^2 \left(\frac{\pi x}{2L}\right) dx \\ &= \frac{EA_0}{8L} \left(1 + \frac{\pi^2}{4}\right) \end{aligned} \quad [e]$$

The maximum kinetic energy of the rod, during harmonic vibration at frequency ω_n , can be determined as:

$$T_{\max} = \frac{\omega_n^2}{2} \int_0^L \rho A(x) \phi_r^2(x) dx \quad [f]$$

where ρ is the density of the rod. Using eqn [c], we obtain:

$$\begin{aligned} T_{\max} &= \frac{\rho \omega_n^2}{2} \int_0^L A_0 \left(1 - \frac{x}{L}\right) \sin^2 \frac{\pi x}{2L} dx \\ &= \frac{\rho A_0 L \omega_n^2}{8} \left(1 - \frac{4}{\pi^2}\right) \end{aligned} \quad [g]$$

By setting $T_{\max} = V_{\max}$, we obtain:

$$\frac{\rho A_0 L \omega_n^2}{8} \left(1 - \frac{4}{\pi^2}\right) = \frac{EA_0}{8L} \left(1 + \frac{\pi^2}{4}\right) \quad [h]$$

from which:

$$\omega_n^2 = \frac{E \pi^2}{4 \rho L^2} \left(\frac{4 + \pi^2}{\pi^2 - 4}\right) = 5.830356 \frac{E}{\rho L^2} \quad [i]$$

This yields the natural frequency of vibration as:

$$\omega_n = 2.414613 \sqrt{\frac{E}{\rho L^2}} \quad [j]$$

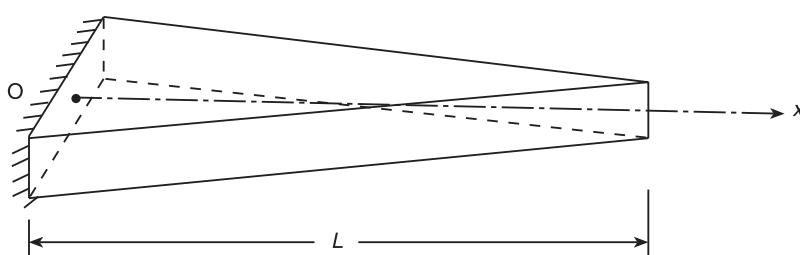

Figure 3 A tapered fixed-free rod.

Transverse Vibration of a String

The equation governing the transverse vibration of a string is given by:

$$\frac{\partial}{\partial x} \left[T(x) \frac{\partial w}{\partial x} \right] = m(x) \frac{\partial^2 w}{\partial t^2} \quad [36]$$

where $T(x)$ is the tension in the string, $m(x)$ is the mass per unit length of string and $w(x, t)$ is the

$$\frac{\partial^2}{\partial x^2} \left[EI(x) \frac{\partial^2 w(x, t)}{\partial x^2} \right] = -\rho A(x) \frac{\partial^2 w(x, t)}{\partial t^2} \quad [40]$$

where E is Young's modulus, $I(x)$ is the area moment of inertia of cross-section, ρ is the density, $A(x)$ is the area of cross-section and $w(x, t)$ is the transverse displacement. When harmonic motion is assumed, $w(x, t) = \phi(x) \sin \omega t$, eqn [40] leads to (for r th mode):

$$R = \omega_r^2 = \frac{\int_0^L EI(x) [\phi_r''(x)]^2 dx + \left\{ [EI(x)\phi_r''(x)]' \phi_r(x) - EI(x)\phi_r''(x)\phi_r'(x) \right\}_0^L}{\int_0^L \rho A(x) [\phi_r(x)]^2 dx} \quad [41]$$

transverse displacement. The Rayleigh's quotient corresponding to eqn [36] is given by:

$$R = \omega_r^2 = \frac{\int_0^L T [\phi_r'(x)]^2 dx}{\int_0^L m [\phi_r(x)]^2 dx} \quad [37]$$

where L is the length of the string, $w(x, t)$ is the $\phi(x) \sin \omega t$ and r th mode is assumed.

Torsional Vibration of a Shaft

The torsional vibration of a shaft is governed by the equation of motion:

$$\frac{\partial}{\partial x} \left[GJ \frac{\partial \theta(x, t)}{\partial x} \right] = J_0 \frac{\partial^2 \theta(x, t)}{\partial t^2} \quad [38]$$

where $GJ(x)$ is the torsional stiffness, G is the shear modulus, $J(x)$ is the polar moment of inertia of the cross-section (for circular sections), $J_0(x)$ is the mass polar moment of inertia is the ρJ for shafts with uniform cross-section, and $\theta(x, t)$ is the angular displacement is $\phi(x) \sin \omega t$ for harmonic motion with frequency ω . The Rayleigh's quotient corresponding to eqn [38] is given by:

$$R = \omega_r^2 = \frac{\int_0^L GJ(x) [\phi_r'(x)]^2 dx}{\int_0^L J_0 [\phi_r(x)]^2 dx} \quad [39]$$

where L is the length of the shaft.

Transverse Vibration of a Thin Beam

The equation of motion governing the bending vibration of thin beams is given by:

where L is the length of the beam. For common boundary conditions such as fixed end ($\phi_r = 0$, $\phi_r' = 0$), pinned end ($\phi_r = 0$, $\phi_r'' = 0$) and free end ($\phi_r'' = 0$, $(EI(x)\phi_r''(x))' = 0$), eqn [41] reduces to:

$$R = \omega_r^2 = \frac{\int_0^L EI(x) [\phi_r''(x)]^2 dx}{\int_0^L \rho A(x) [\phi_r(x)]^2 dx} \quad [42]$$

The expression on the right-hand sides of eqns [41] and [42] are called Rayleigh's quotients.

Application – Transverse Vibration of a Beam with Central Mass

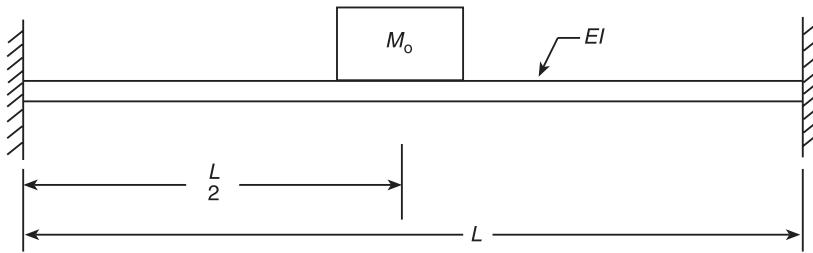

Consider a uniform beam of mass m per unit length and bending stiffness EI , fixed at both ends and carrying a central mass, as shown in Figure 4. The transverse deflection of the beam during free vibration is assumed to be similar to the static deflection shape of a uniform fixed-fixed beam subject to a concentrated load at the middle:

$$\phi_r(x) = \frac{c}{48EI} (3Lx^2 - 4x^3), \quad 0 \leq x \leq \frac{L}{2} \quad [a]$$

where c is a constant, denoting the magnitude of the load applied at the middle of the beam. The maximum strain energy of the beam can be found as:

$$\begin{aligned} U_{\max} &= 2 \left(\frac{EI}{2} \right) \int_0^{L/2} \left(\frac{d^2 \phi_r}{dx^2} \right)^2 dx \\ &= EI \int_0^{L/2} \left[\frac{c}{8EI} (L - 4x) \right]^2 dx = \frac{c^2 L^3}{384EI} \end{aligned} \quad [b]$$

The maximum kinetic energy of the beam and the central mass M_0 can be found as:

**Figure 4** A fixed-fixed beam with a central mass.

$$\begin{aligned} T_{\max} &= 2\left(\frac{m}{2}\right) \int_0^{L/2} \{\phi_r \omega_n\}^2 dx + \frac{M_0}{2} (\phi_r)_{\max}^2 \omega_n^2 \\ &= m \omega_n^2 \int_0^{L/2} \left[\frac{c}{48EI} (3Lx^2 - 4x^3) \right]^2 dx \\ &\quad + \frac{M_0}{2} \omega_n^2 \phi_r^2 \left(x = \frac{L}{2} \right) \\ &= m \omega_n^2 \left(\frac{c}{48EI} \right)^2 L^7 \left(\frac{13}{1120} \right) + \frac{M_0 \omega_n^2}{2} \left(\frac{c}{48EI} \right)^2 \frac{L^2}{16} \end{aligned}$$

[c]

Using the relation $T_{\max} = U_{\max}$, we obtain:

$$\omega_n^2 = \frac{192EI}{L^3 \left(\frac{13}{35} m_0 + M_0 \right)}$$

[d]

where m_0 denotes the mass of the beam.

Transverse Vibration of a Thin Plate

The equation governing the vibration of a thin rectangular plate is given by:

$$\frac{\partial^4 w}{\partial x^4} - 2 \frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} + \frac{m}{D} \frac{\partial^2 w}{\partial t^2} = 0$$

[a]

where $w = w(x, y, t)$ is the transverse deflection, D is the flexural rigidity given by:

$$D = \frac{Eh^3}{12(1-v^2)}$$

[b]

with E is Young's modulus, v is Poisson's ratio, h is the thickness of the plate and m is the mass of the plate per unit area. The strain and kinetic energies of the plate are given by:

$$U = \frac{1}{2} \iint_A D \left\{ \left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} \right)^2 - 2(1-v) \left[\frac{\partial^2 w}{\partial x^2} \frac{\partial^2 w}{\partial y^2} - \left(\frac{\partial^2 w}{\partial x \partial y} \right)^2 \right] \right\} dx dy$$

[c]

$$T = \frac{1}{2} \iint_A m \left(\frac{\partial w}{\partial t} \right)^2 dx dy$$

[d]

where A is the area of the plate. By assuming harmonic motion in r th mode as:

$$w(x, y, t) = \phi_r(x) \sin \omega_r t$$

[e]

the Rayleigh's quotient can be expressed as:

$$R = \omega_r^2 = \frac{\bar{N}}{\bar{D}}$$

[f]

where \bar{N} and \bar{D} are given by:

$$\begin{aligned} \bar{N} &= \iint_A D \left\{ (\phi_{r,xx} + \phi_{r,yy})^2 \right. \\ &\quad \left. - 2(1-v) [\phi_{r,xy}^2 - \phi_{r,xx} \phi_{r,yy}] \right\} dx dy \end{aligned}$$

[g]

$$\bar{D} = \iint_A m \phi_r^2 dx dy$$

[h]

where

$$\phi_{r,xx} = \frac{\partial^2 \phi_r}{\partial x^2}, \quad \phi_{r,yy} = \frac{\partial^2 \phi_r}{\partial y^2}, \quad \phi_{r,xy} = \frac{\partial^2 \phi_r}{\partial x \partial y}$$

A simpler expression can be derived for the approximate natural frequency of transverse vibration of

plates. By considering the plate to be composed of several lumped masses with associated effective spring constants, the natural frequency of vibration in r th mode can be expressed as:

$$\omega_r^2 \approx \frac{g \iint_A \alpha(x, y) \phi_r(x, y) dx dy}{\iint_A \alpha(x, y) \phi_r^2(x, y) dx dy} \quad [i]$$

where $\alpha(x, y)$ is the weight of the plate per unit area, g is the gravitational acceleration and $\phi_r(x, y)$ is the deflection (mode) shape of the plate during vibration. Eqn [i] is known as the modified Rayleigh's quotient or Morley's formula.

Application – Transverse Vibration of a Square Plate

Let the dimensions of the plate be $a \times a$ (Figure 5) and the deflection shape be assumed to be the static deflection shape of the plate under uniformly distributed load as:

$$\phi_r(x, y) = c \sin \frac{\pi x}{a} \sin \frac{\pi y}{a} \quad [a]$$

where:

$$c = 0.00416 \frac{p_0 a^4}{D} = 0.00416 \frac{mga^4}{D} \quad [b]$$

with $p_0 = mg$ is the distributed load (self weight). Substitution of eqn [a] into eqn [i] of the section on Transverse vibration of a thin plate yields:

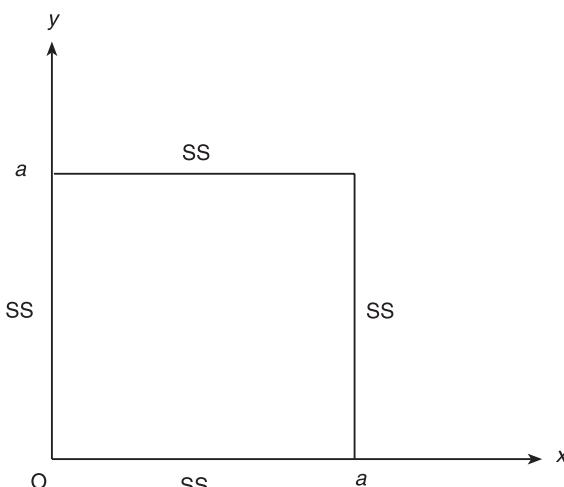

Figure 5 A simply supported square plate. SS = simple support.

$$\begin{aligned} \omega_r^2 &= \frac{g}{c} \left\{ \frac{\int_0^a \int_0^a \sin(\pi x/a) \sin(\pi y/a) dx dy}{\int_0^a \int_0^a \sin^2(\pi x/a) \sin^2(\pi y/a) dx dy} \right\} \\ &= \frac{16g}{c\pi^2} \end{aligned} \quad [c]$$

and hence the frequency of vibration is given by:

$$\omega_r = \frac{19.722}{a^2} \sqrt{\frac{D}{m}} \quad [d]$$

The exact natural frequency of the plate in the fundamental mode is given by:

$$\omega_1 = \frac{19.74}{a^2} \sqrt{\frac{D}{m}} \quad [e]$$

Minimum Value of Rayleigh's Quotient

The Rayleigh's quotient gives an approximate value of the fundamental natural frequency that is higher than the exact value. To show this, let an arbitrary eigenfunction, $\bar{\phi}(x)$, be given by a linear combination of the exact eigenfunctions, $\phi_i(x)$, as:

$$\bar{\phi}(x) = a_1 \phi_1(x) + a_2 \phi_2(x) + \dots = \sum_{i=1}^{\infty} a_i \phi_i(x) \quad [43]$$

where $a_1, a_2 \dots$ are constants. For specificity, consider the Rayleigh's quotient corresponding to the transverse vibration of a thin beam, eqn [42], using eqn [43] for $\phi_r(x)$:

$$\begin{aligned} R &= \frac{\int_0^L EI(x) (\bar{\phi}''(x))^2 dx}{\int_0^L \rho A(x) (\bar{\phi}(x))^2 dx} \\ &= \frac{\int_0^L EI(x) \left(\sum_{i=1}^{\infty} a_i \phi_i''(x) \right)^2 dx}{\int_0^L \rho A(x) \left(\sum_{i=1}^{\infty} a_i \phi_i(x) \right)^2 dx} \end{aligned} \quad [44]$$

The orthogonality of eigenfunctions leads to the following relation (from eqn [42]):

$$R = \frac{\sum_{i=1}^{\infty} k_i a_i^2}{\sum_{i=1}^{\infty} m_i a_i^2} \quad [45]$$

where k_i and m_i denote modal stiffness and modal mass, respectively, in mode i :

$$k_i = \int_0^L EI(x) (\phi_i''(x))^2 dx \quad [46]$$

$$m_i = \int_0^L \rho A(x) (\phi_i(x))^2 dx \quad [47]$$

with:

$$a_i^2 k_i = a_i^2 \omega_i^2 m_i \quad [48]$$

Thus eqn [45] can be rewritten as:

$$R = \frac{\sum_{i=1}^{\infty} a_i^2 \omega_i^2 m_i}{\sum_{i=1}^{\infty} a_i^2 m_i} \quad [49]$$

since $\omega_1 < \omega_2 < \dots$, eqn [49] implies that:

$$\begin{aligned} R &= \frac{\omega_1^2 a_1^2 m_1 + \omega_1^2 (\omega_2/\omega_1)^2 a_2^2 m_2 + \dots}{a_1^2 m_1 + a_2^2 m_2 + \dots} \\ &\geq \frac{\omega_1^2 a_1^2 m_1 + \omega_1^2 a_2^2 m_2 + \dots}{a_1^2 m_1 + a_2^2 m_2 + \dots} = \omega_1^2 \end{aligned} \quad [50]$$

Eqn [50] indicates that the Rayleigh's quotient attains a minimum at the fundamental frequency and any assumed mode shape (eigenfunction) yields an approximate natural frequency that is higher than the exact fundamental frequency.

Rayleigh–Ritz Method

The Rayleigh quotient is defined as:

$$R = \frac{\bar{N}(\phi)}{\bar{D}(\phi)} \quad [51]$$

where ϕ is the eigenfunction. A trial (or approximate) solution $\bar{\phi}(x)$ is chosen for $\phi(x)$ as:

$$\bar{\phi}(x) = \sum_{i=1}^n a_i f_i(x) \quad [52]$$

where a_i are constants, $f_i(x)$ are trial functions satisfying only the essential boundary conditions and n is the number of terms considered in $\bar{\phi}(x)$. The functions $f_i(x)$ are called admissible functions and may not satisfy the natural or free boundary conditions. Basically, by assuming the solution as indicated by eqn [52], the continuous (or infinitely many-degrees-of-freedom) system is approximated by an n -degrees-of-freedom system. When eqn [52] is substituted into eqn [51], one obtains:

$$R = \frac{\bar{N}\left[\sum_{i=1}^n a_i f_i(x)\right]}{\bar{D}\left[\sum_{i=1}^n a_i f_i(x)\right]} \quad [53]$$

Considering R as a function of the unknown constants $a_1, a_2 \dots a_n$, the conditions for the stationarity of R can be stated as:

$$\frac{\partial R}{\partial a_i} = 0, \quad i = 1, 2, \dots, n$$

or:

$$\left[\frac{\bar{D}(\partial \bar{N}/\partial a_i) - \bar{N}(\partial \bar{D}/\partial a_i)}{\bar{D}^2} \right] = 0, \quad i = 1, 2, \dots, n \quad [54]$$

which can be rearranged as:

$$R = \frac{\bar{N}}{\bar{D}} = \frac{(\partial \bar{N}/\partial a_i)}{(\partial \bar{D}/\partial a_i)}, \quad i = 1, 2, \dots, n \quad [55]$$

Eqn [55] yields a set of n equations of the type:

$$\frac{\partial \bar{N}}{\partial a_i} = \lambda_i \frac{\partial \bar{D}}{\partial a_i}, \quad i = 1, 2, \dots, n \quad [56]$$

since the Rayleigh's quotient gives the (approximate) value of the eigenvalue, λ_i . Eqn [56] represents an algebraic eigenvalue problem which can be solved using any of the standard techniques.

The correspondence between eqn [56] and the algebraic eigenvalue problem can be shown by expressing the numerator and denominator of the Rayleigh's quotient of eqn [53], more generally, as:

$$\bar{N}\left[\underline{\phi}(x)\right] = \int_V \underline{\phi}(x) L\left[\underline{\phi}(x)\right] dV \quad [57]$$

$$\bar{D}\left[\underline{\phi}(x)\right] = \int_V \underline{\phi}(x) M\left[\underline{\phi}(x)\right] dV \quad [58]$$

where V is the volume of the body and $L[\cdot]$ and $M[\cdot]$ are the differential operators used in the definition of the eigenvalue problem of the system:

$$L[w] = \lambda M[w] \quad [59]$$

For example, the eigenvalue problem corresponding to the longitudinal vibration of a rod is given by:

$$\frac{d}{dx} \left(EA(x) \frac{dw(x)}{dx} \right) = \lambda m(x) w(x) \quad [60] \quad (\mathbf{k} - \lambda \mathbf{m}) \mathbf{a} = \mathbf{0} \quad [68]$$

where $m(x)$ is the mass per unit length of the rod. In this case, the expressions of $L[\cdot]$ and $M[\cdot]$ can be identified (from eqn [60]) as:

$$L[w] = \frac{d}{dx} \left[EA(x) \frac{dw}{dx} \right] \quad [61]$$

$$M[w] = \rho A(x) w(x) \quad [62]$$

When n terms are used in the assumed solution, eqn [52], eqns [61] and [62] can be used to define the stiffness and mass coefficients as follows:

$$k_{ij} = \int_V f_i L[f_j] dV; \quad i, j = 1, 2, \dots, n \quad [63]$$

$$m_{ij} = \int_V f_i M[f_j] dV; \quad i, j = 1, 2, \dots, n \quad [64]$$

Thus the numerator and denominator of eqn [53] can be expressed as:

$$\begin{aligned} \bar{N} &= \int_V \sum_{i=1}^n a_i f_i L \left[\sum_{j=1}^n a_j f_j \right] dV \\ &= \sum_{i=1}^n \sum_{j=1}^n a_i a_j \int_V f_i L[f_j] dV \quad [65] \\ &= \sum_{i=1}^n \sum_{j=1}^n a_i a_j k_{ij} \end{aligned}$$

$$\begin{aligned} \bar{D} &= \int_V \sum_{i=1}^n a_i f_i M \left[\sum_{j=1}^n a_j f_j \right] dV \\ &= \sum_{i=1}^n \sum_{j=1}^n \int_V f_i M[f_j] dV \quad [66] \\ &= \sum_{i=1}^n \sum_{j=1}^n a_i a_j m_{ij} \end{aligned}$$

Using eqns [65] and [66], eqn [56] can be written, in equivalent form, as:

$$\sum_{j=1}^n (k_{ij} - \lambda m_{ij}) a_j = 0; \quad i = 1, 2, \dots, n \quad [67]$$

In matrix form, eqn [67] becomes:

where:

$$\mathbf{a} = \begin{Bmatrix} a_1 \\ a_2 \\ \vdots \\ \vdots \\ a_n \end{Bmatrix} \quad [69]$$

$\mathbf{k} = k_{ij}$ and $\mathbf{m} = m_{ij}$. Equation [67] or [68] defines an algebraic eigenvalue problem.

Application—Longitudinal Vibration of a Tapered Rod

The natural frequencies of longitudinal vibration of the tapered rod shown in Figure 3 is considered using a three-term solution as:

$$\underline{\phi}(x) = \sum_{i=1}^3 a_i f_i(x) \quad [a]$$

with:

$$f_1(x) = \sin \frac{\pi x}{2L} \quad [b]$$

$$f_2(x) = \sin \frac{3\pi x}{2L} \quad [c]$$

$$f_3(x) = \sin \frac{5\pi x}{2L} \quad [d]$$

where each of the functions $f_i(x)$ satisfies the fixed boundary condition of the problem. Since the area of cross-section of the rod varies as:

$$A(x) = A_0 \left(1 - \frac{x}{L} \right) \quad [e]$$

the operators $L[\cdot]$ and $M[\cdot]$ can be expressed, from eqns [61] and [62], as:

$$L[\cdot] = EA_0 \left\{ \frac{1}{L} \frac{d}{dx} - \left(1 - \frac{x}{L} \right) \frac{d^2}{dx^2} \right\} [\cdot] \quad [f]$$

$$M[\cdot] = \rho A_0 \left(1 - \frac{x}{L} \right) [\cdot] \quad [g]$$

Substituting eqns [a] to [g] into eqns [63] and [64], we obtain the matrices \mathbf{k} and \mathbf{m} as:

$$\mathbf{k} = \begin{bmatrix} k_{11} & k_{12} & k_{13} \\ k_{21} & k_{22} & k_{23} \\ k_{31} & k_{32} & k_{33} \end{bmatrix}$$

$$= \frac{EA_0}{4L} \begin{bmatrix} \left(1 + \frac{\pi^2}{4}\right) & 3 & \frac{5}{9} \\ 3 & \left(1 + \frac{9\pi^2}{4}\right) & 15 \\ \frac{5}{9} & 15 & \left(1 + \frac{25\pi^2}{4}\right) \end{bmatrix} \quad [h]$$

$$\mathbf{m} = \begin{bmatrix} m_{11} & m_{12} & m_{13} \\ m_{21} & m_{22} & m_{23} \\ m_{31} & m_{32} & m_{33} \end{bmatrix}$$

$$= \frac{\rho A_0 L}{4} \begin{bmatrix} \left(1 - \frac{4}{\pi^2}\right) & \frac{4}{\pi^2} & -\frac{4}{9\pi^2} \\ \frac{4}{\pi^2} & \left(1 - \frac{4}{9\pi^2}\right) & \frac{4}{\pi^2} \\ -\frac{4}{9\pi^2} & \frac{4}{\pi^2} & \left(1 - \frac{4}{25\pi^2}\right) \end{bmatrix} \quad [i]$$

The solution of the eigenvalue problem:

$$\mathbf{k}\mathbf{a} = \lambda \mathbf{m}\mathbf{a}$$

gives the eigenvalues of the rod as:

$$\lambda_1 = \omega_1^2 = 5.7837 \frac{E}{\rho L^2}$$

$$\lambda_2 = \omega_2^2 = 30.4878 \frac{E}{\rho L^2}$$

$$\lambda_3 = \omega_3^2 = 75.0751 \frac{E}{\rho L^2}$$

Energy Methods in Finite Element Analysis

Virtual Work Principle

The virtual work principle can be stated as:

$$\int_V \delta \boldsymbol{\epsilon}^T \boldsymbol{\sigma} dV - \int_V \delta \mathbf{u}^T \bar{\mathbf{B}} dV - \int_{S_t} \delta \mathbf{u}^T \bar{\mathbf{t}} dS = 0 \quad [70]$$

where $\boldsymbol{\sigma}$ is the vector of stresses, $\bar{\mathbf{B}}$ is the vector of body forces, $\bar{\mathbf{t}}$ is the vector of prescribed forces or tractions on the surface S_t of the body, V is the volume of the body, $\delta \boldsymbol{\epsilon}$ is the vector of virtual strains, and $\delta \mathbf{u}$ is the vector of virtual displacements that are compatible and consistent with the specified boundary conditions. The virtual work principle can be described as follows. Let an elastic body subject to the forces $\bar{\mathbf{B}}$ and $\bar{\mathbf{t}}$ be in equilibrium. Let the body be given virtual displacements $\delta \mathbf{u}$, corresponding to the forces $\bar{\mathbf{B}}$ and $\bar{\mathbf{t}}$, that are geometrically compatible with the constraints. If $\delta \boldsymbol{\epsilon}$ is the virtual strain vector due to the virtual displacements, then the stress vector must satisfy eqn [70]. Here the forces $\bar{\mathbf{B}}$, $\bar{\mathbf{t}}$ and $\boldsymbol{\sigma}$ are statically compatible and $\delta \mathbf{u}$ and $\delta \boldsymbol{\epsilon}$ are geometrically compatible.

Principle of Minimum Total Potential Energy

When $\boldsymbol{\sigma}$ is expressed as $\boldsymbol{\sigma}(\boldsymbol{\epsilon})$ and $\boldsymbol{\epsilon}$ as $\mathbf{B}\mathbf{u}$ where \mathbf{B} is an appropriate differential operator matrix, then a strain energy function, U , exists such that:

$$\delta U = \int_V \delta \boldsymbol{\epsilon}^T \boldsymbol{\sigma} dV \quad [71]$$

[i] and the virtual work principle will be equivalent to the minimum total potential energy principle. The total potential energy, (π_p), is given by:

$$\pi_p = U(\boldsymbol{\epsilon}) + W(\mathbf{u}) \quad [72]$$

with:

$$W = - \int_V \mathbf{u}^T \bar{\mathbf{B}} dV - \int_{S_t} \mathbf{u}^T \bar{\mathbf{t}} dS \quad [73]$$

[l] and hence eqn [70] is equivalent to $\delta \pi_p = 0$. In words, the principle of minimum total potential energy can be stated as follows. Of all the admissible displacement fields that are consistent with the prescribed boundary conditions, the one that minimizes the potential energy also satisfies the conditions of equilibrium. Thus, by minimizing the potential energy, we can satisfy the equilibrium equations of the body.

Principle of Minimum Total Complementary Energy

Let $\delta \boldsymbol{\sigma}$ be the virtual stress vector satisfying equilibrium with both the body forces and tractions on S_t set to zero. By equating the sum of internal and external virtual work to zero, we have:

$$\int_V \delta \boldsymbol{\sigma}^T \boldsymbol{\epsilon} dV - \int_{S_u} \delta \mathbf{t}^T \bar{\mathbf{u}} dS = 0 \quad [74]$$

where $\bar{\mathbf{u}}$ denotes the vector of prescribed displacements on the boundary S_u and $\delta \mathbf{t} = [E] \delta \boldsymbol{\sigma}$ is the vector of virtual tractions with $[E]$ defining the boundary tractions in terms of stresses. Eqn [74] assures that the boundary displacements on S_u and strains are compatible. Then a complementary strain energy function, U_c , exists such that:

$$\delta U_c = \int_V \delta \boldsymbol{\sigma}^T \boldsymbol{\epsilon} dV \quad [75]$$

By defining the total complementary energy, π_c , as:

$$\pi_c = U_c(\boldsymbol{\sigma}) - \int_{S_u} \mathbf{t}^T \bar{\mathbf{u}} dS \equiv U_c + W_c \quad [76]$$

Eqn [74] is equivalent to $\delta \pi_c = 0$, which is called the principle of minimum total complementary energy. In words, the principle of minimum total complementary energy can be stated as follows. Of all the admissible stress states that satisfy the equations of equilibrium with the given applied loads, the one that minimizes the total complementary energy satisfies the prescribed boundary conditions of displacement.

Hu-Washizu Stationary Principle

The strains are assumed to be related to the displacements as:

$$\boldsymbol{\epsilon} = \mathbf{B}\mathbf{u} \text{ in } V \quad [77]$$

and the displacements at the boundary are assumed to satisfy the prescribed values as:

$$\mathbf{u} - \bar{\mathbf{u}} = \mathbf{0} \text{ on } S_u \quad [78]$$

in defining the potential energy π_p in eqn [72]. By relaxing these constraints, we can define a new function, π_{hw} , as:

$$\pi_{hw} = \pi_p - \int_V \boldsymbol{\lambda}_1^T (\boldsymbol{\epsilon} - \mathbf{B}\mathbf{u}) dV - \int_{S_u} \boldsymbol{\lambda}_2^T (\mathbf{u} - \bar{\mathbf{u}}) dS \quad [79]$$

where $\boldsymbol{\lambda}_1$ and $\boldsymbol{\lambda}_2$ are Lagrange multipliers defined in V and S_u , respectively. By varying each quantity in eqn [79] independently, we can write:

$$\delta \pi_{hw} = \delta \pi_p - \int_V \delta \boldsymbol{\lambda}_1^T (\boldsymbol{\epsilon} - \mathbf{B}\mathbf{u}) dV$$

$$- \int_V \boldsymbol{\lambda}_1^T (\delta \boldsymbol{\epsilon} - \mathbf{B} \delta \mathbf{u}) dV \quad [80]$$

$$- \int_{S_u} \delta \boldsymbol{\lambda}_2^T (\mathbf{u} - \bar{\mathbf{u}}) dS - \int_{S_u} \boldsymbol{\lambda}_2^T \delta \mathbf{u} dS = 0$$

Using the relation:

$$\int_V \boldsymbol{\lambda}_1^T \mathbf{B} \delta \mathbf{u} dV = - \int_V \delta \mathbf{u}^T \mathbf{B}^T \boldsymbol{\lambda}_1 dV + \int_S \delta \mathbf{u}^T [E] \boldsymbol{\lambda}_1 dS \quad [81]$$

where $[E]$ is an operator that gives boundary tractions in terms of stresses and using the variation of π_p given in eqn [72], eqn [80] can be rewritten as:

$$\begin{aligned} & \int_V \delta \boldsymbol{\epsilon}^T (\boldsymbol{\sigma}(\boldsymbol{\epsilon}) - \boldsymbol{\lambda}_1) dV - \int_V \delta \mathbf{u} (\mathbf{B}^T \boldsymbol{\lambda}_1 + \bar{\mathbf{B}}) dV \\ & + \int_{S_l} \delta \mathbf{u}^T ([E] \boldsymbol{\lambda}_1 - \bar{\mathbf{t}}) dS \\ & + \int_{S_u} \delta \mathbf{u}^T ([E] \boldsymbol{\lambda}_1 - \boldsymbol{\lambda}_2) dS - \int_V \delta \boldsymbol{\lambda}_1^T (\boldsymbol{\epsilon} - \mathbf{B}\mathbf{u}) dV \\ & - \int_{S_u} \delta \boldsymbol{\lambda}_2^T (\mathbf{u} - \bar{\mathbf{u}}) dS = 0 \end{aligned} \quad [82]$$

As eqn [82] is true for any variation, we find that the various terms yield the relations:

$$\begin{aligned} \boldsymbol{\lambda}_1 &= \boldsymbol{\sigma}, \quad \mathbf{B}^T \boldsymbol{\lambda}_1 + \bar{\mathbf{B}} = \mathbf{0}, \quad [E] \boldsymbol{\lambda}_1 = \bar{\mathbf{t}} \\ [E] \boldsymbol{\lambda}_1 &= \boldsymbol{\lambda}_2, \quad \boldsymbol{\epsilon} = \mathbf{B}\mathbf{u}, \quad \mathbf{u} = \bar{\mathbf{u}} \end{aligned} \quad [83]$$

Noting that the Lagrange multipliers are given by $\boldsymbol{\lambda}_1 = \boldsymbol{\sigma}$, and $\boldsymbol{\lambda}_2 = \bar{\mathbf{t}}$, the variational principle can be stated as:

$$\delta \pi_{hw} = 0 \quad [84]$$

with:

$$\pi_{hw} = \pi_p(\boldsymbol{\epsilon}, \mathbf{u}) - \int_V \boldsymbol{\sigma}^T (\boldsymbol{\epsilon} - \mathbf{B}\mathbf{u}) dV - \int_{S_u} \mathbf{t}^T (\mathbf{u} - \bar{\mathbf{u}}) dS \quad [85]$$

This is known as the Hu-Washizu stationary principle.

Finite Element Equations

The finite element equations can be derived using any of the energy principles. For example, the use of the principle of minimum total potential energy results in the following finite element equations:

$$\mathbf{KQ} = \mathbf{P} \quad [86]$$

where \mathbf{K} is the stiffness matrix, \mathbf{Q} is the nodal displacement vector and \mathbf{P} is the nodal load vector of the body or assemblage of finite elements given by:

$$\mathbf{K} = \sum_{e=1}^n \mathbf{K}^{(e)} \quad [87]$$

$$\mathbf{K}^{(e)} = \int_{V^{(e)}} \mathbf{B}^T \mathbf{D} \mathbf{B} dV \quad [88]$$

$$\mathbf{P} = \sum_{e=1}^n \left(\mathbf{P}_i^{(e)} + \mathbf{P}_t^{(e)} + \mathbf{P}_b^{(e)} \right) + \mathbf{P}_c \quad [89]$$

Here $\mathbf{K}^{(e)}$ is the element stiffness matrix of element e , n is the total number of finite elements in the body, \mathbf{D} is the elasticity matrix, $\mathbf{P}_i^{(e)}$, $\mathbf{P}_t^{(e)}$, $\mathbf{P}_b^{(e)}$ are the load vectors of element e due to initial strains, tractions, body forces, respectively, \mathbf{P}_c is the vector of concentrated loads at the nodes of the body, and $[\mathbf{N}]$ is the matrix of shape functions used for the variation of displacement within the element e . The element load vectors are given by:

$$\mathbf{P}_i^{(e)} = \int_{V^{(e)}} \mathbf{B}^T \mathbf{D} \boldsymbol{\varepsilon}_0 dV \quad [90]$$

$$\mathbf{P}_t^{(e)} = \int_{S_t^{(e)}} \mathbf{N}^T \bar{\mathbf{t}} dS \quad [91]$$

$$\mathbf{P}_b^{(e)} = \int_{V^{(e)}} \mathbf{N}^T \bar{\mathbf{B}} dV \quad [92]$$

Variational Formulations in Dynamics

The variational formulations are useful to describe motion of a system over an arbitrary period of time. D'Alembert's principle states that:

$$\delta W_I = (\mathbf{F}_k - \dot{\mathbf{B}}_k) \cdot \delta \mathbf{r}_k = 0, \quad k = 1, 2, \dots, N \quad [93]$$

where δW_I is the virtual work done on mass particle k , $\delta \mathbf{r}_k$ is a kinematically admissible virtual displacement (with time held fixed), \mathbf{F}_k is a force acting on mass k , $-\dot{\mathbf{B}}_k$ is the D'Alembert's inertial force (\mathbf{B} is the linear momentum), and N is the number of mass particles.

Hamilton's Principle

The integral of D'Alembert's virtual work expression over an arbitrary period of time is:

$$\int_{t_1}^{t_2} (\mathbf{F}_k - \dot{\mathbf{B}}_k) \cdot \delta \mathbf{r}_k dt = 0 \quad [94]$$

When the virtual displacement vanishes at times t_1 and t_2 and the applied forces possess a potential energy function V , eqn [94] reduces to:

$$\int_{t_1}^{t_2} \delta(T^* - V) dt = \delta\pi_H = 0 \quad [95]$$

where:

$$\pi_H = \int_{t_1}^{t_2} L dt \quad [96]$$

$$L = T^* - V \quad [97]$$

and T^* is the complementary kinetic energy. In Newtonian mechanics, T^* will be same as T , the kinetic energy of the system. Eqn [95] is known as Hamilton's principle and states that 'among all kinematically possible motions in the interval t_1 to t_2 , the actual one is characterized by the stationary condition of the functional π_H '. The stationary conditions of π_H yield the equations of motion of the system.

Complementary Hamilton's Principle

The complementary form of Hamilton's principle can be stated as:

$$\int_{t_1}^{t_2} \delta(T - V^*) dt = \delta\pi_T = 0 \quad [98]$$

where:

$$\pi_T = \int_{t_1}^{t_2} L^* dt \quad [99]$$

$$L^* = T - V^* \quad [100]$$

and T is the kinetic energy and V^* is the complementary potential energy of the system. In words, the complementary form of Hamilton's principle can be stated as 'amongst all possible equilibrating motions in the interval t_1 to t_2 , the actual one is characterized by the stationary condition of the functional π_T '. The stationary conditions of π_T yield the conditions of compatibility.

Lagrange's Equations

The Lagrange's equations can be stated as:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i} \right) - \frac{\partial L}{\partial q_i} = 0, \quad i = 1, 2, \dots, N \quad [101]$$

where $L = T^* - V$ is the Lagrangian, q_i is the generalized displacement and \dot{q}_i is the generalized velocity. In addition to the forces that possess a potential, where generalized forces Q_i (that are not derivable from a potential function) act on the system, then the Lagrange's equations are given by:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i} \right) - \frac{\partial L}{\partial q_i} = Q_i, \quad i = 1, 2, \dots, N \quad [102]$$

Complementary Lagrange's Equations

The complementary form of Lagrange's equations is given by:

$$\frac{d}{dt} \left(\frac{\partial L^*}{\partial \dot{s}_i} \right) - \frac{\partial L^*}{\partial s_i} = S_i, \quad i = 1, 2, \dots, N \quad [103]$$

where $L^* = T - V^*$ is the complementary Lagrangian, s_i is the generalized impulse, and S_i is the generalized velocity.

Principle of Least Action

Although the interval of time t_1 to t_2 is arbitrarily in Hamilton's principle, the limits t_1 and t_2 are fixed. Thus time is held fixed during the variation of the coordinates q_i . The principle of least action can be used when t_1 and t_2 are not fixed:

$$\Delta \int_{t_1}^{t_2} (T + T^*) dt = 0 \quad [104]$$

In words, the principle of least action states that 'amongst all possible motions of conservative systems between any two prescribed configurations, the actual motion will be such as to render the functional in eqn [104] an extremum'.

Using the principle of conservation of energy, $T + V = E = \text{constant}$, the principle of least action can also be expressed as:

$$\Delta \int_{t_1}^{t_2} (L + E) dt = 0 \quad [105]$$

where:

$$L = T^* - V \quad [106]$$

Nomenclature

A	cross-sectional area
B	vector of body forces
D	domain; flexural rigidity
D	elasticity matrix
E	Young's modulus
EI	bending stiffness
g	gravitational acceleration
G	shear modulus
$GJ(x)$	torsional stiffness
h	thickness
I	inertia
$J(x)$	polar moment of inertia
L	length
M_o	mass of the beam
N	matrix of shape functions
P	nodal load vector
Q	nodal displacement vector
S	surface
\mathbf{t}	vector of tractions
T	kinetic energy
$T(x)$	tension in the string
$\bar{\mathbf{u}}$	vector of displacement
$u(x, t)$	longitudinal displacement
$U(t)$	potential (strain) energy
V	volume
$w(x, t)$	transverse displacement
X_i	amplitude
\mathbf{X}	arbitrary vector
v	Poisson's ratio
λ	eigenvalue

ϕ	eigenfunction
ρ	mass of rod; density
σ	vector of stresses

Introduction

Early procedural steps taken in the mathematical analysis of a mechanical vibration problem include: (1) modeling, in which the essentials of a physical system are extracted to produce an idealized model amenable to solution; (2) choosing appropriate coordinates which uniquely describe the system's configuration; and (3) obtaining one or more equations which describe vibration of the modeled system.

The resulting equation(s) of motion (EOM) are ordinary or partial differential equations that govern the manner in which displacements of the system evolve with time. They are used extensively in subsequent analysis and computation in order to predict transient response, steady-state forced vibration, natural frequencies, and mode shapes.

EOM are derived through the application of physical laws and such methods of dynamics as Newton's laws of motion, Lagrange's equation, and Hamilton's principle. For discrete systems, the EOM take the form of ordinary differential equations, while partial differential equations in one or more independent spatial coordinates govern continuous or distributed-parameter models. The mass, stiffness, and damping properties of the model can be constant or time-dependent, and they appear in the EOM as parameters or coefficients of the coordinates and their derivatives. The external forces or torques which are applied to the system in order to excite vibration render the EOM inhomogeneous.

This article presents a brief exposition of EOM, their derivation, mathematical structure, and properties for the illustrative cases of discrete systems having one or more degrees-of-freedom and prototypical models of continuous systems.

Single-degree-of-freedom Models

In the simplest case, a mechanical system can be modeled using methods of lumped parameter analysis whereby motion is described fully by only one time-dependent coordinate. Such a system is termed a 1-degree-of-freedom (DOF) vibration model. Although the transient or steady-state vibration of the system could, in fact, be rather complicated, only one translational or rotational coordinate is presumed necessary to specify within acceptable bounds of accuracy the configuration of the system at any instant. When more than one coordinate becomes necessary, the discrete system is said to have multiple degrees-of-freedom. Figure 1A illustrates the prototypical vibration model having lumped mass m , stiffness k , and damping c elements, in addition to the concentrated external force $F(t)$. The parameters m , c , and k are generally interpreted as being effective values that represent combinations of other, multiple, interconnected components. An example in that regard is several springs that are connected in series and/or parallel connections so as to form a single element of equivalent stiffness k .

In order to obtain the equation of motion, the free-body diagram of the inertia element is drawn as indicated in Figure 1B, and Newton's second law of motion, $f = ma$, for a particle is applied, wherein f

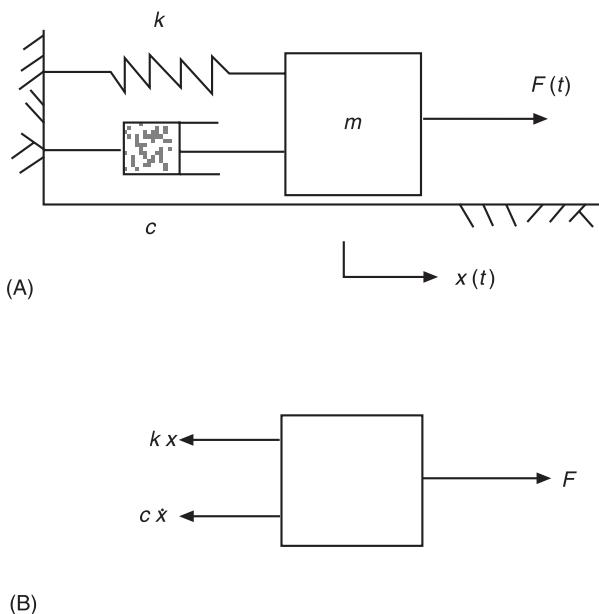

Figure 1 (A) Single-degree-of-freedom vibration model for a particle in translation. (B) Free-body diagram of the inertia element.

represents the resultant force vector, and \mathbf{a} is the particle's absolute acceleration. With displacement measured by the coordinate $x(t)$, the particle's velocity and acceleration are denoted $v = dx/dt = \dot{x}$, and $a = d^2x/dt^2 = \ddot{x}$, respectively. The dot-superscript notation is used conventionally in vibration engineering to denote derivatives taken with respect to time.

With the positive sign convention directed rightward in Figure 1, application of the second law provides $-kx - cx + F = m\ddot{x}$. In its standard form, the EOM is written with all terms involving displacement, velocity, and acceleration on one side, with one or more forcing terms grouped on the other. The final form of the equation of motion becomes:

$$m\ddot{x} + c\dot{x} + kx = F(t) \quad [1]$$

which is a second-order, linear, inhomogeneous, ordinary differential equation having constant coefficients. The solution is found subject to the initial conditions on displacement $x(0) = x_0$ and velocity $\dot{x}(0) = v_0$ as evaluated at $t = 0$. By convention, the EOM is also written:

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x = \frac{F(t)}{m} \quad [2]$$

in terms of the parameters:

$$\omega_n = \sqrt{\frac{k}{m}} \quad \text{and} \quad \zeta = \frac{c}{2\sqrt{mk}} \quad [3]$$

which are the undamped, circular, natural frequency (in units radians per second) and the dimensionless damping ratio.

An analogous procedure is applied to rotational systems, the only distinction being that the principle of angular momentum balance is invoked instead of the second law. The precise form taken by the balance law differs depending on whether it is resolved about a point O fixed in space, the mass center G of a rigid body, or an arbitrary point P ; either method, when properly applied, will result in a valid equation of motion.

When rotational vibration $\theta(t)$ occurs about a fixed point, for instance, $M_0 = J_0\ddot{\theta}$ where M_0 is the resultant moment, J_0 is the mass moment of inertia, and $\ddot{\theta}$ denotes the angular acceleration. For illustration, in Figure 2A, the rigid-body pendulum has centroid located distance L from the support, and oscillation occurs under the restoring influence of gravity g alone. Reactions O_x and O_y produce no moment about the support, and the equation of motion becomes $J_0\ddot{\theta} + mgL \sin \theta = 0$. Due to the explicit presence of the transcendental function, the equation of motion as derived is nonlinear and therefore is valid for arbitrarily large angles of rotation, including multiple clockwise or counterclockwise circulations of the pendulum about O . For the more common circumstance of ‘small’ amplitude motion, the equation of motion is linearized about its stable, trivial, equilibrium point by using the Taylor series expansion $\sin \theta \sim \theta - \theta^3/6 + \dots$, and subsequently retaining only the first-order term. The desired linear EOM then becomes $J_0\ddot{\theta} + mgL\theta = 0$ in the standard form of eqn [1]. The rigid body undergoes free vibration

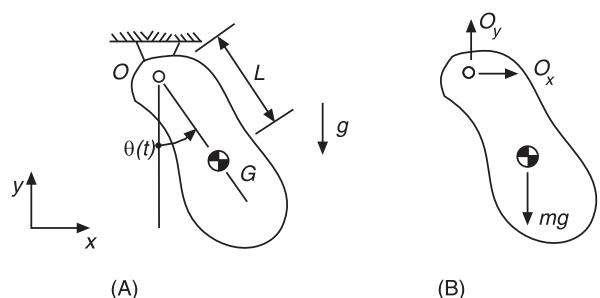

Figure 2 Rotational oscillation of a rigid-body pendulum.

since its equation of motion is homogeneous. In a straightforward application of some practical utility, with both the mass m and offset distance L known, a measurement of the natural frequency can be used to determine the rigid body's mass moment of inertia.

Two or More Degrees-of-freedom Models

For a discrete system that requires more than one coordinate to describe fully its configuration, a system of ordinary differential equations, one written for each coordinate or inertia element, arises. With N such coordinates, the system's overall mass, damping, and stiffness characteristics are embodied by matrices of dimension $N \times N$. Likewise, the translational and/or rotational displacements of individual inertia elements are collected to form an N -dimensional vector, as is also the case for any externally imposed forces or moments that may be present.

In the most general case, the system's matrices will be full, with off-diagonal elements describing the degree of coupling, if any, that exists between the various coordinates. When the mass matrix is not diagonal, for instance, the system is said to be inertially coupled; analogous terminology is applied should off-diagonal elements be present in the damping or stiffness matrices. Such coupling and interaction among the multiple equations of motion is precisely what complicates vibration analysis relative to that seen for a 1-DOF model. By proper choice of coordinates, however, coupling can be reduced, transformed, and even eliminated altogether when modal coordinates are invoked. The latter opportunity motivates the study of normal modes, and provides the emphasis given to them throughout vibration engineering.

In the lumped parameter system of Figure 3A, two masses vibrate with responses $x_1(t)$ and $x_2(t)$ under action of the impressed forces $F_1(t)$ and $F_2(t)$ and the indicated stiffness and damping elements. To establish the equations of motion, the second law is applied to m_1 and m_2 individually using the free-body diagrams of Figure 3B, providing:

$$m_1\ddot{x}_1 + (c_1 + c_2)\dot{x}_1 - c_2\dot{x}_2 + (k_1 + k_2)x_1 - k_2x_2 = F_1(t) \quad [4]$$

$$m_2\ddot{x}_2 - c_2\dot{x}_1 + c_2\dot{x}_2 - k_2x_1 + k_2x_2 = F_2(t) \quad [5]$$

The EOM are then conveniently written in the matrix vector form:

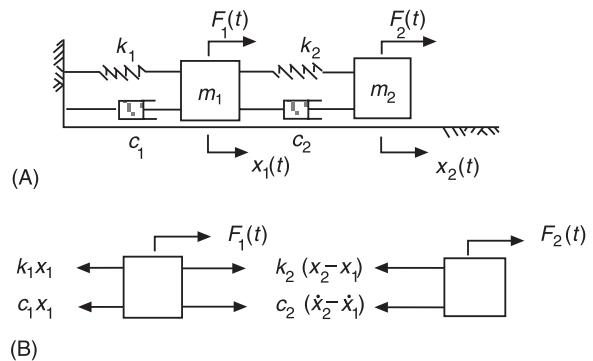

Figure 3 (A) Two-degrees-of-freedom vibration model. (B) Free-body diagrams of the inertia elements.

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} c_1+c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix} + \begin{bmatrix} k_1+k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} F_1(t) \\ F_2(t) \end{Bmatrix} \quad [6]$$

where coupling is present in both damping and stiffness.

More generally, for an N -degrees-of-freedom system subjected to viscous damping forces, the equations of motion will take the form:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{F}(t) \quad [7]$$

where \mathbf{M} , \mathbf{C} , and \mathbf{K} are the mass, stiffness, and damping matrices, and $\mathbf{x}(t)$ and $\mathbf{F}(t)$ are the state and excitation vectors. Solutions are found subject to the initial conditions $\mathbf{x}(0) = \mathbf{x}_0$ and $\dot{\mathbf{x}}(0) = \mathbf{v}_0$.

The precise nature of coupling that arises in the system matrices changes depending on the coordinates that are chosen to describe vibration. In Figure 4, a rigid bar is supported by springs having differing stiffness k_1 and k_2 , and the centroid G is offset from the bar's geometric center. In the first choice of coordinates, translation x of the mass center and rotation θ are used to describe small-amplitude motion, and the equations of motion are:

$$\begin{bmatrix} m & 0 \\ 0 & J_G \end{bmatrix} \begin{Bmatrix} \ddot{x} \\ \ddot{\theta} \end{Bmatrix} + \begin{bmatrix} k_1+k_2 & k_2L_2 - k_1L_1 \\ k_2L_2 - k_1L_1 & k_1L_1^2 + k_2L_2^2 \end{bmatrix} \begin{Bmatrix} x \\ \theta \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix} \quad [8]$$

where m and J_G are the bar's mass and mass moment of inertia about G , respectively. There is no inertial coupling, and the EOM couple statically in stiffness

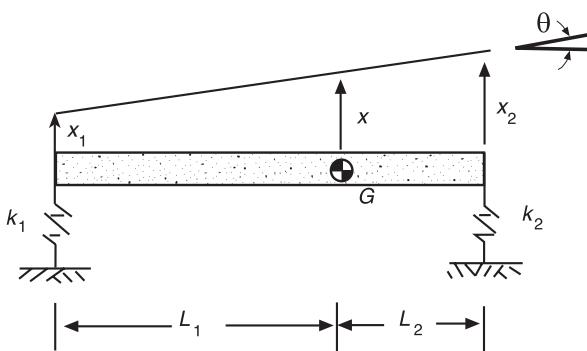

Figure 4 Rigid body with motion described alternatively by (x, θ) or by (x_1, x_2) .

through the off-diagonal elements of \mathbf{K} . With the special parameter values satisfying $k_1L_1 - k_2L_2 = 0$, translational and pitch motions as described by x and θ fully decouple; vibration in that case can be analyzed as if two uncoupled single DOF systems were being treated in parallel. Alternatively, when displacements x_1 and x_2 of the bar's two ends are chosen as coordinates, the equations of motion take the form:

$$\frac{1}{(L_1 + L_2)^2} \begin{bmatrix} mL_2^2 + J_G & mL_1L_2 - J_G \\ mL_1L_2 - J_G & mL_1^2 + J_G \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} k_1 & 0 \\ 0 & k_2 \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix} \quad [9]$$

and the system suffers only inertial coupling. Modal analysis, in short, involves a coordinate transformation which simultaneously decouples both system matrices.

In physical modeling and deriving equations of motion, numerical values for the mass and stiffness parameters can typically be obtained through straightforward analyses or experiments, and they are therefore generally known to within an acceptable level of accuracy. Further, within the context of a conservative mechanical system vibrating about a position of stable equilibrium, substantial theoretical justification exists for the mass and stiffness matrices being symmetric and positive definite, a result which underlies the calculation of normal modes, natural frequencies, and orthogonality among the modes. However, to the degree that a wide variety of energy dissipation mechanisms exists, including internal material damping, friction, sound radiation, and vibration transmission at joints and connections to other structures, damping models, and numerical values for viscous damping coefficients in particular,

are less well-developed. Beyond issues of mathematical convenience and certain restricted cases of laminar fluid flow through a slot or an orifice, there is somewhat less justification for the introduction of the viscous damping matrix \mathbf{C} in an equation of motion.

In certain practical applications, while damping in its various embodiments is recognized as being an important attribute of the system at hand, it will generally not be easily modeled in terms of damping coefficients. In such circumstances and when the effects of damping are judged to be 'light', damping is conventionally ignored insofar as deriving the equations of motion is concerned, so that the EOM are written in terms of \mathbf{M} and \mathbf{K} only. Vibration analysis proceeds with the calculation of natural frequencies and normal modes, on to decoupling of the EOM through modal analysis, at which point dissipation is incorporated within the context of modal damping. In short, an effective damping ratio for each mode, rather than for each physical coordinate as was present in the original model, is introduced with a numerical value determined through appropriate measurements.

The EOM for multiple-degrees-of-freedom systems can also be derived by using the Lagrangian approach of analytical dynamics, which is viewed often as a preferred technique when complicating factors of geometry, kinematics, or modeling are present. Written in terms of the scalar kinetic T and potential U energy functions, Lagrange's equation for each DOF $k = 1, 2, \dots, N$ is:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_k} \right) - \frac{\partial L}{\partial q_k} = Q_k(t) \quad [10]$$

in terms of the Lagrangian function $L = T - U$, the generalized coordinates, $q_k(t)$, and the generalized forces $Q_k(t)$.

Continuous System Models

Although discrete models of mechanical systems are often readily established and can be useful intuitive and predictive tools, in some applications and particularly at moderate or higher frequencies, they are inherently limited by the level of approximation made by lumping mass, stiffness, and damping properties into a relatively small number of elements. To the extent that in all real systems, physical properties are not concentrated at discrete points, the class of continuous or distributed-parameter vibration models provides more accurate structural representations. The higher level of model fidelity, however, is realized

at the expense of EOM having multiple independent variables, both spatial and temporal, and which are commensurately more complicated than their discrete counterparts. The EOM of continuous systems are partial differential equations that govern motion within an elastic body's interior, and they are solved subject to initial conditions in time as well as boundary conditions in space.

A seemingly direct, but primitive, method for deriving the EOM of a continuous system involves approximating it by one that contains a finite number of discrete particles, and then examining the form taken by the EOM as the number of particles becomes large, namely, as the continuous limit is approached. For instance, should more discrete mass, stiffness, and damping elements be added to the configuration of Figure 3, the serial chain would behave in a manner representative of a rod undergoing longitudinal vibration. For that reason, a continuous system can be viewed conceptually as one having infinite degrees-of-freedom, whereby the set of N functions which describe the discrete system's vibration is replaced by a single continuous function as evaluated over a continuum of positions and instants.

While indeed pedagogically useful, such a viewpoint suffers from lack of generality, and so it is not used commonly in practice. The more systematic technique by which to obtain the EOM and boundary conditions is to isolate an infinitesimal element from the body, apply an appropriate constitutive law so as to relate restoring forces or moments to translational or rotational displacements, and invoke Newton's second law or the angular momentum balance principle to a free-body diagram of the element. Specifically, the approach for continuous system vibration models comprises the following major steps:

- Choose coordinates to describe motion of the system and, in particular, an infinitesimal element isolated from it.
- Determine the restoring force/moment-displacement, or stress-strain, relation using an appropriate model applied from strength of materials or elasticity theories.
- Apply force or moment balance principles over the interior of the body to obtain the equation of motion.
- Apply force or moment balance principles over the structure's periphery to obtain the boundary conditions.

In a manner analogous to the utility of Lagrange's equation in analyzing discrete systems, more sophisticated approaches are available for deriving the EOM of continuous systems, including treatments

of three-dimensional vibration, continuum mechanics, and elastic-wave propagation. For structures having coupling between motions, complicated kinematics, or certain constitutive properties, application of the extended Hamilton's principle:

$$\int_{t_1}^{t_2} (\delta T - \delta U + \delta W_{NC}) dt = 0 \quad [11]$$

from the field of analytical dynamics can be a preferred starting point in deriving the EOM and boundary conditions. Here T and U are expressions for the kinetic and potential energies, δ denotes variation, and δW_{NC} is the nonconservative virtual work.

Rod, String, and Shaft Vibration

A simple model of continuous system vibration, and one which enjoys significant practical application, describes longitudinal motion of a rod wherein material particles oscillate in a direction aligned with the rod's axis. The resulting deformation includes local tension and compression, which can be viewed within the context of propagation and superposition of tension and compression waves. Figure 5A illustrates the geometry in which the rod is fixed to a rigid support at its end $x = 0$, free at the other end $x = L$, and excited by the distributed force-per-unit-length $f(x, t)$ directed along the rod's axis. Motion is measured by $u(x, t)$, a function of longitudinal position and time.

In the strength of materials theory for uniaxial tension and compression, the rod deforms with axial stiffness $EA(x)$, where E and A denote local values of the elastic modulus and cross-sectional area, and the product is not necessarily constant. With reference to the free-body diagram of Figure 5B, the internal elastic force within the rod at any point is EAu_x , where the comma-subscript notation is used

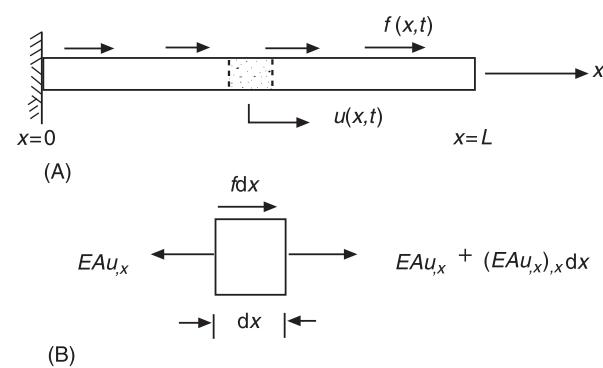

Figure 5 (A) Longitudinal vibration of an elastic rod. (B) Free-body diagram of an infinitesimal element isolated from the rod's interior.

conventionally to indicate a partial derivative, which in this case is taken with respect to x . Application of Newton's second law to the element provides:

$$(\rho A dx) u_{,tt} = -EAu_{,x} + \left(EAu_{,x} + (EAu_{,x})_{,x} dx \right) + f dx \quad [12]$$

where ρ is the material's volumetric density, and the internal force within the rod has already been expanded in a Taylor series about $x = 0$. The equation of motion becomes:

$$\rho A u_{,tt} - (EAu_{,x})_{,x} = f(x, t) \quad [13]$$

which is solved subject to initial conditions on displacement u and velocity $u_{,t}$ at time $t = 0$, as well as boundary conditions that are applied to u and/or $u_{,x}$ at $x = 0$ and L .

Various boundary conditions are possible and admissible depending on the manner in which the rod is supported. One condition must be applied at each end of the rod. In the presence of a built-in support at either end, for instance, the displacement at that point vanishes. Should an end of the rod be free, the tension or compression internal to the rod would likewise vanish at that point, providing the condition $EAu_{,x} = 0$. In cases involving interactions at the boundary between the rod and other components modeled as ideal discrete elements, the appropriate expression for the boundary condition is derived by constructing the free-body diagram of an isolated boundary element, as suggested by the examples given in Figure 6.

When no external forces act on the rod, and the density, cross-sectional area, and elastic modulus do not vary along its length, the EOM assumes the form:

$$u_{,tt} - c^2 u_{,xx} = 0 \quad [14]$$

of the standard-wave equation, where $c = \sqrt{E/\rho}$ is the speed at which tension and compression waves propagate. The wave equation enjoys a rich history in the theory of vibration, and it describes a variety of physical phenomena beyond longitudinal rod vibration. With appropriate substitutions, the wave equation also describes the transverse vibration of a pretensioned flexible string, and the torsional vibration of an elastic shaft – analogies which are outlined further in Figure 7.

Beam Vibration

A beam is defined as a structural member that is long relative to its cross-sectional dimensions, and that executes small amplitude motion v in the direction transverse to its axis, as illustrated in Figure 8A. The most elementary and widely used treatment of beam deformation is attributed to Euler and Bernoulli, and it specifies that the beam's rotary inertia and deformation in shear are each negligible. Those assumptions are relaxed in the Timoshenko beam model, which offers higher-order accuracy at the expense of additional analytical complexity.

In the free-body diagram of Figure 8B for an element that has been isolated from the beam, the internal shear V and bending moment M are expanded in Taylor series about $x = 0$, and their gradients across the element dx produce imbalances in force or moment necessary to generate the requisite acceleration and vibration. With EI denoting the beam's flexural rigidity, subject to the standard restrictions implicit in the linear moment curvature $M = EIv_{,xx}$ and shear $V = -(EIv_{,xx})_{,x}$ relationships invoked from the strength of materials theory, the equation of motion for transverse bending vibration of the beam becomes:

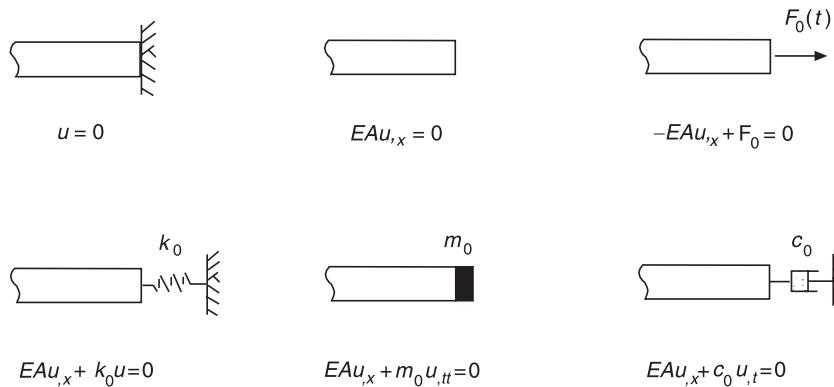

Figure 6 Examples of boundary conditions applied to the longitudinal vibration of an elastic rod, as evaluated on the right-hand end of the rod.

System	Motion	Equation of Motion	Wave Speed, c
Rod	Axial $u(x, t)$	$\rho A u_{,tt} - E A u_{,xx} = 0$	$\sqrt{E/\rho}$
String	Transverse $v(x, t)$	$\rho A v_{,tt} - P v_{,xx} = 0$	$\sqrt{P/\rho A}$
Shaft	Torsional $\theta(x, t)$	$I \theta_{,tt} - JG \theta_{,xx} = 0$	$\sqrt{JG/I}$

Figure 7 Analogies between the longitudinal vibration of a rod, transverse vibration of a string, and torsional vibration of a shaft, for cases in which the models' properties are lengthwise constant. In the string model, P denotes the pre-tension. In the shaft model, JG is the torsional rigidity, and I is the polar moment of inertia per unit-length of the shaft.

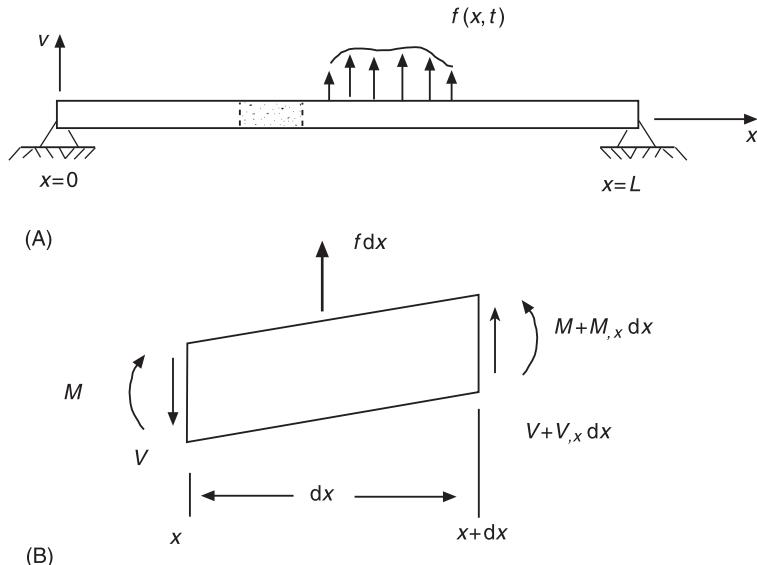

Figure 8 (A) Transverse bending vibration of a beam. (B) Free-body diagram of an infinitesimal interior element.

$$\rho A v_{,tt} + (EI v_{,xx})_{,xx} = f(x, t) \quad [15]$$

where $f(x, t)$ is the transverse force-per-unit-length. The EOM is a linear partial differential equation and, because it is fourth-order, it is necessary to specify two conditions at each point on the beam's boundary.

Specifically, either kinematic conditions on displacement or slope, or force conditions on shear or moment, can be imposed in accordance with specific restrictions on the combinations of conditions that are allowable. For a simply supported beam, the boundary conditions become $v = 0$ and $EI v_{,xx} = 0$.

Conversely, the set of conditions $v_{,x} = 0$ and $EI v_{,xx} = 0$ at the same point cannot be physically realized and is therefore inadmissible. For a clamped-free beam, the kinematic conditions $v = v_{,x} = 0$ are specified at $x = 0$, with vanishing shear and moment at $x = L$ through $EI v_{,xx} = (EI v_{,xx})_{,x} = 0$. Those conditions and others are briefly outlined in Figure 9.

Membrane and Plate Vibration

Membranes and plates are two-dimensional structures that vibrate in the direction transverse to their equilibrium plane. A membrane has negligible

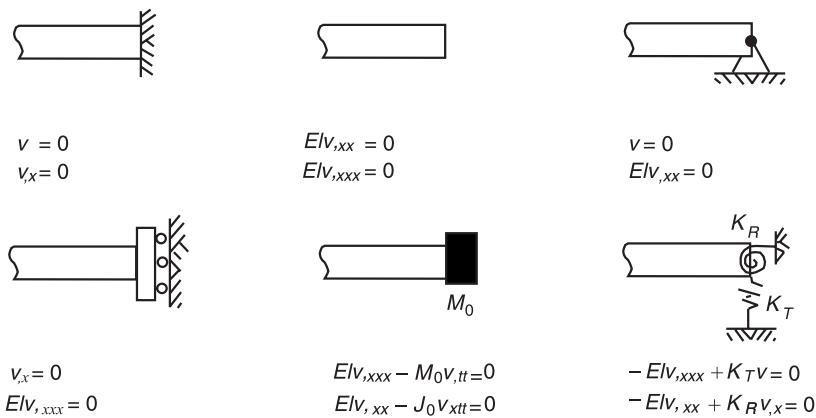

Figure 9 Examples of boundary conditions for lateral bending vibration of a beam, as evaluated on its right-hand end.

bending rigidity and derives restoring stiffness from its initial pretension; a plate, on the other hand, develops curvature-related bending stress as it deforms. In that sense, the more elementary string and beam models are interpreted as being one-dimensional realizations of membranes and plates, respectively.

For a membrane, the equation of motion in rectangular coordinates (x, y) is:

$$\rho h v_{,tt} - (N_x v_{,xx} + N_y v_{,yy}) = f(x, t) \quad [16]$$

where h is the material's thickness, N_x and N_y are the initial tensions-per-unit-length resolved along the coordinate directions, and $f(x, t)$ denotes the transverse force applied per unit of the membrane's surface area. When the tension field is isotropic, $N_x = N_y = N_0$, the EOM takes on its standard form:

$$\rho h v_{,tt} - N_0 \nabla^2 v = f(x, t) \quad [17]$$

in terms of the Laplacian operator in either Cartesian coordinates:

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \quad [18]$$

or polar coordinates (r, θ):

$$\nabla^2 = \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} \quad [19]$$

The most straightforward boundary conditions that can be considered are the constrained $v = 0$ and free $v_{,n} = 0$ cases, the latter of which requires vanishing slope in the direction normal to the

membrane's boundary, namely, a directional derivative. Along a free edge of constant x , for instance, the condition becomes $v_{,x} = 0$. Other conditions which account for coupling between the membrane and discrete inertia, stiffness, or damping elements on the boundary are treated by application of appropriate balance laws to infinitesimal elements of the membrane isolated in a free-body diagram.

In the case of a plate's bending vibration, the EOM is:

$$\rho h v_{,tt} + D \nabla^4 v = f(x, t) \quad [20]$$

in terms of the biharmonic operator $\nabla^4 = (\nabla^2)^2$. The plate's stiffness parameter, analogous to the familiar flexural rigidity from the strength of materials theory for beam deformation, is defined:

$$D = \frac{Eh^3}{12(1-\nu^2)} \quad [21]$$

in terms of the plate's thickness h , elastic modulus E , and Poisson ratio ν . Because the equation of motion is fourth-order, two conditions must be specified at each point on the plate's boundary. Those conditions are expressed in terms of requirements on the displacement, slope, bending moment, or equivalent shear force along the plate's edges.

Special-interest Topics

Other topics which are related to the derivation, structure, and properties of the equations of motion for discrete and continuous systems, but which are

not discussed in this section for reasons of brevity, include:

- Gyroscopic systems where small-amplitude vibration occurs in the presence of a steady superposed motion. Applications include the vibration of rotating disks and shafts, and such translating media as power transmission belts and sheet metal webs.
- Nonconservative forces, including the follower-type loading of the classical Beck or Pflüger problem in the field of dynamic stability, which render the stiffness matrix nonsymmetric.
- Parametric excitation which is present when a parameter in a vibration model, such as rotation speed or tension, is time-dependent and, in particular, periodic.
- Nonlinear systems wherein motion is of sufficiently large amplitude that nonlinear terms must be retained in the equations of motion, complicating their analysis and solution.
- Discretization in which a continuous system model is systematically reduced to an equivalent, potentially high-DOF, discrete model. Local or global techniques such as finite element, Galerkin, and Ritz comprise a powerful class of methods available for developing accurate approximate solutions to the EOM.
- Linear operators for mass, damping, and stiffness effects which are a mathematical formalism facilitating the analysis of continuous system vibration, particularly with respect to modal analysis.

Nomenclature

A	cross-sectional area
E	elastic modulus
$\mathbf{F}(t)$	excitation vector
G	centroid
T	kinetic energy
U	potential energy
$\mathbf{x}(t)$	state vector velocity
δ	variation
$\theta(t)$	rotational vibration
$\ddot{\theta}$	angular acceleration
ρ	density
∇	Laplacian operator

Substructuring

M Sunar, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0117

Substructuring is usually carried out for a vibrating structure, which is large in order. The substructuring can result in substantial savings in computations. The goal in substructuring is to reduce the order of the structure without changing many vibrational characteristics of the remainder. The truncation can be done on those coordinates whose effects are relatively insignificant in vibrations of the structure. Furthermore, if various substructures are analyzed by different people, assembling them by the use of substructuring methods may be very beneficial to predict the complete structural behavior. Among many substructuring methods, three basic ones are considered here: the Rayleigh–Ritz and Guyan reduction methods, and component mode synthesis.

The Rayleigh–Ritz Method

The Rayleigh–Ritz method is used to estimate eigenvalues and eigenvectors (eigenfunctions) of a discrete (continuous) vibrating structure on its reduced-order model. The difficulty with this method lies in the selection of Ritz basis vectors. The rate of convergence of the eigenproblem solution largely depends on the choice of these basis vectors. Guyan reduction

method and component mode synthesis discussed in the following sections are basically Rayleigh–Ritz methods with certain Ritz basis vectors (see **Basic principles**).

Guyan Reduction Method

Static Condensation

Static condensation method can be used to reduce the order of the vibrating structure for approximating its eigenvalues and eigenvectors. The structure is usually discretized using the finite element procedure, which may yield a mass matrix with some zero diagonal elements due to the usage of lumped mass matrix. The method is applied to the structure to reduce its order on the degrees-of-freedom (DOF) corresponding to these zero diagonal elements.

Consider the eigenproblem for the whole (full-order) structure:

$$\mathbf{K}\phi = \lambda\mathbf{M}\phi \quad [1]$$

Assume that some lumping is done on \mathbf{M} and the problem is written in the partitioned form as:

$$\begin{bmatrix} \mathbf{K}_{AA} & \mathbf{K}_{AB} \\ \mathbf{K}_{BA} & \mathbf{K}_{BB} \end{bmatrix} \begin{bmatrix} \phi_A \\ \phi_B \end{bmatrix} = \lambda \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_{BB} \end{bmatrix} \begin{bmatrix} \phi_A \\ \phi_B \end{bmatrix} \quad [2]$$

The following relation can be written from eqn [2]:

$$\mathbf{K}_{AA}\phi_A + \mathbf{K}_{AB}\phi_B = \mathbf{0} \quad [3]$$

and hence:

$$\phi_A = -\mathbf{K}_{AA}^{-1}\mathbf{K}_{AB}\phi_B \quad [4]$$

Substituting ϕ_A in eqn [2] yields:

$$\mathbf{K}_B\phi_B = \lambda\mathbf{M}_{BB}\phi_B \quad [5]$$

where:

$$\mathbf{K}_B = \mathbf{K}_{BB} - \mathbf{K}_{BA}\mathbf{K}_{AA}^{-1}\mathbf{K}_{AB} \quad [6]$$

It can be shown that the static condensation method is a Rayleigh–Ritz method with Ritz basis vectors given as:

$$\Psi = \mathbf{K}^{-1}\mathbf{F} \quad [7]$$

where \mathbf{F} is defined as:

$$\mathbf{F} = \begin{bmatrix} \mathbf{0} \\ \mathbf{I}_{BB} \end{bmatrix} \quad [8]$$

General Method

The finite element model of the structure yields undamped equations of motion (EOM) of the form:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f} \quad [9]$$

Consider any l th substructure of the structure (**Figure 1**) whose EOM are written in the partitioned form as:

$$\begin{bmatrix} \mathbf{M}_{AA} & \mathbf{M}_{AB} \\ \mathbf{M}_{BA} & \mathbf{M}_{BB} \end{bmatrix}_l \begin{bmatrix} \ddot{\mathbf{x}}_A \\ \ddot{\mathbf{x}}_B \end{bmatrix}_l + \begin{bmatrix} \mathbf{K}_{AA} & \mathbf{K}_{AB} \\ \mathbf{K}_{BA} & \mathbf{K}_{BB} \end{bmatrix}_l \begin{bmatrix} \mathbf{x}_A \\ \mathbf{x}_B \end{bmatrix}_l = \begin{bmatrix} \mathbf{f}_A \\ \mathbf{f}_B \end{bmatrix}_l \quad [10]$$

where the subscript A denotes the DOF to be condensed (slave DOF) and B represents the DOF to be retained (master DOF). The above equation can be expressed as:

$$\begin{bmatrix} \mathbf{K}_{AA} - \mathbf{M}_{AA}\omega^2 & \mathbf{K}_{AB} - \mathbf{M}_{AB}\omega^2 \\ \mathbf{K}_{BA} - \mathbf{M}_{BA}\omega^2 & \mathbf{K}_{BB} - \mathbf{M}_{BB}\omega^2 \end{bmatrix}_l \begin{bmatrix} \mathbf{u}_A \\ \mathbf{u}_B \end{bmatrix}_l = \begin{bmatrix} \bar{\mathbf{f}}_A \\ \bar{\mathbf{f}}_B \end{bmatrix}_l \quad [11]$$

Eqn [11] is due to the fact that if a force in the form of:

$$f = \sum_{j=1}^r \bar{f}_j e^{i\omega_j t} \quad [12]$$

is applied, then the substructural response can be written as:

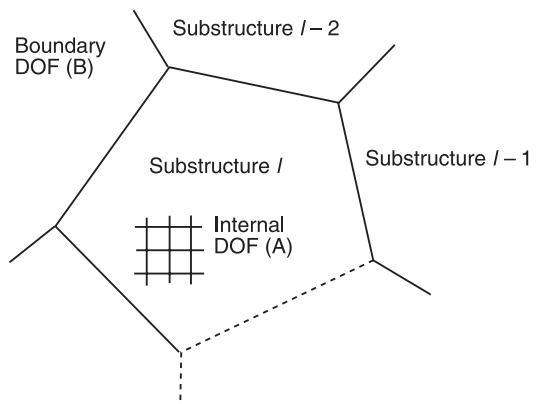

Figure 1 A typical l -th substructure.

$$u = \sum_{j=1}^r u_j e^{i\omega_j t} \quad [13]$$

$$\mathbf{M}_l^* \ddot{\mathbf{x}}_{Bl} + \mathbf{K}_l^* \mathbf{x}_{Bl} = \mathbf{f}_l^* \quad [21]$$

where:

The assumption of no applied force at the slave DOF ($\bar{\mathbf{f}}_A = 0$) yields:

$$[\mathbf{K}_{AA} - \mathbf{M}_{AA}\omega^2]_l \mathbf{u}_{Al} + [\mathbf{K}_{AB} - \mathbf{M}_{AB}\omega^2]_l \mathbf{u}_{Bl} = 0 \quad [14]$$

which can be used to condense the slave DOF as:

$$\mathbf{u}_{Al} = -[\mathbf{K}_{AA} - \mathbf{M}_{AA}\omega^2]_l^{-1} [\mathbf{K}_{AB} - \mathbf{M}_{AB}\omega^2]_l \mathbf{u}_{Bl} \quad [15]$$

Equation (15) can be approximated as:

$$\mathbf{u}_{Al} = -\mathbf{K}_{AA/l}^{-1} [\mathbf{I} + \mathbf{M}_{AA}\mathbf{K}_{AA}^{-1}\omega^2]_l [\mathbf{K}_{AB} - \mathbf{M}_{AB}\omega^2]_l \mathbf{u}_{Bl} \quad [16]$$

which is further approximated by:

$$\mathbf{u}_{Al} = -\mathbf{K}_{AA/l}^{-1} \mathbf{K}_{AB/l} \mathbf{u}_{Bl} \quad [17]$$

For the approximation in eqn [17] to be justified, coefficients of ω^2 must be small. In other words, entries of \mathbf{M}_{AA} and \mathbf{M}_{AB} must be much smaller than those of \mathbf{K}_{AA} and \mathbf{K}_{AB} . This means low mass and high stiffness for the areas of slave DOF. Eqn [17] can also be justified if ω is taken to be nearly zero. This implies that the frequencies of the applied force are small compared to the natural frequencies of the structure. From eqn [17], slave nodal displacements are also condensed as:

$$\mathbf{x}_{Al} = -\mathbf{K}_{AA/l}^{-1} \mathbf{K}_{AB/l} \mathbf{x}_{Bl} \quad [18]$$

The nodal displacement vector is now written as:

$$\mathbf{x}_l = \begin{bmatrix} \mathbf{x}_A \\ \mathbf{x}_B \end{bmatrix}_l = \mathbf{T}_{AB/l} \mathbf{x}_{Bl} \quad [19]$$

The transformation matrix $\mathbf{T}_{AB/l}$ in the above equation is given by:

$$\mathbf{T}_{AB/l} = \begin{bmatrix} -\mathbf{K}_{AA/l}^{-1} \mathbf{K}_{AB/l} \\ \mathbf{I}_{BB} \end{bmatrix}_l \quad [20]$$

Substituting eqn [19] in eqn [10] and premultiplying the resulting equation by $\mathbf{T}_{AB/l}^T$ yield:

$$\begin{aligned} \mathbf{M}_l^* \ddot{\mathbf{x}}_{Bl} + \mathbf{K}_l^* \mathbf{x}_{Bl} &= \mathbf{f}_l^* \\ \mathbf{M}_l^* &= \mathbf{T}_{AB/l}^T \mathbf{M}_l \mathbf{T}_{AB/l} \\ \mathbf{K}_l^* &= \mathbf{T}_{AB/l}^T \mathbf{K}_l \mathbf{T}_{AB/l} \\ \mathbf{f}_l^* &= \mathbf{T}_{AB/l}^T \mathbf{f}_l \end{aligned} \quad [22]$$

The EOM for the whole structure can be written as:

$$\mathbf{M}^* \ddot{\mathbf{x}}_B + \mathbf{K}^* \mathbf{x}_B = \mathbf{f}^* \quad [23]$$

where:

$$\begin{aligned} \mathbf{x}_B &= \sum_{l=1}^n \mathbf{x}_{Bl}, \quad \mathbf{f}^* = \sum_{l=1}^n \mathbf{f}_l^* \\ \mathbf{M}^* &= \sum_{l=1}^n \mathbf{M}_l^*, \quad \mathbf{K}^* = \sum_{l=1}^n \mathbf{K}_l^* \end{aligned} \quad [24]$$

The summations in eqn [24] must be conformable. The EOM of the reduced-order structure given by eqn [23] are solved for \mathbf{x}_B . Thereafter, \mathbf{x}_{Al} for each substructure is recovered from eqn [18].

Component Mode Synthesis

In the constraint mode method of the component mode synthesis, vibrational mode shapes and general nodal displacements at the boundary are included for the l th substructure. The vibrational mode shapes are normal modes of the substructure with totally constrained boundary DOF. On the other hand, the boundary displacements occur due to successive generalized unit displacements at boundary DOF, while all other boundary DOF are totally constrained.

The component mode synthesis relates the internal displacements to the vibrational mode shapes and boundary displacements for the l th substructure shown in Figure 1. This relation is given by:

$$\mathbf{x}_{Al} = \boldsymbol{\Phi}_l \mathbf{x}_M - \mathbf{K}_{AA/l}^{-1} \mathbf{K}_{AB/l} \mathbf{x}_{Bl} \quad [25]$$

The generalized displacement vector \mathbf{x}_l for the l th substructure can be expressed as:

$$\mathbf{x}_l = \begin{bmatrix} \mathbf{x}_A \\ \mathbf{x}_B \end{bmatrix}_l = \mathbf{T}_l \begin{bmatrix} \mathbf{x}_M \\ \mathbf{x}_B \end{bmatrix}_l = \mathbf{T}_l \mathbf{x}_l^* \quad [26]$$

where:

$$\mathbf{T}_l = \begin{bmatrix} \boldsymbol{\Phi} & -\mathbf{K}_{AA}^{-1}\mathbf{K}_{AB} \\ \mathbf{0} & I_{BB} \end{bmatrix}_l \quad [27]$$

The generalized displacement vector \mathbf{x}_l in eqn [26] couples modal coordinates with boundary displacements. The original EOM for the l th substructure are assumed as:

$$\mathbf{M}_l \ddot{\mathbf{x}}_l + \mathbf{K}_l \mathbf{x}_l = \mathbf{f}_l \quad [28]$$

The order of this equation is reduced by substituting eqn [27] and premultiplying the resulting equation by \mathbf{T}_l^T . The reduced-order EOM are now expressed as:

$$\mathbf{M}_l^* \ddot{\mathbf{x}}_l^* + \mathbf{K}_l^* \mathbf{x}_l^* = \mathbf{f}_l^* \quad [29]$$

where:

$$\begin{aligned} \mathbf{M}_l^* &= \mathbf{T}_l^T \mathbf{M}_l \mathbf{T}_l \\ \mathbf{K}_l^* &= \mathbf{T}_l^T \mathbf{K}_l \mathbf{T}_l \\ \mathbf{f}_l^* &= \mathbf{T}_l^* \mathbf{f}_l \end{aligned} \quad [30]$$

The reduced-order EOM for the whole structure are given by:

$$\mathbf{M}^* \ddot{\mathbf{x}}^* + \mathbf{K}^* \mathbf{x}^* = \mathbf{f}^* \quad [31]$$

where \mathbf{M}^* , \mathbf{K}^* and \mathbf{f}^* are found via comformable summations as in eqn [24]. Eqn [31] for the reduced-order structure can be solved for \mathbf{x}^* . Thereafter, \mathbf{x}_A for each substructure is computed from eqn [25].

The component mode synthesis is also a Rayleigh-Ritz method. The Ritz basis vectors are found as in eqn [7], where \mathbf{F} now contains eigenvectors due to the inclusion of vibrational mode shapes. \mathbf{F} is given by:

$$\mathbf{F} = \begin{bmatrix} \vdots & \dots & \vdots & \dots \\ \boldsymbol{\Phi}_{l-1} & \dots & \mathbf{0} & \dots \\ \mathbf{0} & \dots & \mathbf{I}_{l-1,l} & \dots \\ \boldsymbol{\Phi}_l & \dots & \mathbf{0} & \dots \\ \mathbf{0} & \dots & \mathbf{0} & \dots \\ \vdots & \dots & \vdots & \dots \\ \boldsymbol{\Phi}_n & \dots & \mathbf{0} & \dots \end{bmatrix} \quad [32]$$

Nomenclature

\bar{f}_j	magnitude of j th force component
\mathbf{I}	identity matrix

n	number of substructures in structure
u_j	magnitude of j th component of structural response
\mathbf{x}_A	nodal vector of internal generalized displacements
\mathbf{x}_B	nodal vector of generalized displacements at boundary
\mathbf{x}_M	vector of modal coordinates
ϕ	eigenvector
λ	eigenvalue

Impulse Response Function

R K Kapania, Virginia Polytechnic Institute & State University, Blacksburg, VA, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0118

Response of structures to short-duration loads (i.e., the time duration of the external force is much shorter than the time period), is of great interest to a designer. Especially important is the limiting case of these loads, the loads whose time duration approaches zero but their total impulse, area under the force-time curve, stays finite. This happens because the response of a structure to such a load plays an important role both in describing the system and in acting as a building block towards finding the response of the system to any arbitrary excitation. Here we will describe the methods to determine the impulse response function, defined as the response of a single-degree-of-freedom spring-mass-damper system with zero initial displacement and velocity to a unit impulse.

The governing equation of a single-degree-of-freedom system of mass m , stiffness k , damping c , and subjected to an external force $f(t)$ is given as:

$$m\ddot{x} + c\dot{x} + kx = f(t) \quad [1]$$

where x denotes the displacement from the static equilibrium, and a dot denotes the derivative with respect to t .

Mathematically, the impulse applied at a given time $t = \tau$ is described using Dirac's delta function, and is represented as $\delta(t - \tau)$. Dirac's delta function belongs to a class of functions called generalized functions. To understand this function, consider a uniform force $f(t)$ acting at $t = \tau$ over duration $\Delta\tau$ such that the area under the curve, termed impulse I and given as $I = f\Delta\tau$, remains unity. Now, as the value of the load duration $\Delta\tau$ is reduced, the value of the force f will increase so that the product $f\Delta\tau$ remains unity (Figure 1). As $\Delta\tau$ approaches zero, the force f approaches infinity, but the area under the force-time curve remains unity. This function, with value approaching infinity and acting over a vanishingly small time (the independent variable) is called Dirac's delta function. This function, denoted by $\delta(t)$, has the following important properties:

$$\int_{-\infty}^{\infty} \delta(t - \tau) dt = 1 \quad [2]$$

$$\int_{-\infty}^{\infty} g(t)\delta(t - \tau) dt = g(\tau) \quad [3]$$

Here $g(t)$ is an arbitrary function of time.

Consider the single degree of freedom system of eqn [1], and subjected to an impulse of magnitude I at $t = 0$. The governing equation then becomes:

$$m\ddot{x} + c\dot{x} + kx = I\delta(t) \quad [4]$$

Dividing both sides of the above equation by the mass m , we obtain:

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x = v_{imp}\delta(t) \quad [5]$$

where $\omega_n = \sqrt{(k/m)}$ is the natural frequency of the system in radians per second, $\zeta = c/c_c$ is the damping ratio with $c_c = 2\sqrt{(km)}$; $v_{imp} = I/m$. Note that c_c is called critical damping. Physically v_{imp} is the change in the velocity of a mass m when subjected to an impulse $I\delta(t)$.

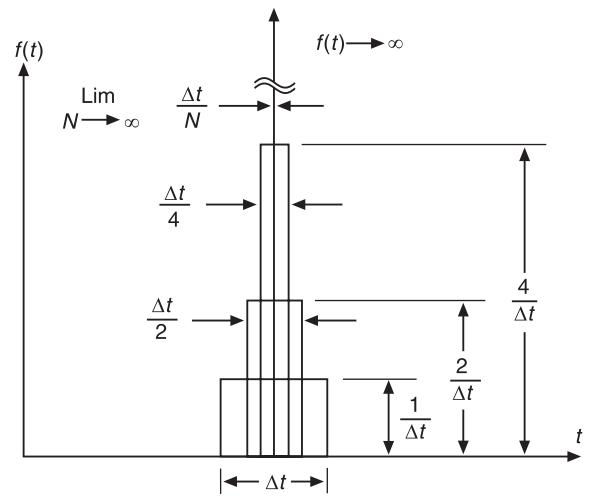

Figure 1 Dirac's delta function. The area under the load-time duration remains unity.

The response of the system to a unit impulse, termed the impulse response function, is represented as $h(t)$. It is the solution of the above equation with $v_{imp} = 1/m$ and initial conditions $x(0) = \dot{x}(0) = 0$, i.e. both initial velocity and initial displacement are zero. In terms of $h(t)$, the above equation becomes:

$$\ddot{h} + 2\zeta\omega_n\dot{h} + \omega_n^2h = \frac{1}{m}\delta(t) \quad [6]$$

$$h(0) = 0; \quad \text{and} \quad \dot{h}(0) = 0$$

A number of methods can be used to obtain $h(t)$. Here, we present two classical methods: first, the Laplace transformation method; and second the Fourier series and integral method. Both methods are extensively used in determining the response of a system to an arbitrary excitation.

Laplace Transformation Method

The Laplace transform of a function $g(t)$, written as $G(s)$ is defined as:

$$G(s) = L[g(t)] = \int_0^{\infty} e^{-st}g(t) dt \quad [7]$$

The function $g(t)$ is defined for $t < 0$ and s is a complex variable. It is assumed that the function $g(t)$ is such that the above integral exists. The Laplace transform is a linear operator, i.e.:

$$L[ag(t) + br(t)] = aL[g(t)] + bL[r(t)] \quad [8]$$

$$= aG(s) + bR(s)$$

Here a and b are constants, and g and r both are functions of t . Other properties of importance to us here are:

$$\begin{aligned} L[\dot{g}(t)] &= sG(s) - g(0) \\ L[\ddot{g}(t)] &= s^2G(s) - sg(0) - \dot{g}(0) \end{aligned} \quad [9]$$

Knowing the Laplace transform of a function, the original function is obtained by taking the inverse Laplace transform:

$$g(t) = L^{-1}[G(s)] = \frac{1}{2\pi i} \int_{\gamma-i\infty}^{\gamma+i\infty} G(s) e^{st} ds \quad [10]$$

Here $i = \sqrt{(-1)}$. Often tables of Laplace transform pairs, widely available in many books on engineering or operational mathematics, are used to obtain the Laplace transform of a function of interest. Tables are also used to obtain the inverse transform. Determining the inverse Laplace transform of a function, not given in the tables of Laplace transform pairs, may be a rather difficult task.

Laplace transform of some functions that are important in the theory of vibrations are given in **Table 1**.

The impulse response function $h(t)$ can now be obtained by taking the Laplace transform of both sides of eqn [6]:

$$\begin{aligned} s^2H(s) - sh(0) - \dot{h}(0) \\ + 2\zeta\omega_n(sH(s) - h(0)) + \omega_n^2H(s) = \frac{1}{m} \end{aligned} \quad [11]$$

Substituting $h(0) = 0$, and $\dot{h}(0) = 0$, and combining all the coefficients of $H(s)$, we obtain:

$$(s^2 + 2\zeta\omega_n s + \omega_n^2)H(s) = \frac{1}{m} \quad [12]$$

Note that the function $H(s)$ is called the transfer function for the given system and it represents the ratio of the output of the system to the input to the system in the Laplace domain. It is given as:

$$H(s) = \frac{1}{m(s^2 + 2\zeta\omega_n s + \omega_n^2)} \quad [13]$$

The impulse response function $h(t)$ is obtained by taking the inverse Laplace transform of $H(s)$, i.e. $h(t) = L^{-1}[H(s)]$. We can obtain the inverse transform of $H(s)$ by using partial fractions. To that end, we need to factor the denominator, i.e. represent the

denominator in the form $(s - s_1)(s - s_2)$, where s_1 and s_2 , the two roots of the quadratic equation, $s^2 + 2\zeta\omega_n s + \omega_n^2 = 0$, are called the poles of the transfer function.

The poles, s_1 , and s_2 are given as:

$$s_{1,2} = -\zeta\omega_n \pm \omega_n\sqrt{(\zeta^2 - 1)} \quad [14]$$

Thus, the nature of the poles depends upon the value of the nondimensional damping parameter ζ . The two roots would be complex and distinct if $\zeta < 1$ (underdamped case), equal and real negative if $\zeta = 1$ (critically damped), and distinct and real negative if $\zeta > 1$ (overdamped). These three cases lead to three completely distinct type of systems as is shown in the following.

Underdamped case ($\zeta < 1$): The two, complex, poles are:

$$s_{1,2} = -\zeta\omega_n \pm i\omega_n\sqrt{(1 - \zeta^2)} = -\zeta\omega_n \pm i\omega_d \quad [15]$$

where $\omega_d = \omega_n\sqrt{(1 - \zeta^2)}$ is the so-called damped natural frequency. The transfer function in terms of the partial fractions is given as:

$$\frac{1}{m(s^2 + 2\zeta\omega_n s + \omega_n^2)} = \frac{1}{m} \left[\frac{A}{s - s_1} + \frac{B}{s - s_2} \right] \quad [16]$$

Table 1 Laplace transform of some functions that are important in the theory of vibrations

$L[\delta(t-\tau)] = e^{-\tau s}$	$L[\sin \omega t] = \frac{\omega}{s^2 + \omega^2}$
$L[u(t)] = \frac{1}{s}$	$L[\cosh \omega t] = \frac{s}{s^2 - \omega^2}$
$L[t^n] = \frac{n!}{s^{n+1}} \quad n = 0, 1, 2, \dots$	$L[\sinh \omega t] = \frac{\omega}{s^2 - \omega^2}$
$L[e^{at}] = \frac{1}{(s-a)}$	$L[e^{at} \cos \omega t] = \frac{s-a}{(s-a)^2 + \omega^2}$
$L\left[\int_0^t g(\tau)d\tau\right] = \frac{1}{s}G(s)$	$L[e^{at} \sin \omega t] = \frac{\omega}{(s-a)^2 + \omega^2}$
$L[e^{at}g(t)] = G(s-a)$	$L[e^{at} \cosh \omega t] = \frac{s-a}{(s-a)^2 - \omega^2}$
$L[\cos \omega t] = \frac{s}{s^2 + \omega^2}$	$L[e^{at} \sinh \omega t] = \frac{\omega}{(s-a)^2 - \omega^2}$

Multiplying both sides by the denominator in the above equation, we obtain:

$$A(s - s_2) + B(s - s_1) = 1 \quad [17]$$

Substituting $s = s_1$ and $s = s_2$, respectively, we obtain:

$$A = -B = \frac{1}{(s_1 - s_2)} = \frac{1}{2i\omega_d} = -\frac{i}{2\omega_d} \quad [18]$$

The impulse response function, for the underdamped case, is thus given as:

$$\begin{aligned} h(t) &= L^{-1}H(s), \quad t > 0 \\ &= \frac{-i}{2m\omega_d} L^{-1} \left[\frac{1}{s - s_1} - \frac{1}{s - s_2} \right] \end{aligned}$$

Recalling $L^{-1}[1/(s - a)] = e^{at}$, and $s_{1,2} = -\zeta\omega_n \pm i\omega_d$, we obtain:

$$\begin{aligned} h(t) &= \frac{-i}{2m\omega_d} [e^{s_1 t} - e^{s_2 t}] \\ &= \frac{-i}{2m\omega_d} e^{-\zeta\omega_n t} [e^{i\omega_d t} - e^{-i\omega_d t}] \quad [19] \\ &= \frac{1}{m\omega_d} e^{-\zeta\omega_n t} [\sin \omega_d t], \quad t > 0 \end{aligned}$$

Here we have made use of the Euler formula $e^{i\theta} = \cos \theta + i \sin \theta$. Note that the impulse function for the underdamped case, because of the two poles being complex conjugate for this case, is oscillatory in nature. This is shown in Figure 2A.

Critically damped case ($\zeta = 1$): Both the roots are equal $s_{1,2} = -\omega_n$. The impulse response function is given as:

$$h(t) = L^{-1} \left[\frac{1}{m(s + \omega_n)^2} \right] = \frac{te^{-\omega_n t}}{m}, \quad t > 0 \quad [20]$$

Overdamped case ($\zeta < 1$): Both the roots are distinct and are given as: $s_{1,2} = -\zeta\omega_n \pm \omega_n\sqrt{(\zeta^2 - 1)} = -\zeta\omega_n \pm \omega_d^*$. The impulse response function becomes:

$$\begin{aligned} h(t) &= L^{-1} \left[\frac{1}{m(s - s_1)(s - s_2)} \right] \\ &= \frac{1}{m\omega_d^*} e^{-\zeta\omega_n t} [\sin \omega_d^* t], \quad t > 0 \quad [21] \end{aligned}$$

where $\omega_d^* = \omega_n\sqrt{(\zeta^2 - 1)}$. Note that the impulse response function for the critical and overdamped case are nonoscillatory in nature. This can be seen in Figure 2B. In both Figures 2A and 2B, the plot of nondimensional displacement $m\omega_n h(t)/I$ is given as a function of nondimensional time $\omega_n t$. Observe that as the value of the damping is increased from the critical value, the value of the nondimensional peak amplitude decreases but the time it takes for the response to die down increases.

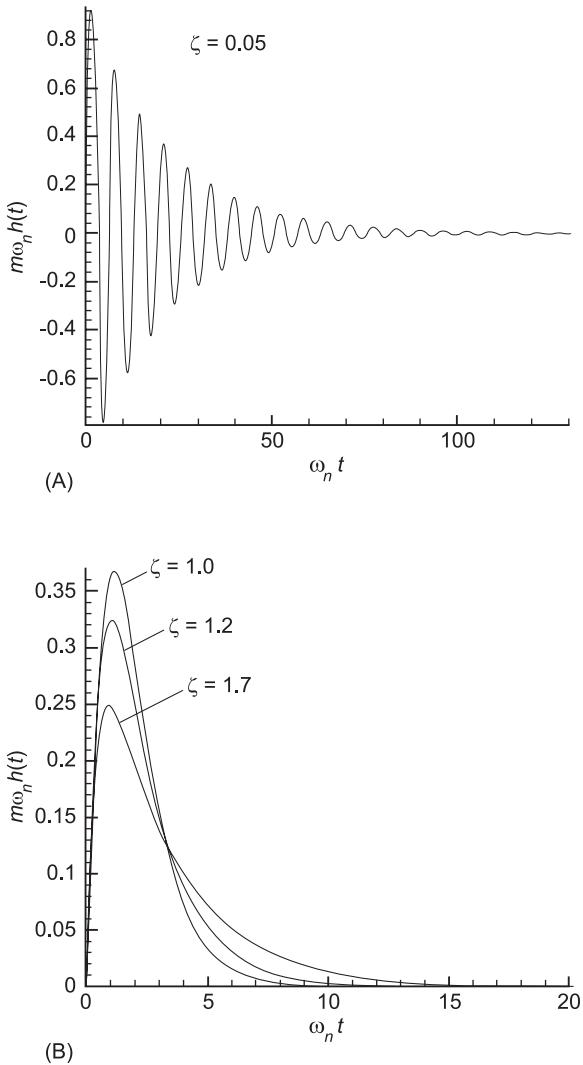

Figure 2 Nondimensional response of a single-degree-of-freedom spring-mass-damper system of mass m , and natural frequency ω_n , to an impulse I applied at $t = 0$ for different values of nondimensional damping (ζ). (A) underdamped systems ($\zeta < 1$); (B) critically ($\zeta = 1$) and overdamped systems ($\zeta > 1$). Note that the impulse response function $h(t)$ is simply $x(t)/I$.

Response to Initial Conditions

In the preceding section, we obtained the response of a dynamic system to a unit impulse by treating it as a special forcing function applied at $t = 0$. Since the effect of applying a unit impulse is to impart a sudden velocity $v_{imp} = 1/m$ at $t = 0$, the impulse response function can also be obtained by studying the response of the system under an initial velocity $\dot{x}(0) = 1/m$ but keeping both the force $f(t)$ and the initial displacement x_0 equal to zero. In this section, we present the response of a second-order system under the influence of nonzero initial conditions: $x(0) = x_0$, and $\dot{x}(0) = v_0$. The impulse response function can then be obtained by substituting $x_0 = 0$, and $v_0 = 1/m$. The response under these initial conditions, in the absence of $f(t)$, can be obtained by taking the Laplace transform of both sides of eqn [1]:

$$s^2 X(s) - sx(0) - \dot{x}(0) + 2\zeta\omega_n(sX(s) - x(0)) + \omega_n^2 X(s) = 0 \quad [22]$$

The Laplace transform, $X(s)$, of the desired response becomes

$$X(s) = \frac{sx_0 + v_0 + 2\zeta\omega_n x_0}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad [23]$$

The response $x(t)$ is obtained using inverse Laplace transform by keeping in mind that three distinct cases (underdamped, critically damped, and overdamped) arise, depending on the value of the nondimensional damping parameter ζ .

The response for the three cases, obtained using inverse Laplace transform (see Table 1), is given as

Underdamped case

$$x(t) = e^{-\zeta\omega_n t} \left[x_0 \cos \omega_d t + \frac{(v_0 + \zeta\omega_n x_0)}{\omega_d} \sin \omega_d t \right] \quad [24]$$

Critically damped case

$$x(t) = e^{-\omega_n t} [x_0 + (v_0 + \omega_n x_0)t] \quad [25]$$

Overdamped case

$$x(t) = e^{-\zeta\omega_n t} \left[x_0 \cos \omega_d^* t + \frac{(v_0 + \zeta\omega_n x_0)}{\omega_d^*} \sin \omega_d^* t \right] \quad [26]$$

For the special case of $x_0 = 0$ and $v_0 = 1/m$, all the three equations reduce to the respective expressions for the impulse response function given in eqns [19]–[21], respectively.

Most of the systems of practical interest are underdamped systems where the nondimensional damping factor ζ is of the order of 0.02–0.05. The response due to the initial conditions (as was also seen for the case of the impulse response function in Figures 2A and 2B) are oscillatory in nature only for the underdamped case.

Fourier Series and Transform

For many practical cases, we are interested in finding the response of the system to external excitation, such as buildings subjected to wind and earthquake loads, an aircraft wing subjected to gusts, an automobile on uneven pavements and so on. The impulse response function derived above can be used to obtain the response of any system to any external excitation, say $f(t)$. The response can be written as a sum of a complementary solution and a particular solution:

$$x(t) = x_c(t) + x_p(t) \quad [27]$$

The complementary part x_c is the solution of the governing equation with the right-hand side equal to zero, the so-called homogeneous equation, as was done in the previous section on determining the response of the solution to initial conditions. The complementary part with arbitrary constants, due to the presence of $e^{-\zeta\omega_n t}$ term, is transitory in nature and approaches zero as t increases. While determining the response due to loads that are of longer duration, the complementary solution is often ignored and emphasis is placed only on the particular solution $x_p(t)$. This part of the solution, which does not have any arbitrary constants, can be obtained using the convolution (Duhamel's) integral:

$$x_p(t) = (f * h)(t) = \int_0^t f(\tau)h(t - \tau) d\tau \quad [28]$$

Performing the above integral, at times, may be quite a difficult task, especially when the forcing function $f(t)$ is not a simple function. Numerical and transform methods, Laplace and Fourier, are used in such cases. Using transform methods we can transform the above integral into an algebraic product which is easy to compute. Then, the solution in the time domain is obtained by performing the inverse transform. In previous years, the Laplace transform was the transform of choice for many engineers. However, its use is limited to only those functions whose Laplace transform is easy to obtain and also the inverse transform of the product $[H(s)F(s)]$ is easily available. Moreover, determining the Laplace transform of a function and determining the response as function in time by performing inverse Laplace transformation does not lend itself easily to the tremendous power of a modern digital computer. It should, however, be mentioned that the availability of symbolic manipulators like Mathematica and MAPLE has considerably improved our ability to obtain inverse Laplace transform. (Caution: an effective way to compute inverse Laplace transforms of long or complex expressions in Mathematica is to first produce the partial fraction expansion in the Laplace domain and then to take the inverse of each resulting term separately. Also, it has been our experience that if inverse Laplace transforms of long expressions are taken without first performing the partial fraction expansion, one may get incorrect results.)

It is because of its ability in using the power of modern computers that the Fourier transform has gained a widespread popularity for determining the system response as well as in determining the system model using experimental methods. Moreover, since the Fourier transform works in the frequency domain, it provides an additional advantage: the system parameters for many systems of practical interest can be described easier in the frequency domain than in the time domain.

To understand the use of Fourier transform in vibration theory it is important to understand the use of Fourier sine and cosine series in expressing periodic, not necessarily harmonic, functions, and to understand an extension of these series for aperiodic functions, called Fourier integrals.

The Fourier series for a function $f(t)$ of period $2T$ can be written as:

$$f(t) = \frac{a_0}{2} + \sum_{k=1}^{\infty} a_k \cos \omega_k t + \sum_{k=1}^{\infty} b_k \sin \omega_k t, \quad [29]$$

$$\omega_k = \left(\frac{2\pi}{2T}\right)k$$

In general, one only needs few terms in the series to achieve a good accuracy with respect to the given function. Here ω_k , called harmonics, are the discrete frequencies, and the Fourier coefficients a_k and b_k in eqn [29] are given by:

$$a_k = \frac{1}{T} \int_{-T}^T f(t) \cos \omega_k t \, dt \quad k = 0, 1, 2, \dots \quad [30]$$

$$b_k = \frac{1}{T} \int_{-T}^T f(t) \sin \omega_k t \, dt \quad k = 1, 2, 3, \dots$$

Note that the coefficients a_k vanish for odd functions [$f(t) = -f(-t)$] and the coefficients b_k vanish for even functions [$f(t) = f(-t)$]. The Fourier series converges to $f(t)$ for all t if $f(t)$ is continuous for $(0 \leq t \leq 2T)$, and converges to $[f(t^+) + f(t^-)]/2$ if there is a discontinuity at t . It can be shown that the coefficients obtained by eqn [30] yield the best approximation for a given number of terms used in the Fourier expansion. That is, for a given number of terms used in the Fourier series, the square of the error between the function and its Fourier representation is a minimum if the coefficients given by eqn [30] are used in eqn [29]. This implies that the accuracy of the Fourier series can only be improved by adding additional terms in the Fourier series.

In vibration theory, especially in experimental structural dynamics, a complex representation is often used. It can be shown that for a periodic function $f(t)$, the Fourier representation in terms of complex exponential harmonic function, $e^{i\omega_k t}$ can be written as:

$$f(t) = \frac{1}{2\pi} \sum_{k=-\infty}^{k=\infty} \bar{f}(\omega_k) e^{i\omega_k t} \Delta\omega \quad [31]$$

where, $\Delta\omega$, the difference between two consecutive discrete frequencies ω_k and ω_{k+1} is given as:

$$\Delta\omega = \omega_{k+1} - \omega_k = \frac{2\pi}{2T} \quad [32]$$

In eqn [31], $\bar{f}(\omega_k)$ is given as:

$$\bar{f}(\omega_k) = \int_{-T}^T f(t) e^{-i\omega_k t} \, dt \quad [33]$$

Note that in the complex representation, the integer k varies from $-\infty$ to $+\infty$. The negative frequencies are thus also included. But this representation is convenient in extending the notion of Fourier series to Fourier transform as described below.

The Fourier series described above can be used to represent an aperiodic function, since such a function can be considered as a periodic function with the period $2T$ approaching ∞ . For this case, $\Delta\omega \rightarrow 0$. Thus, instead of a discrete representation in the frequency domain, one gets a continuous variation over ω . The Fourier series, in eqn [31], becomes an integral, called the Fourier integral, as given below:

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \bar{f}(\omega) e^{i\omega t} d\omega \quad [34]$$

In the above equation, $\bar{f}(\omega)$ is given as:

$$\bar{f}(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt \quad [35]$$

Functions $f(t)$ and $\bar{f}(\omega)$ are considered to form a transform pair, the Fourier transform pair. Note that, in some references on Fourier transform, the factor 2π , seen here in the denominator of eqn [34] may be placed in the denominator of eqn [35] instead and still in some other sources it may be placed as $\sqrt{(2\pi)}$ in the denominator of both eqns [34] and [35]. Also note that, unlike the case here, some references define eqn [34] as the Fourier transform and eqn [35] as the inverse Fourier transform whereas in other references the names of the two equations are reversed.

As is the case for the Laplace transform, the Fourier transform, denoted as $F[\cdot(t)]$, is a linear operation:

$$\begin{aligned} F[ag(t) + br(t)] &= aF[g(t)] + bF[r(t)] \\ &= aG(\omega) + bR(\omega) \end{aligned} \quad [36]$$

Also, as is the case for Laplace transform, the Fourier transform of a convolution integral in the time domain becomes an algebraic product of the respective transforms in the frequency domain. That is:

$$\begin{aligned} F[(g * h)(t)] &= F \left[\int_0^t g(\tau)h(t - \tau) d\tau \right] \\ &= F[g(t)]F[h(t)] \\ &= G(\omega)H(\omega) \end{aligned} \quad [37]$$

where $G(\omega)$ is the Fourier transform of $g(t)$ and $H(\omega)$ is the Fourier transform of $h(t)$ as defined by eqn [35]. To obtain $(g * h)(t)$ from $G(\omega)H(\omega)$, one needs to apply the inverse Fourier transform given by eqn [34]. That is:

$$\begin{aligned} (g * h)(t) &= F^{-1}[G(\omega)H(\omega)] \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} G(\omega)H(\omega)e^{i\omega t} d\omega \end{aligned} \quad [38]$$

The transfer function in the frequency domain $H(\omega)$ is the Fourier transform of the impulse response function. For the underdamped case the result obtained by, using eqns [34] and [19], is given as:

$$\begin{aligned} H(\omega) &= \int_{-\infty}^{\infty} h(t)e^{-i\omega t} dt \\ &= \frac{1}{m\omega_d} \int_0^{\infty} e^{-\zeta\omega_n t} [\sin \omega_d t] e^{-i\omega t} dt \end{aligned} \quad [39]$$

Here we have used the fact that $h(t) = 0$ for $t \leq 0$. The integral on the right-hand side of this equation can be easily obtained as:

$$\begin{aligned} H(\omega) &= \frac{1}{m(\omega_n^2 + 2i\zeta\omega_n - \omega^2)} \\ &= \frac{1}{k} \left[\frac{(1 - \beta^2) - i(2\zeta\beta)}{(1 - \beta^2)^2 + (2\zeta\beta)^2} \right] \end{aligned} \quad [40]$$

where $\beta = (\omega/\omega_n)$. It is interesting to note that the transfer function in the frequency domain is the same as the steady-state (i.e. the transient part of the response containing $e^{-\zeta\omega_n t}$ term has died down) response of the system to a harmonic exponential excitation of unit amplitude and excitation frequency ω (i.e. $f(t) = e^{i\omega t}$ in eqn [1]) and is called the frequency response function (FRF). The frequency of the steady-state response will be the same as that of the excitation. The complex nature of $H(\omega)$ implies that there exists a phase difference (ϕ) between the harmonic excitation and the resulting harmonic steady-state response. This steady-state response, $x_{ss}(\omega)$, is given as:

$$\begin{aligned} x_{ss}(\omega) &= H(\omega)e^{i\omega t} = |H(\omega)|e^{i(\omega t - \phi)} \\ &= \frac{1}{k} \left[\frac{1}{(1 - \beta^2)^2 + (2\zeta\beta)^2} \right]^{1/2} e^{i(\omega t - \phi)} \end{aligned} \quad [41]$$

Here ϕ represents the phase difference between the harmonic excitation and the resulting steady-state response. This phase angle is given as:

$$\phi = \tan^{-1} [(2\zeta\beta)/(1 - \beta^2)]$$

Also, since $1/k$ represents the response of the system under a unit static force, the term inside the square brackets in eqn [40] can be considered as the magnification of the static response if the unit load is instead applied in a harmonic manner with frequency ω . The term, inside the square brackets, is called the magnification factor. In some references, the transfer function (or the FRF) given above is denoted as $H(i\omega)$.

The impulse response function can be obtained by taking the inverse Fourier transform of $H(\omega)$ as shown in the following:

$$\begin{aligned} h(t) &= F^{-1}[H(\omega)] \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{1}{m(\omega_n^2 + 2i\zeta\omega\omega_n - \omega^2)} e^{i\omega t} d\omega \quad [42] \end{aligned}$$

The integral on the right of the preceding equation can be performed by using Cauchy's relation, namely:

$$\oint_C \frac{f(z)}{(z - z_0)} dz = 2\pi i f(z_0)$$

Here C is any simple closed path around z_0 which is traversed in the anticlockwise direction and $f(z)$ is analytic within C . To apply this relation to the integral in eqn [42], consider the following integral, obtained by replacing ω with z , a complex variable, in eqn [42]:

$$I_c = \frac{1}{2\pi m} \oint_C \frac{e^{izt}}{(\omega_n^2 + 2i\zeta z\omega_n - z^2)} dz \quad [43]$$

Consider the path C to be the upper half plane, i.e., a semicircle of radius r as $r \rightarrow \infty$ (Figure 3).

Realizing that the denominator in the integrand in eqn [43] when equated to zero has two complex roots: $z_{1,2} = i\zeta\omega_n \pm \omega_d$, the integral becomes:

$$\begin{aligned} I_c &= -\frac{1}{2\pi m} \oint_C \frac{e^{izt}}{2\omega_d(z - i\zeta\omega_n - \omega_d)} dz \\ &\quad + \frac{1}{2\pi m} \oint_C \frac{e^{izt}}{2\omega_d(z - i\zeta\omega_n + \omega_d)} dz \\ &= \left(\frac{2\pi i}{4\pi m\omega_d} \right) \left[-e^{i(i\zeta\omega_n + \omega_d)t} + e^{i(i\zeta\omega_n - \omega_d)t} \right] \\ &= \frac{1}{m\omega_d} e^{-\zeta\omega_n t} [\sin \omega_d t] \quad [44] \end{aligned}$$

The integral in eqn [43] can also be written, by splitting the contour C in two parts: the real axis

$(z = \omega)$ and the semicircular arc (denoted as S) of radius r with $r \rightarrow \infty$; as:

$$\begin{aligned} I_c &= \frac{1}{2\pi m} \int_{-\infty}^{\infty} \frac{e^{i\omega t}}{(\omega_n^2 + 2i\zeta\omega\omega_n - \omega^2)} d\omega \\ &\quad + \frac{1}{2\pi m} \int_S \frac{e^{izt}}{(\omega_n^2 + 2i\zeta z\omega_n - z^2)} dz \quad [45] \end{aligned}$$

The second integral on the right-hand side of the above integral approaches zero as the integrand contains z^2 term in the denominator. Comparing eqns [44] and [45], we obtain the impulse response function to be given as:

$$h(t) = \frac{1}{m\omega_d} e^{-\zeta\omega_n t} [\sin \omega_d t] \quad [46]$$

The transfer function in the frequency domain (or the FRF) $H(\omega)$ and the impulse response function $h(t)$ thus form a Fourier transform pair.

In determining the impulse response function, the inverse Fourier transform was performed using an analytical approach that used the so-called Cauchy relation (or contour integral) to perform the improper integral. Such an approach is limited only to simple functions for which such integrals can be easily obtained either using Cauchy's relation or from the tables of Fourier and inverse Fourier transform (similar to the case for the Laplace transform). However, the Fourier transform, using its discretized version, can be performed numerically for all sorts of functions using the fast Fourier transform (FFT).

Fast Fourier Transform

Let f_n represent the value of a function at a discrete point $t_n = n\Delta t$ where $\Delta t = 2T/N$, N being the total number of discrete points in the time period $2T$ or the time-history duration. Similarly \bar{f}_m represents the Fourier coefficient corresponding to the m th discrete frequency ω_m given as $\omega_m = 2\pi m/(2T)$. Values of f_n and \bar{f}_m are given as:

$$\begin{aligned} f_n &= \frac{1}{N} \sum_{m=0}^{N-1} \bar{f}_m \exp [i(2\pi mn/N)] \\ n &= 0, 1, 2, 3, \dots, N-1 \\ \bar{f}_m &= \sum_{n=0}^{N-1} f_n \exp [i(2\pi mn/N)] \\ m &= 0, 1, 2, 3, \dots, N-1 \quad [47] \end{aligned}$$

The preceding set of equations constitutes the discrete Fourier transform (DFT) pair and can easily be computed. However, if the computations are done using these equations in a direct manner, a transform will take N^2 complex multiplications. A fast method to evaluate the DFT was proposed by Cooley and Tukey. This algorithm called the fast Fourier transform (FFT), needs only $O(N \log_2 N)$ complex multiplications if $N = 2^\gamma$, where γ is an integer. This results in a substantial reduction in computational time. For example, for $N = 1024 = 2^{10}$, the direct evaluation to calculate the Fourier transform will take $1024^2 = 1\,048\,576$ complex multiplications. On the other hand, one requires only $O(10\,240)$ multiplications if FFT is employed, around 1% of the effort required otherwise.

To understand the logic behind FFT, let us consider any one of the two equations in eqn [47], say the second one. It can be rewritten as:

$$\bar{f}_m = \sum_{n=0}^{N-1} f_n \exp[-i(2\pi mn/N)] = \sum_{n=0}^{N-1} f_n W^{mn} \quad [48]$$

$m = 0, 1, 2, 3, \dots, N - 1$

Here $W = \exp[-i(2\pi/N)]$. The FFT is based on the fact that $W^0 = W^N = W^{2N} = \dots = 1$, and $W^{N+m} = W^m$. As a result, for a given value of γ ($N = 2^\gamma$), the DFT can be performed in γ stages. This is easily understood for $N = 4$ (i.e. $\gamma = 2$). For this case, eqn [48], becomes:

$$\begin{Bmatrix} \bar{f}_0 \\ \bar{f}_1 \\ \bar{f}_2 \\ \bar{f}_3 \end{Bmatrix} = \begin{bmatrix} W^0 & W^0 & W^0 & W^0 \\ W^0 & W^1 & W^2 & W^3 \\ W^0 & W^2 & W^4 & W^6 \\ W^0 & W^3 & W^6 & W^9 \end{bmatrix} \begin{Bmatrix} f_0 \\ f_1 \\ f_2 \\ f_3 \end{Bmatrix} \quad [49]$$

Obviously a straightforward matrix-vector multiplication will take 4^2 complex multiplications. If, however, we make use of the fact that $W^0 = W^4 = 1$ and $W^6 = W^2$, etc., we can reduce the number of multiplications to eight by performing the above multiplication in two ($= \gamma$) stages. In the first stage, using N complex multiplications, we calculate an intermediary vector \mathbf{g} whose components are given as:

$$\begin{aligned} g_0 &= f_0 + W^0 f_2 \\ g_1 &= f_1 + W^0 f_3 \\ g_2 &= W^2 f_2 + f_0 \\ g_3 &= W^2 f_3 + f_1 \end{aligned}$$

In the second (γ th or last) stage, also the last stage for

$N = 4$ case, we calculate the DFT, once again using N complex multiplications, as:

$$\begin{aligned} \bar{f}_0 &= g_0 + W^0 g_1 \\ \bar{f}_2 &= W^2 g_1 + g_0 \\ \bar{f}_1 &= g_2 + W^1 g_3 \\ \bar{f}_3 &= W^3 g_3 + g_2 \end{aligned}$$

Note that the values of \bar{f} are scrambled. The same approach can be easily implemented for other values of γ . For example, for $N = 8$ ($\gamma = 3$) we will require three stages and each stage will have eight complex multiplications.

The computer programs capable of performing FFT are readily available. For example, the commercially available packages Mathematica and MATLAB both contain commands for obtaining the FFT.

Nomenclature

C	closed path
f	force
I	impulse
v	velocity
$X(s)$	Laplace transform
$\delta(t)$	Dirac's delta function
ϕ	phase angle
ζ	damping factor

Introduction

Vibration problems can be formulated either according to vectorial dynamics, based on the concepts of force and momentum, or to variational dynamics, based on the concepts of kinetic energy and work done by the forces. In vectorial dynamics, Newton's laws are used directly to derive the equations of motion. In variational dynamics, the conditions of extremization of a functional are used to derive the equations of motion of a system. Whereas Newton is considered by most people to be the originator of vectorial dynamics, Leibniz is considered by some and John Bernoulli and/or d'Alembert by others as the originator of variational dynamics. In solid mechanics, the principles of minimum potential energy, minimum complementary energy, and stationary Reissner energy can be used to formulate statics problems while the Hamilton's principle can be used to formulate dynamics problems. All these principles represent variational approaches that can also be used to formulate the finite element equations. Hamilton's principle can be considered to be rooted in the concept that nature will insure efficiency as a system moves freely from one configuration to another. Of all possible paths a system might traverse, that chosen by nature will always be one that minimizes a quantity that can be called action. In Hamilton's principle, the action is the integral of the Lagrangian from time t_1 to t_2 , where these two times are arbitrary. When calculus of variations is used, the necessary conditions for the minimum of this action result in Lagrange's equations.

The variational approaches have the following advantages:

1. The forces that do no work, such as forces of constraint on masses, need not be considered.
2. The accelerations of masses need not be considered; only velocities are needed.
3. The mathematical operations are to be performed on scalars, not on vectors, in deriving the equations of motion.

This article presents the basic ideas of calculus of variations followed by the description of different

variational principles of solid mechanics and the application of Hamilton's principle in the formulation of the equations of motion of a variety of discrete and continuous vibrating systems.

Calculus of Variations

The calculus of variations deals with the determination of extrema (maxima and minima) or stationary values of functionals. The basic problem in variational calculus is to find the function $\phi(x)$ which makes the integral functional:

$$I = \int_{x_1}^{x_2} F(x, \phi, \phi_x) dx \quad [1]$$

stationary. Here, x is the independent variable and $\phi_x = d\phi/dx$ and as the condition for the stationarity of I , the variation of I is set equal to zero so that:

$$\delta I = \int_{x_1}^{x_2} \left(\frac{\partial F}{\partial x} \delta \phi + \frac{\partial F}{\partial \phi_x} \delta \phi_x \right) dx = \int_{x_1}^{x_2} \delta F dx = 0 \quad [2]$$

The mathematical manipulation of eqn [2] leads to the governing differential equation of the system, known as Euler or Euler-Lagrange equation, as well as the boundary conditions. The rules of variation used in the manipulation of eqn [2] are summarized in Table 1. The Euler-Lagrange equation and the boundary conditions corresponding to eqn [2] can be expressed as:

$$\frac{\partial F}{\partial \phi} - \frac{d}{dx} \left(\frac{\partial F}{\partial \phi_x} \right) = 0, \quad x_1 < x < x_2 \quad [3]$$

$$\frac{\partial F}{\partial \phi_x} \delta \phi|_{x_1}^{x_2} = 0 \quad [4]$$

When the function F is defined as $F(x, \phi, \phi_x, \phi_{xx})$ where $\phi_{xx} = \partial^2 \phi / \partial x^2$, the Euler-Lagrange equation and the boundary conditions are given by:

$$\frac{\partial F}{\partial \phi} - \frac{d}{dx} \left(\frac{\partial F}{\partial \phi_x} \right) + \frac{d^2}{dx^2} \left(\frac{\partial F}{\partial \phi_{xx}} \right) = 0, \quad x_1 < x < x_2 \quad [5]$$

Table 1 Rules of variation

$$\delta(\phi_1 + \phi_2) = \delta\phi_1 + \delta\phi_2$$

$$\delta(\phi_1\phi_2) = \phi_2\delta\phi_1 + \phi_1\delta\phi_2$$

$$\delta(\phi^n) = n\phi^{n-1}\delta\phi$$

$$\delta\left(\frac{\phi_1}{\phi_2}\right) = \frac{\phi_2\delta\phi_1 - \phi_1\delta\phi_2}{\phi_2^2}$$

$$\delta\left(\frac{d\phi}{dt}\right) = \frac{d}{dt}(\delta\phi)$$

$$\delta\left(\frac{\partial\phi}{\partial t}\right) = \frac{\partial}{\partial t}(\delta\phi)$$

$$\delta f(\phi) = \frac{df(\phi)}{d\phi}\delta\phi$$

$$\delta f(\dot{\phi}) = \frac{df(\dot{\phi})}{d\dot{\phi}}\delta\dot{\phi}, \quad \dot{\phi} = \frac{d\phi}{dt}$$

$$\delta f(\phi, \dot{\phi}) = \frac{\partial f(\phi, \dot{\phi})}{\partial \phi}\delta\phi + \frac{\partial f(\phi, \dot{\phi})}{\partial \dot{\phi}}\delta\dot{\phi}$$

$$\delta[f(\phi_1, \phi_2, \dots, \phi_n)] = \sum_{j=1}^n \frac{\partial f}{\partial \phi_j} \delta\phi_j$$

$$\delta \int_{t_1}^{t_2} f(\phi) dt = \int_{t_1}^{t_2} \delta f(\phi) dt$$

$$\delta \int_{t_1}^{t_2} f(\phi) dx = \int_{t_1}^{t_2} \delta f(\phi) dx$$

$$\delta \int_0^\phi f(\theta) d\theta = f(\phi) d\phi$$

$$\left[\frac{\partial F}{\partial \phi_x} - \frac{d}{dx} \left(\frac{\partial F}{\partial \phi_{xx}} \right) \right] \delta\phi|_{x_1}^{x_2} = 0 \quad [6]$$

$$\frac{\partial F}{\partial \phi_{xx}} \delta\phi_x|_{x_1}^{x_2} = 0 \quad [7]$$

When several dependent variables are involved as:

$$I = \int_{x_1}^{x_2} (F(x, \phi_1, \dots, \phi_n, (\phi_1)_x, \dots, (\phi_n)_x, (\phi_1)_{xx}, \dots, (\phi_n)_{xx})) dx \quad [8]$$

where $(\phi_i)_x = \partial\phi_i/\partial x$ and $(\phi_i)_{xx} = \partial^2\phi_i/\partial x^2$, the Euler-Lagrange equation can be expressed as:

$$\frac{d^2}{dx^2} \left(\frac{\partial F}{\partial (\phi_i)_{xx}} \right) - \frac{d}{dx} \left(\frac{\partial F}{\partial (\phi_i)_x} \right) + \frac{\partial F}{\partial \phi_i} = 0, \quad [9]$$

$$x_1 < x < x_2, \quad i = 1, 2, \dots, n$$

If the integrand involves derivatives of higher order than the second order as:

$$I = \int_{x_1}^{x_2} F(x, \phi_i, \phi_i^{(1)}, \phi_i^{(2)}, \dots, \phi_i^{(n)}) dx \quad [10]$$

where $\phi_i^{(j)} = d^j\phi_i/dx^j$, $i = 1, 2, \dots, n$, then the corresponding Euler-Lagrange equations are given by:

$$\sum_{j=0}^n (-1)^{n-j} \frac{d^{n-j}}{dx^{n-j}} \left(\frac{\partial F}{\partial \phi_i^{(n-j)}} \right) = 0, \quad [11]$$

$$x_1 < x < x_2, \quad i = 1, 2, \dots, n$$

If the functional I is defined in terms of several independent variables and one dependent variable as:

$$I = \iiint_V F(x, y, z, \phi, \phi_x, \phi_y, \phi_z) dV \quad [12]$$

where $\phi_x = \partial\phi/\partial x$, $\phi_y = \partial\phi/\partial y$ and $\phi_z = \partial\phi/\partial z$, the Euler-Lagrange equation can be obtained as:

$$\frac{\partial F}{\partial \phi} - \frac{\partial}{\partial x} \left(\frac{\partial F}{\partial \phi_x} \right) - \frac{\partial}{\partial y} \left(\frac{\partial F}{\partial \phi_y} \right) - \frac{\partial}{\partial z} \left(\frac{\partial F}{\partial \phi_z} \right) = 0 \quad [13]$$

Some variational problems, known as isoperimetric problems, involve auxiliary constraints:

$$\text{Extremize } I = \int_{x_1}^{x_2} F(x, \phi, \phi_x) dx \quad [14]$$

subject to the condition that $\phi(x)$ also satisfy the equation:

$$J = \int_{x_1}^{x_2} G(x, \phi, \phi_x) dx = \text{known constant} \quad [15]$$

Using the technique of Lagrange multipliers, the Euler-Lagrange equation corresponding to the constrained variational problem can be expressed as:

$$\frac{\partial F_s}{\partial \phi} - \frac{d}{dx} \left(\frac{\partial F_s}{\partial \phi_x} \right) = 0, \quad x_1 < x < x_2 \quad [16]$$

where $F_s = F + \lambda G$ and λ is the Lagrange multiplier whose value is chosen so that eqn [15] is satisfied.

When potential energy, U , is used as the functional, I , eqn [2] yields the principle of minimum potential

energy. The principles of minimum potential energy, minimum complementary energy, and Reissner energy are used to formulate the problems in solid mechanics, that is, to derive the governing differential equations and the boundary conditions. When the Lagrangian function, L , is used as the functional, I , eqn [2] yields the governing equations of motion and the boundary conditions of the system. The corresponding variational principle, in this case, is called Hamilton's principle. Hamilton's principle is an integral principle that considers the entire motion of the system between two instants of time t_1 and t_2 . This permits the treatment of a dynamics problem in terms of a scalar integral. A specific advantage of this formulation is that it is invariant with respect to the coordinate system used. All the variational methods of static and dynamic problems are discussed in this article.

Variational Methods in Solid Mechanics

Principle of Minimum Potential Energy

The potential energy of an elastic body, U , is defined as:

$$U = \pi - W_p \quad [17]$$

where π is the strain energy and W_p is the work done on the body by the external forces. The principle of minimum potential energy can be stated as follows: 'Of all possible displacement states (u , v , and w) a body can assume which satisfy compatibility and specified kinematic or displacement boundary conditions, the state which satisfies the equilibrium equations makes the potential energy assume a minimum value'. If the potential energy is expressed in terms of the displacement components u , v , and w , the principle of minimum potential energy gives, at the equilibrium state:

$$\delta U(u, v, w) = \delta\pi(u, v, w) - \delta W_p(u, v, w) = 0 \quad [18]$$

It is important to note that the variation is taken with respect to the displacements in eqn [18] while the forces and stresses are assumed to be constant. The strain energy of a linear elastic body is given by:

$$\pi = \frac{1}{2} \iiint_V \boldsymbol{\epsilon}^T \boldsymbol{\sigma} dV \quad [19]$$

where $\boldsymbol{\epsilon}$ is the strain vector, $\boldsymbol{\sigma}$ is the stress vector, V is the volume of the body and the superscript T denotes the transpose. By expressing the stress-strain relations as:

$$\boldsymbol{\sigma} = \mathbf{D}\boldsymbol{\epsilon} \quad [20]$$

where \mathbf{D} is the elasticity matrix, the strain energy can be expressed (in the absence of initial strains) as:

$$\pi = \frac{1}{2} \iiint_V \boldsymbol{\epsilon}^T \mathbf{D} \boldsymbol{\epsilon} dV \quad [21]$$

If initial strains are present, with the initial strain vector $\boldsymbol{\epsilon}_0$, the strain energy of the body is given by:

$$\pi = \frac{1}{2} \iiint_V \boldsymbol{\epsilon}^T \mathbf{D} \boldsymbol{\epsilon} dV - \iiint_V \boldsymbol{\epsilon}^T \mathbf{D} \boldsymbol{\epsilon}_0 dV \quad [22]$$

The work done by the external forces is given by:

$$W_p = \iiint_V (\bar{\phi}_x u + \bar{\phi}_y v + \bar{\phi}_z w) dV + \iint_{S_1} (\bar{\Phi}_x u + \bar{\Phi}_y v + \bar{\Phi}_z w) dS_1 \quad [23]$$

where S_1 is the surface of the body on which surface forces (tractions) are prescribed. By denoting the known body force vector, $\bar{\boldsymbol{\phi}}$, the prescribed surface force (traction) vector, $\bar{\boldsymbol{\Phi}}$ and the displacement vector, \mathbf{u} , as:

$$\bar{\boldsymbol{\phi}} = \begin{Bmatrix} \bar{\phi}_x \\ \bar{\phi}_y \\ \bar{\phi}_z \end{Bmatrix}, \quad \bar{\boldsymbol{\Phi}} = \begin{Bmatrix} \bar{\Phi}_x \\ \bar{\Phi}_y \\ \bar{\Phi}_z \end{Bmatrix}, \quad \mathbf{u} = \begin{Bmatrix} u \\ v \\ w \end{Bmatrix}$$

Equation [23] can be rewritten as:

$$W_p = \iiint_V \bar{\boldsymbol{\Phi}}^T \mathbf{u} dV + \iint_{S_1} \bar{\boldsymbol{\Phi}}^T \mathbf{u} dS_1 \quad [24]$$

Using eqns [22] and [24] the potential energy of the body can be expressed as:

$$U(u, v, w) = \frac{1}{2} \iiint_V \boldsymbol{\epsilon}^T \mathbf{D}(\boldsymbol{\epsilon} - 2\boldsymbol{\epsilon}_0) dV - \iiint_V \bar{\boldsymbol{\Phi}}^T \mathbf{u} dV - \iint_{S_1} \bar{\boldsymbol{\Phi}}^T \mathbf{u} dS_1 \quad [25]$$

As stated above, the displacement field $\mathbf{u}(x, y, z)$ that minimizes U and satisfies all the boundary conditions is the one that satisfies the equilibrium equations. If the principle of minimum potential energy is used, we minimize the functional U and the resulting equations denote the equilibrium equations while the compatibility conditions are identically satisfied.

Principle of Minimum Complementary Energy

The complementary energy of an elastic body (U_c) is defined as:

U_c = complementary strain energy in terms of stresses (π) – work done by the applied loads during stress changes (\bar{W}_p)

The principle of minimum complementary energy can be stated as follows: ‘Of all possible stress states which satisfy the equilibrium equations and the stress boundary conditions, the state which satisfies the compatibility conditions will make the complementary energy assume a minimum value’. By expressing the complementary energy U_c in terms of the stresses σ_{ij} , the principle of minimum complementary energy gives, for compatibility:

$$\delta U_c(\sigma_{xx}, \sigma_{yy}, \dots, \sigma_{zz}) = \delta \bar{\pi}(\sigma_{xx}, \sigma_{yy}, \dots, \sigma_{zz}) \quad [26]$$

$$- \delta \bar{W}_p(\sigma_{xx}, \sigma_{yy}, \dots, \sigma_{zz}) = 0$$

It is to be noted that variation is taken with respect to stress components in eqn [26] while the displacements are assumed to be constant. The complementary strain energy of a linear elastic body can be expressed as:

$$\bar{\pi} = \frac{1}{2} \iiint_V \boldsymbol{\sigma}^T \boldsymbol{\epsilon} \, dV \quad [27]$$

The complementary strain energy can be written, in the presence of known initial strains $\boldsymbol{\epsilon}_0$, as:

$$\bar{\pi} = \frac{1}{2} \iiint_V \boldsymbol{\sigma}^T (\mathbf{C}\boldsymbol{\sigma} + 2\boldsymbol{\epsilon}_0) \, dV \quad [28]$$

where the strain–stress relations are assumed to be of the form:

$$\boldsymbol{\epsilon} = \mathbf{C}\boldsymbol{\sigma} \quad [29]$$

The work done by the applied loads during stress change, also known as the complementary work, is given by:

$$\bar{W}_p = \iint_{S_2} (\phi_x \bar{u} + \phi_y \bar{v} + \phi_z \bar{w}) \, dS_2 = \iint_{S_2} \boldsymbol{\Phi}^T \bar{\mathbf{u}} \, dS_2 \quad [30]$$

where S_2 is the part of the surface of the body on which the values of displacements are prescribed as:

$$\bar{\mathbf{u}} = \begin{Bmatrix} \bar{u} \\ \bar{v} \\ \bar{w} \end{Bmatrix}$$

Eqns [28] and (30) can be used to express the complementary energy of the body as:

$$U_c(\sigma_{xx}, \sigma_{yy}, \dots, \sigma_{zz}) = \frac{1}{2} \iiint_V \boldsymbol{\sigma}^T (\mathbf{C}\boldsymbol{\sigma} + 2\boldsymbol{\epsilon}_0) \, dV$$

$$- \iint_{S_2} \boldsymbol{\sigma}^T \bar{\mathbf{u}} \, dS_2 \quad [31]$$

If the principle of minimum complementary energy is used, we minimize the functional U_c and the resulting equations denote the compatibility equations while the equilibrium equations are identically satisfied.

Principle of Stationary Reissner Energy

In the principle of minimum potential energy, we expressed the potential energy, U , in terms of displacements and permitted variations of u , v , and w . Similarly, in the case of the principle of minimum complementary energy, we expressed the complementary energy, U_c , in terms of stresses and permitted variations of σ_{xx} , σ_{yy} ... σ_{zz} . In the present case, we express Reissner energy, U_r , in terms of both displacements and stresses and permit variations with respect to both displacements and stresses. The Reissner energy for a linearly elastic body is defined as:

$U_r = \iiint_V \{(\text{internal stresses}) \times (\text{strains expressed in terms of displacements}) - \text{complementary strain energy in terms of stresses}\} \, dV - \text{work done by applied forces}$

$$= \iiint_V \left\{ \left[\sigma_{xx} \frac{\partial u}{\partial x} + \sigma_{yy} \frac{\partial v}{\partial y} + \dots + \sigma_{zx} \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right) \right] - \bar{\pi} \right\} \, dV$$

$$- \iint_V (\bar{\phi}_x u + \bar{\phi}_y v + \bar{\phi}_z w) \, dV$$

$$- \iint_{S_1} (\bar{\Phi}_x u + \bar{\Phi}_y v + \bar{\Phi}_z w) \, dS_1$$

$$- \iint_{S_2} [(u - \bar{u})\Phi_x + (v - \bar{v})\Phi_y + (w - \bar{w})\Phi_z] \, dS_2$$

$$= \iiint_V \left[\boldsymbol{\sigma}^T \boldsymbol{\epsilon} - \frac{1}{2} \boldsymbol{\sigma}^T \mathbf{C} \boldsymbol{\sigma} - \bar{\boldsymbol{\Phi}}^T \bar{\mathbf{u}} \right] \, dV$$

$$- \iint_{S_1} \mathbf{u}^T \bar{\boldsymbol{\Phi}} \, dS_1 - \iint_{S_2} (\mathbf{u} - \bar{\mathbf{u}})^T \bar{\boldsymbol{\Phi}} \, dS_2 \quad [32]$$

The variation of U_r is set equal to zero by considering variations in both displacements and stresses:

$$\delta U_r = \sum \frac{\partial U_r}{\partial \sigma_{ij}} \delta \sigma_{ij} + \left(\frac{\partial U_r}{\partial u} \delta u + \frac{\partial U_r}{\partial v} \delta v + \frac{\partial U_r}{\partial w} \delta w \right) = 0 \quad [33]$$

The first term on the right-hand side of eqn [33] gives the stress-displacement relations while the second term gives the equilibrium equations and the boundary conditions. The principle of stationary Reissner energy can be stated in words as follows: 'Of all possible stress and displacement states the body can have, the particular set which makes the Reissner energy stationary gives the correct stress-displacement and equilibrium equations along with the boundary conditions'.

Hamilton's Principle

The variational principle that can be used for dynamic problems is called the Hamilton's principle. According to this principle, the variation of the functional is taken with respect to time. The functional, similar to U , U_c , and U_r , used in Hamilton's principle is called the Lagrangian (L) and is defined as follows:

$$L = T - U = \text{kinetic energy} - \text{potential energy} \quad [34]$$

The kinetic energy of the body, T , can be expressed as:

$$T = \frac{1}{2} \iiint_V \rho \dot{\mathbf{u}}^T \dot{\mathbf{u}} dV \quad [35]$$

where ρ is the density of the material and $\dot{\mathbf{u}}$ is the vector of velocity components at any point in the body:

$$\dot{\mathbf{u}} = \begin{Bmatrix} \dot{u} \\ \dot{v} \\ \dot{w} \end{Bmatrix}$$

Thus, the Lagrangian can be written as:

$$L = \frac{1}{2} \iiint_V (\rho \dot{\mathbf{u}}^T \dot{\mathbf{u}} - \mathbf{\epsilon}^T \mathbf{D} \mathbf{\epsilon} + 2 \mathbf{u}^T \bar{\mathbf{\Phi}}) dV + \iint_{S_1} \mathbf{u}^T \bar{\mathbf{\Phi}} dS_1 \quad [36]$$

Hamilton's principle can be stated in words as follows:

Of all possible time histories of displacement states which satisfy the compatibility equations and the constraints or the kinematic boundary conditions and which also satisfy the conditions at initial and final times (t_1 and t_2), the history corresponding to the actual solution makes the Lagrangian functional a minimum.

Hamilton's principle can thus be expressed as:

$$\delta \int_{t_1}^{t_2} L dt = 0 \quad [37]$$

Generalized Hamilton's Principle

The generalized Hamilton's principle can be stated as follows:

$$\delta \int_{t_1}^{t_2} L dt = \delta \int_{t_1}^{t_2} (T - \pi + W) dt = 0 \quad [38]$$

where T is the kinetic energy, π is the strain energy, W is the work done by external forces, and $L = T - \pi + W$ is called the generalized Lagrangian function. The expressions of T , π and W are given by:

$$T = \iiint_V \frac{1}{2} \rho \dot{u}_i \dot{u}_i dV \quad [39]$$

where u_i is the i th component of displacement, \dot{u}_i is the i th component of velocity and ρ is the density:

$$\pi = \iiint_V [\sigma_{ij} (\gamma_{ij} - \epsilon_{ij}) + \pi_0] dV, \quad i, j = 1, 2, 3 \quad [40]$$

where σ_{ij} are the components of stress vector, γ_{ij} are the expressions of strain in terms of the derivatives of u_i , ϵ_{ij} are the components of the strain vector, and π_0 is the the initial strain energy function:

$$W = \iiint_V \phi_i u_i dV + \iint_{S_1} \bar{\Phi}_i u_i dS_1 + \iint_{S_2} \Phi_i (u_i - \bar{u}_i) dS_2 \quad [41]$$

where ϕ_i is the i th component of body force, Φ_i is the i th component of surface tractions, a bar over a

symbol denotes a prescribed quantity, S_2 is part of the surface of the body on which displacements are prescribed and S_1 is part of the surface of the body on which surface tractions are prescribed. Note that Cartesian tensor notations and summation convention for repeated indices is used in eqns [39]–[41]. In addition, eqn [38] has the same form as in the ordinary Hamilton's principle, but π and W are now different. When variations of the displacements, strains, and stresses are taken independently, we obtain:

$$\delta \int_{t_1}^{t_2} T dt = \iiint_V \rho \dot{u}_i \delta u_i dV|_{t_1}^{t_2} - \int_{t_1}^{t_2} dt \iiint_V \rho \ddot{u}_i \delta u_i dV \quad [42]$$

$$\delta \int_{t_1}^{t_2} \pi dt = \int_{t_1}^{t_2} dt \iiint_V \left[\sigma_{ij} \delta \gamma_{ij} + (\gamma_{ij} - \varepsilon_{ij}) \delta \sigma_{ij} - \left(\sigma_{ij} - \frac{\partial \pi_0}{\partial \varepsilon_{ij}} \right) \delta \varepsilon_{ij} \right] dV \quad [43]$$

$$\delta \int_{t_1}^{t_2} W dt = \int_{t_1}^{t_2} \left[\iiint_V \phi_i \delta u_i dV + \iint_{S_1} \bar{\Phi}_i \delta u_i dS_1 + \iint_{S_2} (u_i - \bar{u}_i) \delta \Phi_i dS_2 \right] dt \quad [44]$$

Since γ_{ij} are functions of the first derivatives of u_i , we can obtain:

$$\iiint_V \sigma_{ij} \delta \varepsilon_{ij} dV = \iint_{S_1} \frac{1}{2} \left[\sigma_{ij} \left(\frac{\partial \gamma_{ij}}{\partial e_{mn}} + \frac{\partial \gamma_{ij}}{\partial \omega_{mn}} \right) v_n \delta_{1m} + \dots \right] dS_1 \quad [45]$$

where $\gamma_{ij} = \gamma_{ij}(e_{mn}, \omega_{mn})$ for a general nonlinear problem ($m, n = 1, 2, 3$) with:

$$e_{mn} = \frac{1}{2} (u_{m,n} + u_{n,m}) \quad [46]$$

$$\omega_{mn} = \frac{1}{2} (u_{m,n} - u_{n,m}) \quad [47]$$

with $u_{mn} = \partial u_m / \partial x_n$, $x_1 = x$, $x_2 = y$, $x_3 = z$, $v_n = \cos(\nu n)$ = direction cosine and δ_{lm} = Kronecker delta. Using eqns [42]–[45], eqn [38] can be rewritten as:

$$\begin{aligned} & \int_{t_1}^{t_2} dt \iiint_V \left\{ \frac{1}{2} \left[\sigma_{ij} \left(\frac{\partial \gamma_{ij}}{\partial e_{mn}} + \frac{\partial \gamma_{ij}}{\partial \omega_{mn}} \right) \right]_{,n} \delta_{1m} \right. \\ & + \frac{1}{2} \left[\sigma_{ij} \left(\frac{\partial \gamma_{ij}}{\partial e_{mn}} - \frac{\partial \gamma_{ij}}{\partial \omega_{mn}} \right) \right]_{,m} \delta_{1n} + \phi_1 - \rho \ddot{u}_1 \Big\} \delta u_1 dV \\ & - \int_{t_1}^{t_2} dt \iint_{S_1} \left[\frac{1}{2} \sigma_{ij} \left(\frac{\partial \gamma_{ij}}{\partial e_{mn}} + \frac{\partial \gamma_{ij}}{\partial \omega_{mn}} \right) v_n \delta_{1m} \right. \\ & + \frac{1}{2} \sigma_{ij} \left(\frac{\partial \gamma_{ij}}{\partial e_{mn}} + \frac{\partial \gamma_{ij}}{\partial \omega_{mn}} \right) v_m \delta_{1n} - \bar{\Phi}_1 \Big] \delta u_1 dS_1 \\ & + \int_{t_1}^{t_2} dt \iiint_V \left(\sigma_{ij} - \frac{\partial \pi_0}{\partial \varepsilon_{ij}} \right) \delta \varepsilon_{ij} dV \\ & - \int_{t_1}^{t_2} dt \iiint_V (\gamma_{ij} - \varepsilon_{ij}) \delta \sigma_{ij} dV \\ & \left. + \int_{t_1}^{t_2} dt \iint_{S_2} (u_i - \bar{u}_i) \delta \Phi_i dS_2 dt = 0 \right] \quad [48] \end{aligned}$$

Since the variations δu_i , $\delta \sigma_{ij}$, and $\delta \varepsilon_{ij}$ are arbitrary throughout the volume of the body (V), δu_i is arbitrary on S_1 and $\delta \Phi_i$ is arbitrary on S_2 , their coefficients in the five integrands in eqn [48] must be zero independently. This gives the stress equations of motion, traction boundary conditions, stress-strain relations, strain-displacement relations, and displacement boundary conditions. These equations constitute the complete set of equations (and are valid for large elastic deflections also). The generalized Hamilton's principle can be stated in words as follows:

The displacements, strains and stresses, which, over the time interval t_1 to t_2 , satisfy the stress equations of motion and the stress-strain-displacement relations throughout the body, the traction boundary conditions on S_1 and the displacement boundary conditions on S_2 , are determined by setting the variation of the time integral of the generalized Lagrangian function equal to zero, provided that the variations of the displacements, strains and stresses are taken independently and simultaneously, and the variations of displacements vanish at t_1 and t_2 throughout the body

and the variations of displacements and tractions satisfy the prescribed boundary conditions.

Applications – Continuous Systems

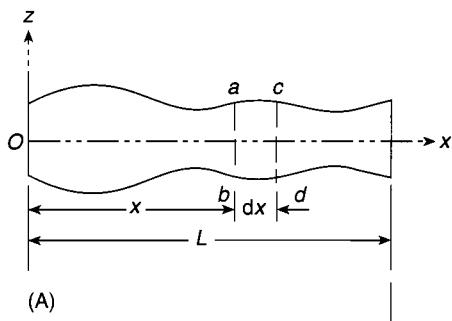

Equation of Motion of a Uniform Bar under Axial Load

The derivation of the equation governing the longitudinal motion of a uniform bar is considered to illustrate the application of Hamilton's principle.

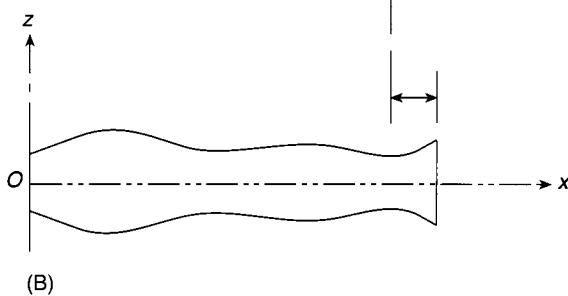

Strain energy, U To derive a general expression for the strain energy of the bar, consider the bar to be of variable cross-section under an axial load as shown in Figure 1. If $u(x, t)$ denotes the axial displacement of the cross-section at x , an element of length dx will assume a value of $dx + (\partial u / \partial x)dx$ due to axial deformation under the axial load F (Figure 1B). The elongation of the element dx is given by $\delta(dx) = (\partial u / \partial x)dx$ and hence the strain at point x can be expressed as:

$$\varepsilon = \frac{\delta(dx)}{dx} = \frac{\partial u(x, t)}{\partial x}$$

The stress induced (σ) can be expressed, using Hooke's law, as:

(A)

(B)

Figure 1AB Longitudinal vibration of a bar. (A) Before deformation; (B) after deformation.

$$\sigma = E \varepsilon = E \frac{\partial u(x, t)}{\partial x}$$

where E is the Young's modulus of the bar. The strain energy associated with the element dx (of volume $A dx$) can be expressed as:

$$dU = \left(\frac{1}{2} \sigma \varepsilon \right) A dx = \frac{1}{2} EA \left(\frac{\partial u}{\partial x} \right)^2 dx$$

where $A = A(x)$ denotes the cross-section area of the bar at x . Thus the strain energy of the bar can be expressed as:

$$U = \int_{x=0}^L dU dx = \frac{1}{2} \int_0^L EA(x) \left[\frac{\partial u(x, t)}{\partial x} \right]^2 dx \quad [a]$$

where L is the length of the bar.

Kinetic energy, T The kinetic energy of the bar with variable cross-section can be expressed as:

$$T = \frac{1}{2} \int_0^L m(x) \left[\frac{\partial u(x, t)}{\partial t} \right]^2 dx \quad [b]$$

where $m(x) = \rho A(x)$ is the mass per unit length of the bar and ρ is the density of the bar. By using eqns [a] and [b], the Hamilton's principle can be used to obtain:

$$\begin{aligned} & \delta \int_{t_1}^{t_2} (T - U) dt \\ &= \delta \int_{t_1}^{t_2} \left[\frac{1}{2} \int_0^L m \left(\frac{\partial u}{\partial t} \right)^2 dx - \frac{1}{2} \int_0^L EA \left(\frac{\partial u}{\partial x} \right)^2 dx \right] dt \\ &= 0 \end{aligned} \quad [c]$$

By carrying out the variation operation, the various terms of eqn [c] can be rewritten, noting that δ and $\partial/\partial t$ as well as δ and $\partial/\partial x$ are commutative, as:

$$\begin{aligned} & \delta \int_{t_1}^{t_2} \left[\frac{1}{2} \int_0^L m \left(\frac{\partial u}{\partial t} \right)^2 dx \right] dt \\ &= - \int_{t_1}^{t_2} \int_0^L m \frac{\partial^2 u}{\partial t^2} \delta u dx dt \end{aligned} \quad [d]$$

assuming that u is prescribed at t_1 and t_2 so that $\delta u = 0$ at t_1 and t_2 . Similarly:

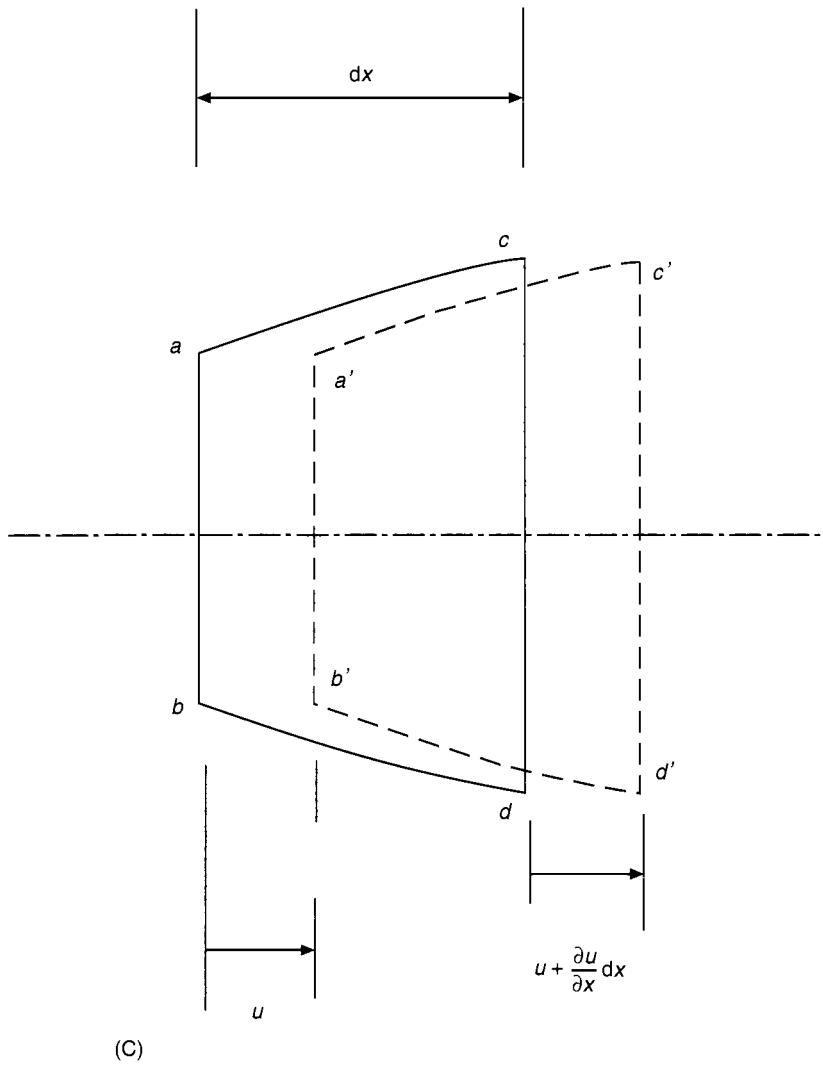

Figure 1C An element of bar.

$$\delta \int_{t_1}^{t_2} \left[\frac{1}{2} \int_0^L EA \left(\frac{\partial u}{\partial x} \right)^2 dx \right] dt \\ = \int_{t_1}^{t_2} \left[EA \frac{\partial u}{\partial x} \delta u \Big|_0^L - \int_0^L \frac{\partial}{\partial x} \left(EA \frac{\partial u}{\partial x} \right) \delta u dx \right] dt \quad [e]$$

Assuming that $\delta u = 0$ at $x = 0$ and $x = L$, and δu is arbitrary in $0 < x < L$, eqn [f] requires that:

$$\frac{\partial}{\partial x} \left(EA \frac{\partial u}{\partial x} \right) - m \frac{\partial^2 u}{\partial t^2} = 0, \quad 0 < x < L \quad [g]$$

and:

Thus eqn [c] becomes:

$$\int_{t_1}^{t_2} \left\{ \int_0^L \left[\frac{\partial}{\partial x} \left(EA \frac{\partial u}{\partial x} \right) - m \frac{\partial^2 u}{\partial t^2} \right] \delta u dx - \left(EA \frac{\partial u}{\partial x} \right) \delta u \Big|_{t_1}^{t_2} \right\} dt = 0 \quad [f]$$

$$\left(EA \frac{\partial u}{\partial x} \right) \delta u = 0 \quad \text{at } x = 0 \quad \text{and} \quad x = L \quad [h]$$

Thus the Hamilton's principle yields eqn [g], which denotes the equation of motion of the bar, and eqn [h], which indicates the boundary conditions.

The boundary conditions require that either $EA(\partial u / \partial x) = 0$ (stress = 0) or $\delta u = 0$ (u = specified) at $x = 0$ and $x = L$.

Transverse Vibration of a Timoshenko Beam

Consider an element of a thick beam in bending as shown in Figure 2B. For a thick beam, when the effects of shear deformation and rotatory (or rotary) inertia are considered, the theory is known as the Timoshenko beam theory. The deflection of the beam at any point x is caused by bending as well as shear deformation. The slope of the deflected center line of the beam, $\partial w / \partial x$, can be expressed as:

$$\frac{\partial w(x, t)}{\partial x} = \phi(x, t) + \gamma(x, t) \quad [a]$$

where $\phi(x, t)$ = angular rotation due to bending and $\gamma(x, t)$ = angular rotation due to shear deformation. The bending moment (M) and shear force (V) at x are given by:

$$M(x, t) = EI(x) \frac{\partial \phi(x, t)}{\partial x} \quad [b]$$

$$V(x, t) = kA(x)G\beta(x, t) \quad [c]$$

where E is Young's modulus, $I(x)$ is the moment of inertia of the cross-section, $A(x)$ is the area of cross-

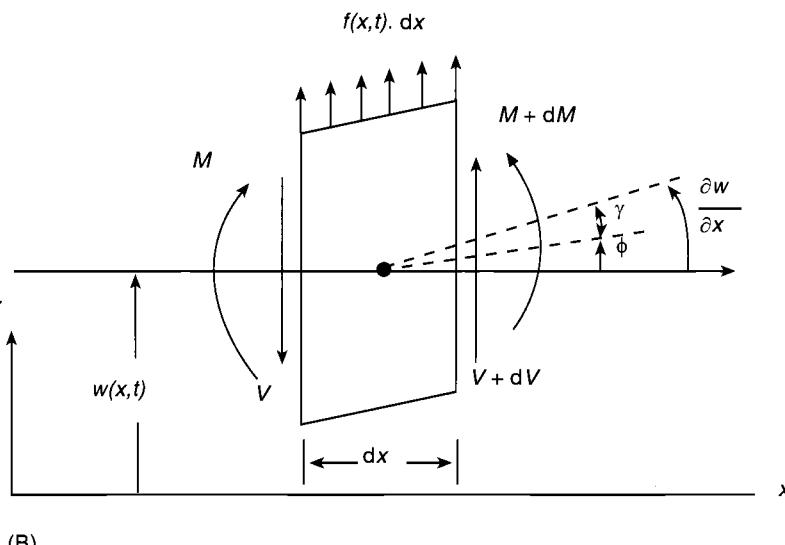

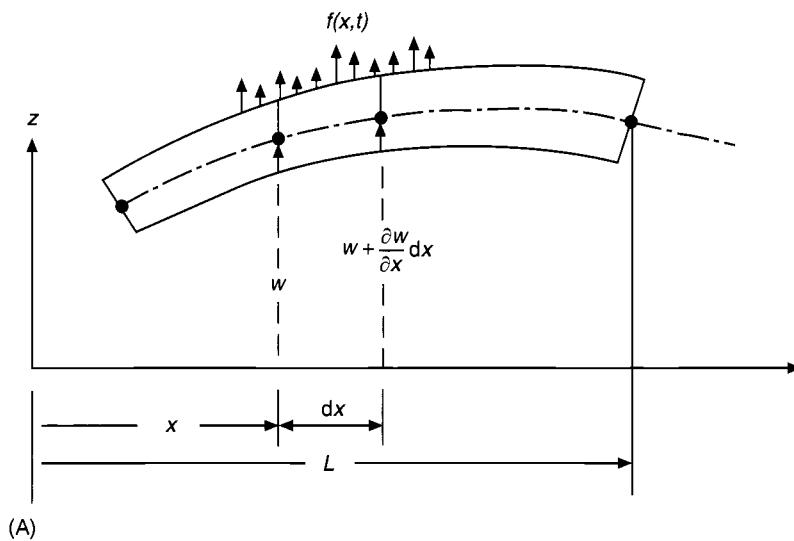

Figure 2 A nonuniform thick beam in bending. (A) Deformed configuration; (B) free-body diagram of an element of beam.

section of the beam and k is a constant whose value depends on the shape of the cross-section of the beam.

Strain energy, U The strain energy of the beam is composed of energies due to bending and shear deformation:

$$\begin{aligned} U(t) &= \frac{1}{2} \int_0^L M \frac{\partial \phi}{\partial x} dx + \frac{1}{2} \int_0^L V \gamma dx \\ &= \frac{1}{2} \int_0^L EI(x) \left[\frac{\partial \phi(x, t)}{\partial x} \right]^2 dx \\ &\quad + \frac{1}{2} \int_0^L kGA(x) \left[\frac{\partial w(x, t)}{\partial x} - \phi(x, t) \right]^2 dx \end{aligned} \quad [d]$$

Kinetic energy, T The kinetic energy of the beam due to translational and rotational motions can be expressed as:

$$\begin{aligned} T(t) &= \frac{1}{2} \int_0^L m(x) \left[\frac{\partial w(x, t)}{\partial t} \right]^2 dx \\ &\quad + \frac{1}{2} \int_0^L J(x) \left[\frac{\partial \gamma(x, t)}{\partial t} \right]^2 dx \end{aligned} \quad [e]$$

where $m(x) = \rho A(x)$ is the mass per unit length of the beam, ρ is density, $A(x)$ is the area of cross-section of the beam and $J(x) = \rho I(x)$ is the mass moment of inertia of the beam per unit length.

Virtual work of nonconservative forces, δW The virtual work of the applied distributed force, $f(x, t)$, is given by:

$$\delta W(t) = \int_0^L f(x, t) \delta w(x, t) dx \quad [f]$$

Noting that the order of integrations with respect to t and x can be interchanged and the operators δ and d/dx or δ and d/dt are commutative, the variations of U and T can be written as:

$$\begin{aligned} \delta U &= \delta \int_{t_1}^{t_2} \int_0^L EI \left(\frac{\partial \phi}{\partial x} \right)^2 dx dt + \delta \int_{t_1}^{t_2} \int_0^L kGA \gamma^2 dx dt \end{aligned}$$

$$\begin{aligned} &= \int_{t_1}^{t_2} \left[EI \frac{\partial \phi}{\partial x} \delta \phi|_0^L - \int_0^L \frac{\partial}{\partial x} \left(EI \frac{\partial \phi}{\partial x} \right) \delta \phi dx \right. \\ &\quad \left. + kGA \left(\frac{\partial w}{\partial x} - \phi \right) \delta w|_0^L \right. \\ &\quad \left. - \int_0^L \frac{\partial}{\partial x} \left[kGA \left(\frac{\partial w}{\partial x} - \phi \right) \right] \delta w dx \right. \\ &\quad \left. - \int_0^L kGA \left(\frac{\partial w}{\partial x} - \phi \right) \delta \phi dx \right] dt \end{aligned} \quad [g]$$

$$\begin{aligned} \delta T &= \delta \int_{t_1}^{t_2} \left[\frac{1}{2} \int_0^L m \left(\frac{\partial w}{\partial t} \right)^2 dx + \frac{1}{2} \int_0^L J \left(\frac{\partial \gamma}{\partial t} \right)^2 dx \right] dt \\ &= - \int_0^L \left[\int_{t_1}^{t_2} \frac{\partial}{\partial t} \left(m \frac{\partial w}{\partial t} \right) \delta w dt \right] dx \\ &\quad - \int_0^L \left[\int_{t_1}^{t_2} \frac{\partial}{\partial t} \left(J \frac{\partial \gamma}{\partial t} \right) \delta \gamma dt \right] dx \end{aligned} \quad [h]$$

Using eqns [f], [g], and [h], the Hamilton's principle can be stated as:

$$\begin{aligned} &\int_{t_1}^{t_2} \left\{ - \int_0^L m \frac{\partial^2 w}{\partial t^2} \delta w dx - \int_0^L J \frac{\partial^2 \gamma}{\partial t^2} \delta \gamma dx \right. \\ &\quad - \left(EI \frac{\partial \phi}{\partial x} \right) \delta \phi|_0^L + \int_0^L \frac{\partial}{\partial x} \left(EI \frac{\partial \phi}{\partial x} \right) \delta \phi dx \\ &\quad - \left[KGA \left(\frac{\partial w}{\partial x} - \phi \right) \right] \delta w|_0^L \\ &\quad \left. + \int_0^L \frac{\partial}{\partial x} \left[kGA \left(\frac{\partial w}{\partial x} - \phi \right) \right] \delta w dx \right. \\ &\quad \left. + \int_0^L kGA \left(\frac{\partial w}{\partial x} - \phi \right) \delta \phi dx + \int_0^L f \delta w dx \right\} dt \\ &= \int_{t_1}^{t_2} \left\{ \int_0^L \left\{ \frac{\partial}{\partial x} \left[kGA \left(\frac{\partial w}{\partial x} - \phi \right) \right] \right. \right. \\ &\quad \left. \left. - m \frac{\partial^2 w}{\partial t^2} + f \right\} \delta w dx + \int_0^L \left\{ \left[\frac{\partial}{\partial x} \left(EI \frac{\partial \phi}{\partial x} \right) \right. \right. \right. \\ &\quad \left. \left. \left. - KGA \left(\frac{\partial w}{\partial x} - \phi \right) \right] \delta \phi dx \right\} dt \right\} \end{aligned}$$

$$\left. + kGA \left(\frac{\partial w}{\partial x} - \phi \right) \right] - J \frac{\partial^2 \phi}{\partial t^2} \} \delta \phi \, dx \\ - \left(EI \frac{\partial \phi}{\partial x} \right) \delta \phi|_0^L - kGA \left(\frac{\partial w}{\partial x} - \phi \right) \delta w|_0^L \} \, dt = 0 \quad [i]$$

Assuming that the virtual displacements, δw and $\delta \phi$, to be zero, at $x = 0$ and $x = L$, and arbitrary in $0 < x < L$, eqn [i] leads to:

$$\frac{\partial}{\partial x} \left\{ kGA \left(\frac{\partial w}{\partial x} - \phi \right) \right\} - m \frac{\partial^2 w}{\partial t^2} + f = 0, \quad 0 < x < L \quad [j]$$

$$\frac{\partial}{\partial x} \left(EI \frac{\partial \phi}{\partial x} \right) + kGA \left(\frac{\partial w}{\partial x} - \phi \right) - J \frac{\partial^2 \phi}{\partial t^2} = 0, \quad 0 < x < L \quad [k]$$

$$\left(EI \frac{\partial \phi}{\partial x} \right) \delta \phi|_0^L = 0 \quad [l]$$

$$kGA \left(\frac{\partial w}{\partial x} - \phi \right) \delta w|_0^L = 0 \quad [m]$$

Eqns [j] and [k] denote the equations of motion for the transverse and shear motions of the beam, respectively, and eqns [l] and [m] represent the boundary conditions. Eqn [l] requires that either $EI(\partial \phi / \partial x) = 0$ or $\delta \phi = 0$ at $x = 0$ and $x = L$. Similarly, eqn [m] requires that either $kGA[(\partial w / \partial x) - \phi] = 0$ or $\delta w = 0$ at $x = 0$ and $x = L$. Eqns [l] and [m] can be seen to be satisfied for the following common boundary conditions:

- Clamped (fixed) end: $w =$ transverse deflection $= 0$, $\phi =$ bending slope $= 0$
- Hinged (pinned) end: $w =$ transverse deflection $= 0$, $M = EI(\partial \phi / \partial x) =$ bending moment $= 0$
- Free end: $M = EI(\partial \phi / \partial x) =$ bending moment $= 0$, $V = kGA[(\partial w / \partial x) - \phi] =$ shear force $= 0$

Coupled Twist-bending Vibrations of Circular Rings

Figure 3 shows an element of a ring along with the sign convention used for the forces and moments. The slope of the transverse deflection curve can be written as:

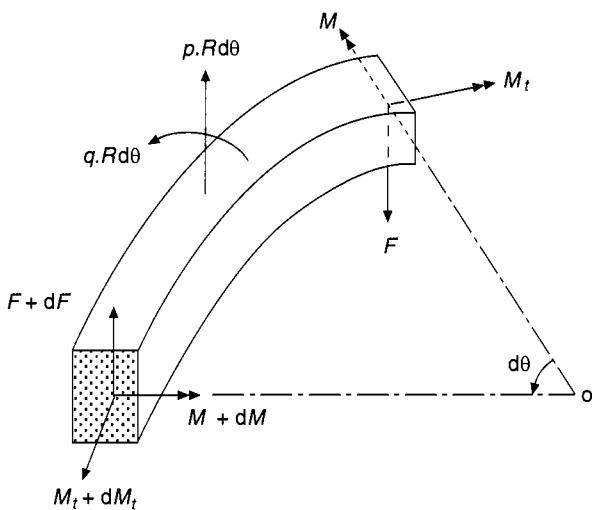

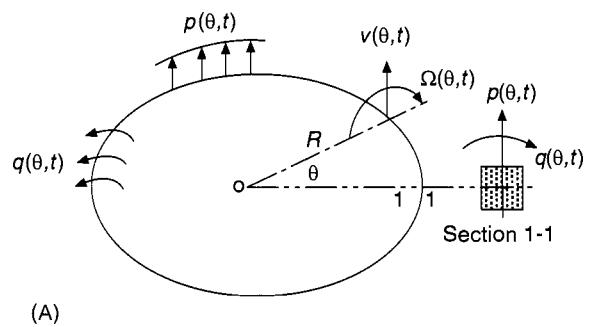

Figure 3 An element of circular ring.

$$\frac{1}{R} \frac{\partial v}{\partial \theta} = \alpha + \beta \quad [a]$$

where R is the radius of the undeformed center line of the ring, v is the transverse deflection, θ is the angular coordinate, α is the slope of the deflection curve when the shearing force is neglected, and β is the angle of shear at the neutral axis in the same cross-section. The transverse shearing force, F , is given by:

$$F = kAG\beta \quad [b]$$

where k is a numerical factor used to account for the variation of β through the cross-section, and is a constant for any given cross-section, A is the area of cross-section and G is the shear modulus. The moment-displacement relations, with a consideration for the shear deformation effect, can be expressed as:

$$M = \frac{EI}{R} \left(\Omega - \frac{\partial \alpha}{\partial \theta} \right) \quad [c]$$

$$M_t = \frac{C}{R} \left(\alpha + \frac{\partial \Omega}{\partial \theta} \right) \quad [d]$$

where M is the bending moment about a radial axis, M_t is the torsional moment about the tangential axis, E is the Young's modulus, I is the moment of inertia of the cross-section about a radial axis, C is the torsional stiffness, and Ω is the angular deformation of the cross-section of the ring. The strain and kinetic energies of a ring segment can be written as:

$$U = \int_0^\phi \left\{ \frac{EI}{2R^2} \left(\Omega - \frac{\partial \alpha}{\partial \theta} \right)^2 + \frac{C}{2R^2} \left(\alpha + \frac{\partial \Omega}{\partial \theta} \right)^2 + \frac{kAG}{2} \beta^2 - p\alpha - q\Omega \right\} R d\theta \quad [e]$$

$$T = \int_0^\phi \frac{m}{2} \left\{ \left(\frac{\partial \nu}{\partial t} \right)^2 + \frac{I}{A} \left(\frac{\partial \alpha}{\partial t} \right)^2 + \frac{J}{A} \left(\frac{\partial \Omega}{\partial t} \right)^2 \right\} R d\theta \quad [f]$$

where ϕ is the angle subtended by the ring segment at the center, p is the distributed transverse load acting through the shear center, q is the distributed twisting moment acting about the shear center, m is the mass per unit length, and J is the polar moment of inertia of the cross-section of the ring. When the expressions for U and T are used, the Hamilton's principle results in the following equations:

$$\frac{\partial}{\partial \theta} \left[kAG \left(\frac{I}{R} \frac{\partial \nu}{\partial \theta} - \alpha \right) \right] + Rp - \frac{\gamma AR}{g} \frac{\partial^2 \nu}{\partial t^2} = 0 \quad [g]$$

$$\begin{aligned} \frac{\partial}{\partial \theta} \left[\frac{EI}{R} \left(\Omega - \frac{\partial \alpha}{\partial \theta} \right) \right] - kAGR \left(\frac{I}{R} \frac{\partial \nu}{\partial \theta} - \alpha \right) \\ + \frac{C}{R} \left(\alpha + \frac{\partial \Omega}{\partial \theta} \right) + \frac{\gamma IR}{g} \frac{\partial^2 \alpha}{\partial t^2} = 0 \end{aligned} \quad [h]$$

$$\begin{aligned} \frac{\partial}{\partial \theta} \left[\frac{C}{R} \left(\alpha + \frac{\partial \Omega}{\partial \theta} \right) \right] - \frac{EI}{R} \left(\Omega - \frac{\partial \alpha}{\partial \theta} \right) \\ + Rq - \frac{\gamma JR}{g} \frac{\partial^2 \Omega}{\partial t^2} = 0 \end{aligned} \quad [i]$$

$$kAG \left(\frac{I}{R} \frac{\partial \nu}{\partial \theta} - \alpha \right) \delta \nu \Big|_0^\phi = 0 \quad [j]$$

$$\frac{EI}{R} \left(\Omega - \frac{\partial \alpha}{\partial \theta} \right) \delta \alpha \Big|_0^\phi = 0 \quad [k]$$

$$\frac{C}{R} \left(\alpha + \frac{\partial \Omega}{\partial \theta} \right) \delta \Omega \Big|_0^\phi = 0 \quad [l]$$

Eqns [g], [h], and [i] denote the equations of motion corresponding to the variables ν , α , and Ω and eqns [j], [k], and [l] represent the boundary conditions which are satisfied for any combination of the pinned, free, and fixed end conditions.

Hamilton's Principle for Discrete Systems

Consider a system of N mass particles. Let a particle of mass m_i be acted upon by a system of external and constraint forces with resultants \mathbf{F}_i and \mathbf{f}_i , respectively. If the system is in equilibrium, the resultant force is zero and the work done over a virtual displacement, $\delta \mathbf{r}_i$, must be zero, that is:

$$\delta W_i = (\mathbf{F}_i + \mathbf{f}_i) \cdot \delta \mathbf{r}_i = 0 \quad [49]$$

The constraint forces, usually, do not perform any work since the displacements do not have any components in the direction of the constraint forces. Thus, for the system of all N particles, the total virtual work can be expressed as:

$$\delta W = \sum_{i=1}^N \delta W_i = \sum_{i=1}^N \mathbf{F}_i \cdot \delta \mathbf{r}_i = 0 \quad [50]$$

D'Alembert's principle states that a particle of mass m_i subject to an unbalanced force \mathbf{F}_i can be considered to be in equilibrium with the inertia force, $m_i \ddot{\mathbf{r}}_i$, so that:

$$m_i \ddot{\mathbf{r}}_i - \mathbf{F}_i = 0 \quad [51]$$

where $\ddot{\mathbf{r}}_i$ is the acceleration of the particle. Thus, for N particles, the virtual work expression, in conjunction with D'Alembert's principle, can be stated as:

$$\sum_{i=1}^N (m_i \ddot{\mathbf{r}}_i - \mathbf{F}_i) \cdot \delta \mathbf{r}_i = 0 \quad [52]$$

with:

$$\sum_{i=1}^N \mathbf{F}_i \cdot \delta \mathbf{r}_i = \delta W \quad [53]$$

denoting the virtual work done by the applied forces. The time derivative of $\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i$ yields:

$$\frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) = \ddot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i + \dot{\mathbf{r}}_i \cdot \delta \dot{\mathbf{r}}_i = \ddot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i + \delta \left(\frac{1}{2} \dot{\mathbf{r}}_i \cdot \dot{\mathbf{r}}_i \right) \quad [54]$$

which can be rewritten as:

$$\ddot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i = \frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) - \delta \left(\frac{1}{2} \dot{\mathbf{r}}_i \cdot \dot{\mathbf{r}}_i \right) \quad [55]$$

By multiplying eqn [55] by m_i and summing over all the masses gives:

$$\begin{aligned} \sum_{i=1}^N m_i \ddot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i &= \sum_{i=1}^N m_i \frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) - \delta \sum_{i=1}^N \frac{1}{2} m_i (\dot{\mathbf{r}}_i \cdot \dot{\mathbf{r}}_i) \\ &= \sum_{i=1}^N m_i \frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) - \delta T \end{aligned} \quad [56]$$

where T denotes the kinetic energy of the system. Using eqns [53] and [56], eqn [52] can be expressed as:

$$\delta T + \delta W = \sum_{i=1}^N m_i \frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) \quad [57]$$

Let the system of mass particles be defined in terms of n generalized coordinates. Then the configuration of the system at any instant is defined by the values of the generalized coordinates which define a point in the n -dimensional configuration space. When the configuration of the system changes with time, the various configurations define points which yield a path, which can be called the true path of the system in the configuration space. At any specific instant, if a small variation in the position of the i th mass, $\delta \mathbf{r}_i$, with no associated change in time ($\delta t = 0$), is considered, we obtain another path, known as the varied path of the system. The true and varied paths of the system are shown in Figure 4. If the true and varied paths are assumed to coincide at two instants t_1 and t_2 , we have:

$$\delta \mathbf{r}_i = 0 \quad \text{at} \quad t = t_1 \quad \text{and} \quad t = t_2 \quad [58]$$

The multiplication of eqn [57] by dt and integration from t_1 to t_2 yields:

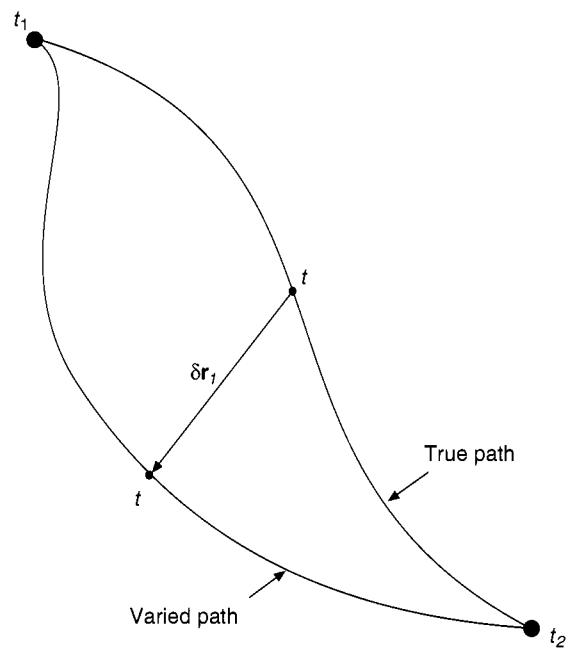

Figure 4 True and varied paths of the system.

$$\begin{aligned} \int_{t_1}^{t_2} \delta(T + W) dt &= \int_{t_1}^{t_2} \sum_{i=1}^N m_i \frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) dt \\ &= \sum_{i=1}^N \int_{t_1}^{t_2} m_i \frac{d}{dt}(\dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i) dt = \sum_{i=1}^N m_i \dot{\mathbf{r}}_i \cdot \delta \mathbf{r}_i \Big|_{t_1}^{t_2} \end{aligned} \quad [59]$$

Since $\delta \mathbf{r}_i = 0$ at t_1 and t_2 (eqn [58]), eqn [59] reduces to:

$$\delta \int_{t_1}^{t_2} (T + W) dt = 0 \quad [60]$$

In the particular case where the forces are conservative, the virtual work is equal to the negative of the variation in the potential energy of the system (δU) so that:

$$\delta W = -\delta U \quad [61]$$

and hence eqn [60] can be rewritten as:

$$\delta \int_{t_1}^{t_2} L dt = 0 \quad [62]$$

where L is called the Lagrangian and is defined as:

$$L = T - U \quad [63]$$

Eqn [62] denotes the mathematical statement of Hamilton's principle which can be stated in words as follows:

Of all possible paths that the system can assume between the instants of time t_1 and t_2 , the path that makes the value of the integral $\int_{t_1}^{t_2} L dt$ stationary represents the true or actual path provided that the initial and final configurations of the system are prescribed.

The stationary value is actually a minimum. Eqn [62] can be considered as the generalized Hamilton's principle where W denotes the virtual work due to conservative and nonconservative forces. Hamilton's principle is often written as:

$$\delta \int_{t_1}^{t_2} (T - U) dt + \int_{t_1}^{t_2} \delta W_{nc} dt = 0 \quad [64]$$

where U is the potential energy, which includes both strain energy and the potential of any conservative external forces, and δW_{nc} is the virtual work done by the nonconservative forces acting on the system. As can be seen from eqns [60] and [62], Hamilton's principle reduces the problems of dynamics to the study of a scalar integral that does not depend on the coordinates used. Note that Hamilton's principle yields merely the equations of motion of the system but not the solution of the dynamics problem.

Applications – Discrete Systems

Single-degree-of-freedom System

The derivation of the differential equation of motion of a single-degree-of-freedom system, shown in Figure 5, is considered to illustrate the application of Hamilton's principle to discrete systems. The kinetic and strain energies of the system are given by:

$$T = \frac{1}{2} m \dot{x}^2 \quad [a]$$

$$U = \frac{1}{2} k x^2 \quad [b]$$

The virtual work corresponding to the applied force $F(t)$ and the damping (nonconservative) force $c\dot{x}$ is given by:

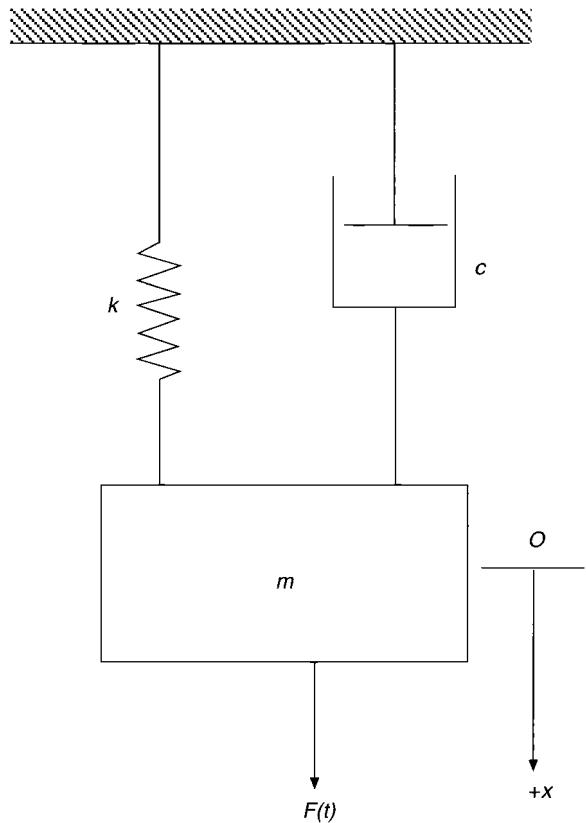

Figure 5 A single-degree-of-freedom system.

$$\delta W_{nc} = F(t)\delta x - c\dot{x}\delta x \quad [c]$$

The application of Hamilton's principle yields:

$$\delta \int_{t_1}^{t_2} (T - U) dt + \int_{t_1}^{t_2} \delta W_{nc} dt = 0 \quad [d]$$

with T , U , and δW_{nc} given by eqns [a], [b] and [c], respectively. The first term of eqn [d] can be rewritten as:

$$\delta \int_{t_1}^{t_2} \left(\frac{1}{2} m \dot{x}^2 - \frac{1}{2} k x^2 \right) dt = \int_{t_1}^{t_2} (m\dot{x}\delta\dot{x} - kx\delta x) dt \quad [e]$$

The integration of the first term on the right-hand side of eqn [e] by parts results in:

$$\begin{aligned} & \delta \int_{t_1}^{t_2} (T - U) dt \\ &= m\dot{x}\delta x|_{t_1}^{t_2} - \int_{t_1}^{t_2} (m\ddot{x}\delta x + kx\delta x) dt \end{aligned} \quad [f]$$

Assuming that x is prescribed at t_1 and t_2 , eqn [f] gives:

$$\int_{t_1}^{t_2} (m\ddot{x} + cx - F(t) + c\dot{x})\delta x \, dt = 0 \quad [g]$$

Since δx is arbitrary, eqn [g] leads to the desired equation of motion of the system:

$$m\ddot{x} + cx + kx = F(t) \quad [h]$$

Two-degree-of-freedom System

Next, the two-degree-of-freedom system, shown in Figure 6, is considered. The kinetic and strain energies of the system can be expressed as:

$$T = \frac{1}{2}m_1\dot{x}_1^2 + \frac{1}{2}m_2\dot{x}_2^2 \quad [a]$$

$$U = \frac{1}{2}k_1x_1^2 + \frac{1}{2}k_2(x_2 - x_1)^2 \quad [b]$$

The virtual work associated with the applied forces and the damping (nonconservative) forces can be written as:

$$\delta W_{nc} = F_1(t)\delta x_1 + F_2(t)\delta x_2 - c_1\dot{x}_1\delta x_1 - c_2(\dot{x}_2 - \dot{x}_1)\delta(x_2 - x_1) \quad [c]$$

The variations of the time integrals of T and U are given by:

$$\begin{aligned} \delta \int_{t_1}^{t_2} T \, dt &= \delta \int_{t_1}^{t_2} \left(\frac{1}{2}m_1\dot{x}_1^2 + \frac{1}{2}m_2\dot{x}_2^2 \right) \, dt \\ &= \int_{t_1}^{t_2} (m_1\dot{x}_1\delta\dot{x}_1 + m_2\dot{x}_2\delta\dot{x}_2) \, dt \end{aligned} \quad [d]$$

$$\begin{aligned} \delta \int_{t_1}^{t_2} U \, dt &= \delta \int_{t_1}^{t_2} \left[\frac{1}{2}k_1x_1^2 + \frac{1}{2}k_2(x_2 - x_1)^2 \right] \, dt \\ &= \int_{t_1}^{t_2} [k_1x_1\delta x_1 + k_2(x_2 - x_1)\delta(x_2 - x_1)] \, dt \end{aligned} \quad [e]$$

By using integration by parts, eqn [d] can be rewritten as:

$$\delta \int_{t_1}^{t_2} T \, dt = \int_{t_1}^{t_2} (-m_1\ddot{x}_1\delta x_1 - m_2\ddot{x}_2\delta x_2) \, dt \quad [f]$$

Hamilton's principle can be expressed as:

$$\delta \int_{t_1}^{t_2} (T - U) \, dt + \int_{t_1}^{t_2} \delta W_{nc} \, dt = 0 \quad [g]$$

which, in view of eqns [c]–[f], becomes:

$$\begin{aligned} &- \int_{t_1}^{t_2} \{ [m_1\ddot{x}_1 + (k_1 + k_2)x_1 - k_2x_2]\delta x_1 \\ &+ (m_2\ddot{x}_2 + k_2x_2 - k_2x_1)\delta x_2 \} \, dt \\ &+ \int_{t_1}^{t_2} [F_1(t)\delta x_1 + F_2(t)\delta x_2 - c_1\dot{x}_1\delta x_1 \\ &- c_2(\dot{x}_2 - \dot{x}_1)\delta(x_2 - x_1)] \, dt = 0 \end{aligned} \quad [h]$$

Assuming that x_1 and x_2 are independent coordinates, eqn [h] yields the equations of motion of the system as:

$$\begin{aligned} m_1\ddot{x}_1 + (c_1 + c_2)\dot{x}_1 - c_2\dot{x}_2 \\ + (k_1 + k_2)x_1 - k_2x_2 = F_1(t) \end{aligned} \quad [i]$$

$$m_2\ddot{x}_2 + c_2\dot{x}_2 - c_2\dot{x}_1 + k_2x_2 - k_2x_1 = F_2(t) \quad [j]$$

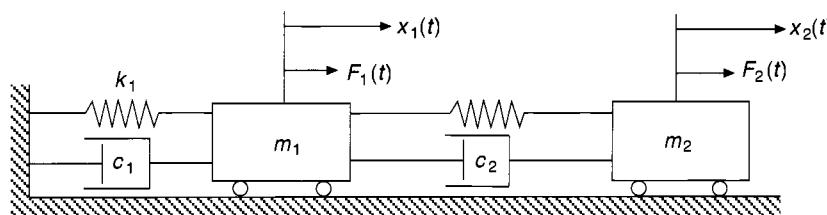

Figure 6 A two-degree-of-freedom system.

Nomenclature

A	area of cross-section of a bar	π	strain energy
C	torsional stiffness	ρ	density
c, c_i	damping constant	$\sigma_{xx}, \sigma_{yy}, \dots$	
C	matrix relating strain and stress vectors	$\sigma_{xy}, \dots, \sigma_{ij}, \dots$	stress components
D	elasticity matrix	$\boldsymbol{\sigma}$	stress vector
E	Young's modulus	ϕ	function of x ; dependent variable; angular rotation
$F(t), F_i(t)$	external force	$\dot{\phi}_x$	first derivative of ϕ with respect to x
F	function	$\ddot{\phi}_{xx}$	second derivative of ϕ with respect to x
F_i	i th external force	Φ_i	i th component of body force
f_i	i th constraint force	$\bar{\phi}_x, \bar{\phi}_y, \bar{\phi}_z$	body force per unit volume along x, y, z axes
G	function; shear modulus	$\bar{\Phi}$	vector of prescribed body forces
I	area moment of inertia of a bar; integral function	Φ_x, Φ_y, Φ_z	surface traction along x, y, z axes
J	integral function; mass moment of inertia of a rod per unit length	$\bar{\Phi}_i$	i th component of surface traction
k	shear coefficient	$\bar{\Phi}_x, \bar{\Phi}_y, \bar{\Phi}_z$	prescribed surface forces (tractions)
k, k	stiffness	Φ	vector of prescribed surface forces (tractions)
L	Lagrangian; length of a bar	θ	angular coordinate
M	bending moment	δ_{ij}	Kronecker delta
M_t	torsional moment	γ	angular rotation due to shear deformation
m	mass for unit length of a bar; mass	γ_{ij}	strain component in terms of derivatives of u_i
m_i	i th mass	ϵ_{ij}	strain component
N	number of masses	$\boldsymbol{\epsilon}$	strain vector
n	number of dependent variables	ϵ_0	initial strain vector
p, q	distributed loads	Ω	angular deformation
R	radius of a ring	$(\)^T$	transpose of ()
r_i	i th radial vector		
\ddot{r}_i	i th acceleration vector		
S_1	surface on which tractions are prescribed		
S_2	surface on which displacements are prescribed		
T	kinetic energy		
t	time		
U	potential energy		
U_c	complementary energy		
U_r	Reissner energy		
u, v, w	displacements along x, y, z axes		
\mathbf{u}	vector of displacement components		
u_i	i th displacement component		
\bar{u}_i	i th prescribed displacement component		
V	volume of a body (or domain of a system); shear force		
W, W_p	work done by external forces		
\bar{W}_p	work done by the applied loads during stress changes		
W_{nc}	work done by nonconservative forces		
x, y, z	Cartesian coordinates		
x_1, x_2	initial and final values of x		
α, β	slopes		
δ	variation operator		
δr_i	i th virtual displacement vector		
λ	Lagrange multiplier

Introduction

The principles of frequency analysis have found wide application in many areas of vibration analysis. Using these techniques one represents a time domain signal as a function of frequency. A frequency domain representation allows one to observe readily which are the important frequencies within a signal. Such a representation gives incomplete information when the signal under analysis is nonstationary, i.e., when the signal's spectrum varies as a function of time. A more complete representation of such signals is provided by time-frequency methods, which seek to represent a signal's energy as a function of time and frequency simultaneously.

This article begins with a discussion of conventional spectral analysis techniques, then proceeds to introduce the principles of bilinear time-frequency methods.

Fourier Analysis

The use of Fourier methods for analysing signals is one of the most familiar signal-processing techniques. The basis of Fourier methods is the transform pair:

$$X(f) = \int_{-\infty}^{\infty} x(t)e^{-2\pi ift} dt \quad [1a]$$

$$x(t) = \int_{-\infty}^{\infty} X(f)e^{2\pi ift} df \quad [1b]$$

where $x(t)$ is the signal, nominally in the time domain, and $X(f)$ is its Fourier transform, and f is the frequency variable. The interpretation of eqn [1b] is that a signal can be constructed by forming a

weighted sum of complex exponentials, the weighting function being the signal's Fourier transform, as given by eqn [1a]. The Fourier transform is a linear operation, so that the Fourier transform of $x(t) = c_1a(t) + c_2b(t)$ is given by:

$$c_1A(f) + c_2B(f)$$

where $A(f)$ and $B(f)$ are the Fourier transforms of $a(t)$ and $b(t)$ respectively. It is important to realize that the exponentials in eqn [1b] are defined over the entire time axis, i.e., for $-\infty < t < \infty$, which makes them inefficient tools for decomposing signals with a finite duration. So that, for example, if the signal is such that $x(t) = 0$ for $|t| < T/2$ then the Fourier decomposition requires many frequency components to represent the signal accurately. It is this basic shortcoming of the Fourier transform that leads to effects such as side lobes and spectral leakage.

In many cases one chooses to work, not with the complete Fourier transform, but only to consider its squared magnitude, which here we refer to as the signal's spectrum. (The term spectrum can have a variety of meanings but herein it is taken to represent $|X(f)|^2$.) One reason for concentrating on the spectrum is because the spectrum is invariant to time shifts in the signal, so that the spectrum of $x(t - \tau)$ is identical to the spectrum of $x(t)$. This shift invariance arises because in computing the spectrum, the phase of the Fourier transform is discarded and it is this phase which conveys information about the temporal location of signal components.

The spectrum is sufficient to represent the signal's energy distribution over frequency, in the sense that one can express the energy in the frequency band (f_1, f_2) as:

$$\int_{f_1}^{f_2} |X(f)|^2 df$$

The spectrum is a bilinear transform, so that the transform relates to the signal through a quadratic

function. Hence, unlike the Fourier transform, the spectrum does not obey a superposition principle; specifically, the spectrum of $x(t) = c_1a(t) + c_2b(t)$ is given by:

$$|X(f)|^2 = c_1^2|A(f)|^2 + c_2^2|B(f)|^2 + 2c_1c_2\operatorname{Re}\{A(f)B(f)^*\} \quad [2]$$

where the asterisk denotes complex conjugation. The third term on the right-hand side of eqn [2] is an interaction term arising as a consequence of the squaring operation. This interaction term will be only be significant if there are frequency bands where $A(f)$ and $B(f)$ are both large. The interaction term will be small if the two components occupy different frequency bands.

In summary, the Fourier transform, which is a linear signal representation, contains information about the location of signal components in time, encoded, predominantly, in its phase. It is difficult to interpret this phase information directly. The spectrum, which is a bilinear signal representation, contains no information about the absolute location of a signal, but is easily interpreted. The goal of time-frequency methods is to construct signal representations that concisely represent (nonstationary) signals, allowing the user to identify rapidly which frequency components are present in a signal at a particular time and how each component evolves with time.

Time-Frequency Methods

The Wigner–Ville Distribution

Conventionally, time-frequency methods are classified into linear and bilinear methods; the linear representations preserve phase information, whilst bilinear representations dispense with phase information. This distinction is very closely allied to that drawn above between the Fourier transform and the spectrum. This discussion will concentrate on the more widely used bilinear time-frequency methods.

Considering the signal spectrum, $|X(f)|^2$, one can readily show the following familiar result (the Wiener–Khintchine theorem):

$$\begin{aligned} |X(f)|^2 &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} x(u)^* x(v) e^{-2\pi i f(u-v)} du dv \\ &= \int_{-\infty}^{\infty} r(\tau) e^{-2\pi i f\tau} d\tau \end{aligned} \quad [3]$$

where $r(\tau)$ is the instantaneous correlation function which may be defined as:

$$\begin{aligned} r(\tau) &= \int_{-\infty}^{\infty} x(t-\tau)^* x(t) dt \\ &= \int_{-\infty}^{\infty} x(t-\tau/2)^* x(t+\tau/2) dt \end{aligned}$$

An alternative formulation of eqn [3] is obtained by reordering the integrals to read:

$$\begin{aligned} |X(f)|^2 &= \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\infty} x(t-\tau/2)^* x(t+\tau/2) e^{-2\pi i f\tau} d\tau \right\} dt \\ &= \int_{-\infty}^{\infty} W(t, f) dt \end{aligned} \quad [4]$$

where $W(t, f)$ is the notation adopted to represent the term in the braces, i.e.:

$$W(t, f) = \int_{-\infty}^{\infty} x(t-\tau/2)^* x(t+\tau/2) e^{-2\pi i f\tau} d\tau \quad [5]$$

This function is in fact the central distribution to the class of bilinear time-frequency representations and is called the Wigner–Ville distribution (WVD). The spectrum can be thought of as the time-integrated WVD. Note that, whilst the spectrum is assuredly nonnegative, the same is not true for the WVD; indeed, it is almost always the case that the WVD of a signal is negative for some values of t and f . It is also elementary to show that:

$$\begin{aligned} |x(t)|^2 &= \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\infty} x(t-\tau/2)^* x(t+\tau/2) e^{-2\pi i f\tau} d\tau \right\} dt \\ &= \int_{-\infty}^{\infty} W(t, f) df \end{aligned}$$

so that the frequency-integrated WVD is the instantaneous energy. Hence, the function $W(t, f)$ may be considered as a fundamental way of representing a signal's energy as a function of time and frequency.

The signal enters the WVD through a quadratic operation (see eqn [5]) and so is a bilinear transform. This means that it inevitably generates interaction terms; the WVD of $x(t) = c_1a(t) + c_2b(t)$ is given by:

$$W_x(t, f) = c_1^2 W_a(t, f) + c_2^2 W_b(t, f) + 2c_1 c_2 \operatorname{Re}\{W_{a,b}(t, f)\}$$

where the subscript in the notation for the WVD is (temporarily) used to indicate the signal used to compute the WVD. The function $W_{a,b}(t, f)$ is a cross-Wigner–Ville distribution (CWVD), defined as:

$$W_{a,b}(t, f) = \int_{-\infty}^{\infty} a(t - \tau/2)^* b(t + \tau/2) e^{-2\pi i f \tau} d\tau$$

Whilst interaction terms in the spectrum (see eqn [2]) are small, assuming the two signals are separated in frequency, the same is not true for interaction terms in the WVD. In general, the CWVD is of the same magnitude as the WVD, leading to significant interaction terms in the WVD, regardless of whether the signal components occupy the same frequency band. The CWVD is an oscillatory function, the rate of oscillation increasing as the separation between components increases.

Briefly consider where the interaction terms make their greatest contributions. In the case of the spectrum the interaction terms are largest at frequencies where the signals' spectra are large. For the WVD the interaction terms are largest midway (in the time–frequency plane) between two components. Consequently there is the possibility of interaction terms being confused with true signal components.

The WVD arises as a natural technique for representing the energy of a signal as a function of time and frequency. However, there are two basic problems that act as limitations on the interpretation of the WVD as a decomposition of a signal's energy. The first is that the WVD will (almost certainly) be negative for some values of t and f , causing obvious problems with interpreting $W(t, f)$ as the energy in a signal at that time and frequency. The second problem is that the interaction terms in the WVD are of a significant magnitude and further they appear in regions of the time–frequency plane away from the true signal components. The result is that the interaction terms can make the appearance of the WVD rather confused and can be misleading. The central theme of much work in time–frequency analysis has centered on reducing the effect of the interaction terms whilst maintaining many of the positive aspects of the WVD.

To illustrate the behavior of WVD, consider an example signal consisting of the sum of two components. The first component is a 100-Hz sine wave

windowed using a Gaussian modulating function. The second component, windowed in the same manner, is a sinusoid whose frequency increases linearly with time, starting at 100 Hz and finishing at 400 Hz. **Figure 1A** and **1B** shows the WVDs computed for the individual components. (The plots of time–frequency representations in this chapter use a logarithmic gray scale, with dark colors representing large values. Negative points are not displayed, nor are values 30 dB less than the largest value in the distribution.) Note that resolution of WVD is the same for the tone and the swept sinusoid. It is a fundamental property of the WVD that its resolution, for a linearly swept sinusoid, is independent of the sweep rate. **Figure 1C** shows the WVD of the sum of these two signals. The interaction terms are those elements shown in **Figure 1C** that are not present in either of **Figure 1A** or **1B**. These interaction terms can be seen to oscillate, with the rate of oscillation increasing as the signal components separate in frequency.

Reduction of the Interaction Terms

The oscillatory nature of the interaction terms is the key to their reduction. The classical method to reduce interaction terms is to low-pass filter the WVD in the time–frequency plane. The result is a new time–frequency distribution, $P(t, f)$, defined below:

$$P(t, f) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W(\tau, \nu) \Phi(t - \tau, f - \nu) d\tau d\nu \quad [6]$$

The $\Phi(t, f)$ is referred to as the kernel function. The set of time–frequency distributions generated using eqn [6] is referred to as Cohen's class. For example if the kernel function is selected as $\Phi(t, f) = \delta(t)$, where $\delta(t)$ is the Dirac delta function, then $P(t, f) = |X(f)|^2$, that is to say that the time–frequency distribution degenerates to the signal's spectrum, in which case the interaction terms are small, as discussed above. In general, one seeks to select a kernel function that, like the above example, suppresses cross-terms whilst maintaining time and frequency information.

To suppress interaction terms effectively the kernel function should have the form of a low-pass filter, so that its double Fourier transform is a two-dimensional function that is large at the origin and decays away from there. The two-dimensional Fourier transform of $\Phi(t, f)$ is denoted $\phi(\theta, \tau)$, so that:

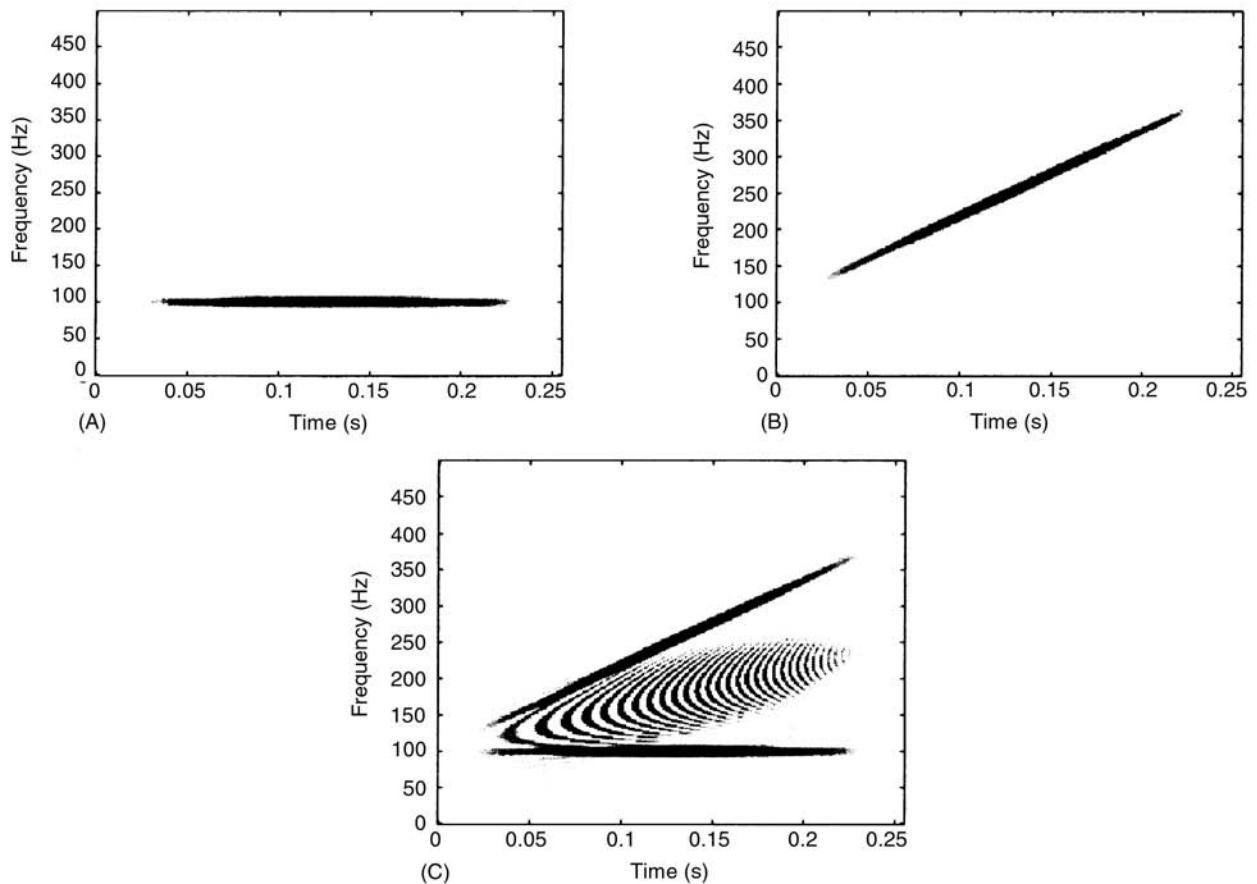

Figure 1 Wigner–Ville distributions of (A) tonal signal; (B) linearly swept sinusoid; and (C) sum of (A) and (B).

$$\phi(\theta, \tau) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Phi(t, f) e^{-2\pi i(\theta t + f\tau)} dt df$$

The low-pass nature of the kernel will serve to attenuate the oscillatory interaction terms but will also smear the desirable signal components; this smearing results in a loss of resolution. Consequently, the choice of kernel function involves a tradeoff between the degree of attenuation of the interaction terms and loss of resolution.

Kernel Design

Unless care is taken the smoothing operation (eqn [6]) will destroy some of the desirable properties of the WVD. For example, the marginal properties, eqns [4] and [5], do not generally hold for members of Cohen's class. To overcome this it is possible to derive conditions that the kernel must satisfy in order that

the distribution has specified properties. For example, it can be shown that if the kernel is such that:

$$\phi(0, \tau) = \phi(\theta, 0) = 1 \quad \text{for all } \tau \text{ and } \theta \quad [7]$$

then the distribution $P(t, f)$ will be such that:

$$\int_{-\infty}^{\infty} P(t, f) df = |x(t)|^2 \text{ and } \int_{-\infty}^{\infty} P(t, f) dt = |X(f)|^2 \quad [8]$$

i.e., the new distribution, like the WVD, will satisfy the marginal conditions.

The Spectrogram

One important example of a distribution that is a member of Cohen's class is obtained by using a kernel function satisfying:

$$\begin{aligned}\Phi(t, f) &= W_b(t, f) \\ &= \int_{-\infty}^{\infty} h(t - \tau/2)^* h(t + \tau/2) e^{-2\pi i f \tau} d\tau\end{aligned}$$

where $h(t)$ is an arbitrary function. By substitution of this kernel into eqn [4], and performing some manipulations one can show that:

$$P(t, f) = \left| \int_{-\infty}^{\infty} h(t - \tau) x(\tau) e^{-2\pi i f \tau} d\tau \right|^2 \quad [9]$$

This distribution has the property of being nonnegative, a condition required if $P(t, f)$ is to be interpreted as an energy distribution. The distribution defined in eqn [9] is probably the most widely used time-frequency distribution, namely the spectrogram, and will be denoted $S(t, f)$. The spectrogram is the squared modulus of the short-term Fourier transform (STFT) (for more details, see **Transforms, wavelets**). Whilst formally there are no restrictions that are placed upon the function $h(t)$, in practice it is chosen as a windowing function, i.e., a function which is nonnegative, symmetrical, unimodal, and of finite duration. In this case the product $h(t - \tau)x(\tau)$ (considered as a function of τ) is a windowed version of the signal localized about the point t . Hence, the spectrogram is the spectrum of the signal localized about t . This represents one natural extension of the Fourier transform (spectrum) for the case of nonstationary signals. The spectrogram has a long history and remains the most widely used time-frequency distribution. As such, it is often the benchmark against which other distributions are judged. This role arises largely for historical reasons; from a theoretical standpoint the only remarkable property that the spectrogram possesses is that it is guaranteed to be nonnegative.

When using the spectrogram the choice of the duration of the windowing function $h(t)$ must be made. This critically affects the appearance of the spectrogram – a fact that betrays the *ad hoc* nature of the spectrogram. If a short-duration windowing function is used then the spectrogram is able to resolve short-duration events well, but its frequency resolution is poor. When longer windows are used, then the frequency resolution is improved, but at the expense of temporal resolution. This is a fundamental limitation of the spectrogram.

The spectrogram is constructed by concatenating spectra, so the interaction terms in the spectrogram share the properties of the interaction terms appearing in the spectrum. Specifically, the interaction terms are at their largest when the signal components are large. This is a consequence of the fact that the kernel

function is an aggressive low-pass filter, which is very effective at suppressing the interaction terms but also results in a great loss of resolution. As will be shown, other members of Cohen's class allow one to reduce the level of interaction term suppression, with the benefit of increasing resolution.

Other Examples of Cohen's Class of Distributions

A range of time-frequency methods have been proposed that fall under the auspices of Cohen's class. Two of the most widely considered are outlined below, with the intention of giving a flavor of the available techniques.

The Choi-Williams distribution (CWD) uses a kernel function of the form:

$$\phi(\theta, \tau) = e^{-\theta^2 \tau^2 / \sigma}$$

The parameter $\sigma (< 0)$ is selected by the user and controls the rate of decay of $\phi(\theta\tau)$, i.e., the bandwidth of the low-pass filter, and controls the degree of interaction term suppression. This kernel function is designed so that it satisfies the condition [7] and so the resulting distribution satisfies the marginal conditions [8]. In general, the CWD is negative for some times t at some frequencies f , so it cannot be regarded as a true energy distribution. Whilst the CWD has smaller interaction terms than the WVD, this reduction is far from complete. The CWD is particularly poor at reducing interaction terms between signal elements that occur simultaneously or at different times but within the same frequency band.

Consider a signal that is zero for all times prior to time t_0 and after time t_1 . One condition that can be specified is that the time-frequency distribution should be zero for values of $t \notin [t_0, t_1]$; this is referred to as the weak finite support property. Most members of Cohen's class do not satisfy this condition, including the CWD and spectrogram. One method that is specifically designed to satisfy the weak finite support property is referred to as a cone kernel distribution (CKD). This is a Cohen's class distribution that uses a kernel function of the form:

$$\phi(\theta, \tau) = g(\tau) |\tau| \frac{\sin a\theta\tau}{a\theta\tau}$$

where a is a user-selected parameter (often taken as $\frac{1}{2}$) and $g(\cdot)$ is a user-defined function (often taken as unity, i.e. $g(\tau) = 1$). This distribution, like the CWD, suppresses cross-terms whilst maintaining a specified property (in this case, the weak finite support property).

The CKD does not satisfy the marginal properties. Indeed, the weak finite support and marginal properties are incompatible; that is, if a kernel is designed to

satisfy one condition, then the other condition is necessarily violated.

It is often the case when designing a kernel that to achieve one set of properties then a second set of properties is lost. This is further illustrated if one considers the problem of designing a kernel that yields a nonnegative time-frequency representation. This condition is necessary if one wishes to interpret a time-frequency representation as representing a signal's energy as a function of time and frequency. But one can show that, for a distribution to be nonnegative for all signals, it must be a spectrogram, which does not satisfy the marginal constraints or the finite support property. This is a fundamental limit to time-frequency distributions within Cohen's class, namely that they can never yield distributions that are both positive and satisfy other desirable properties.

Figure 2 shows the results of applying a spectrogram, CWD, and CKD to the test signal, the WVD of which is shown in Figure 1C. The spectrogram,

shown in Figure 2A, exhibits no visible interaction terms; however the resolution of the swept component is poor. (The window for the spectrogram was a Gaussian, with a root mean square duration of 12 ms. This was deemed to produce the most visually appealing results.) By contrast, in the CWD the interaction terms are large (Figure 2B), but the resolution of the two individual components is only slightly worse than that seen in the WVD (Figure 1C). For this example the most visually satisfying result is given by the CKD. The interaction terms are only noticeable when the two signal components are close, and there is little loss of resolution.

Whilst Cohen's class encompasses a great many of the distributions detailed in the literature, it does not cover all of them. This section briefly discusses some of the other methods that are not members of Cohen's class.

Cohen's class deals with signal representations that are bilinear (quadratic). There are linear representations, such as the STFT, and the wavelet transform.

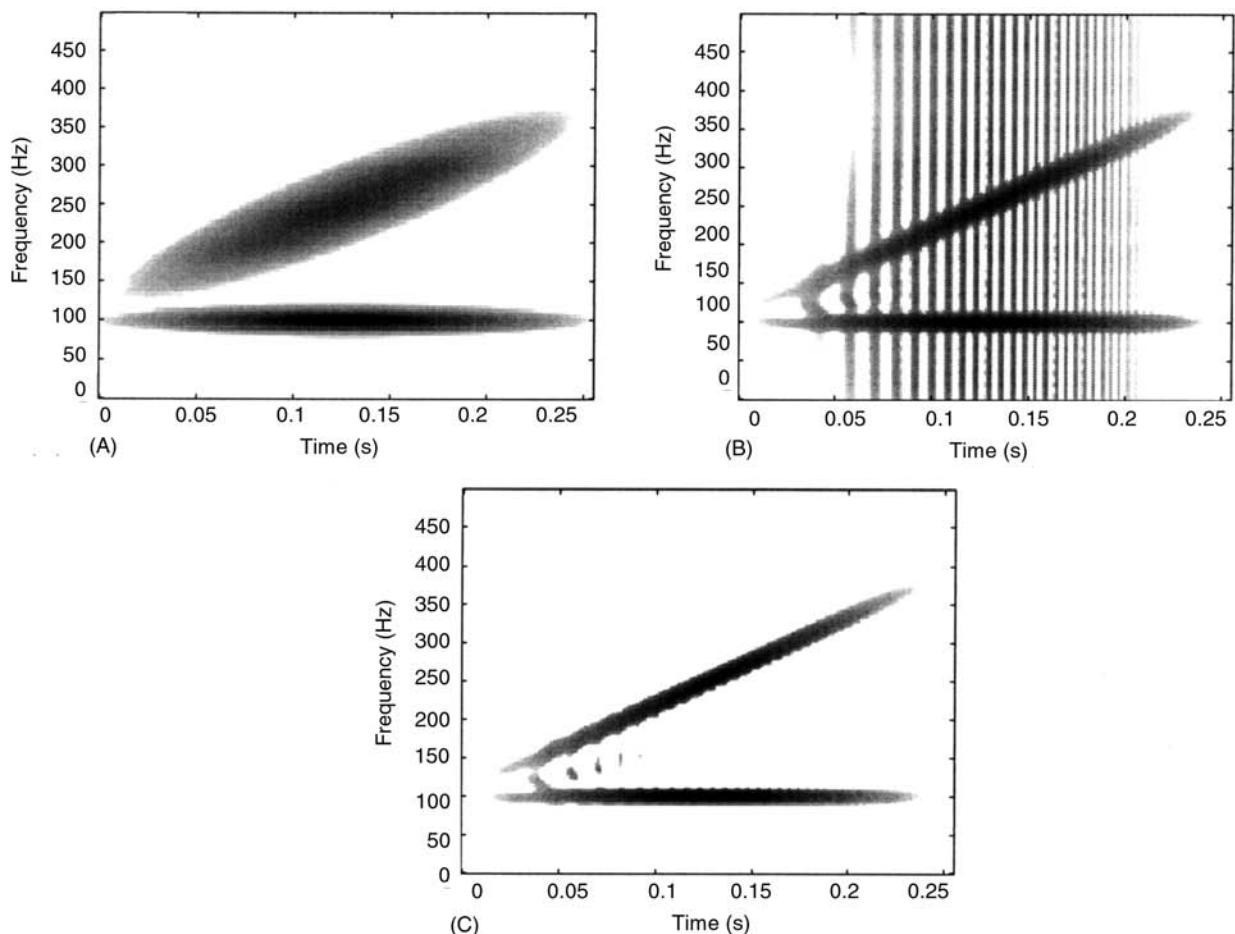

Figure 2 Various bilinear distributions for the test signal. (A) Spectrogram; (B) Choi-Williams distribution; (C) cone kernel distribution.

The linear representations obey the principle of superposition and so exhibit no interaction terms. However, the linear representations generate complex valued distributions, which are usually examined via their modulus and phase. The squared modulus of a linear representation is bilinear, e.g., as already stated, the squared modulus of the STFT is the spectrogram. Several methods are based on manipulating linear distributions. These methods are capable of giving good performance for certain classes of signals.

There also exist a variety of methods that adjust (adapt) the kernel function to suit the data set being considered.

Applications

There are many vibration-based applications to which time-frequency analysis can be applied. Here the results from two data sets will be briefly discussed so as to provide a realistic indication of the performance of the methods discussed above. The application is the analysis of frequency response measurements. It will be shown how the use of time-frequency methods allows one to glean information from structural response data that is often overlooked by considering either an impulse response function or a frequency response function (FRF).

Impulse Response Data

This section presents results from data collected using two experimental set-ups, shown in Figure 3. The first experiment was designed to yield simple signals that allow one to characterize a beam's dispersive behavior. The second experiment is a more realistic measurement that produces a more complex response, from which the aim is still to obtain information about the dispersive nature of the beam.

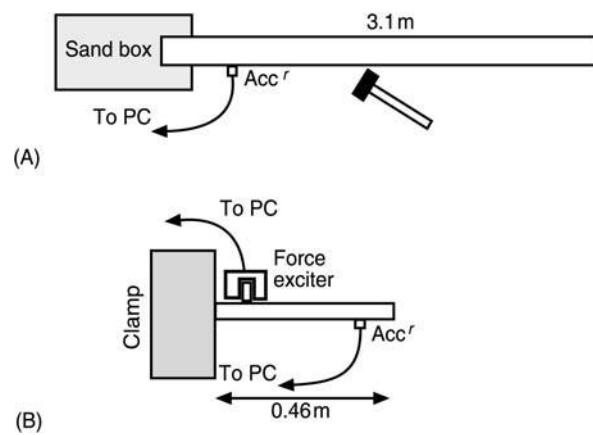

Figure 3 Experimental configurations.

The first experiment employed a simply supported beam, one end of which was embedded in sand to create a semianechoic termination. The other end was free. Response data were collected by exciting the beam with an impulse and measuring acceleration at a single point. The semianechoic termination reduced reflections: from one end such that the measured acceleration predominantly contains only two reflections, the direct signal and the signal reflected from the free end. This signal is depicted in Figure 4. The two reflections can be clearly distinguished, having epochs at approximately 0.004 and 0.01 s.

The first component arrives after traveling a short distance along the beam, whereas the second component arrives having traveled to the free end and been reflected back to the measuring point. This difference in path lengths for the two paths gives rise to different amounts of dispersion in the two components; the second component is more disperse than the first. Evidence for this can be observed in Figure 4, where the second component is significantly longer in duration than the first.

Figure 5 shows various time-frequency distributions computed for this signal. In the spectrogram (Figure 5A), one can readily identify the two components as distinct loci in the time-frequency plane. The first component, starting at approximately 0.004 s, is approximately vertical above 1000 Hz, but its behavior below that frequency is obscured by the poor resolution of the spectrogram. The second component, starting at approximately 0.01 s, is clearly curved, the curvature being due to dispersion, ensuring that the lower-frequency components arrive at the measurement site after the higher frequencies. From the WVD (shown in Figure 5B), one can more confidently define the time-frequency curves describing each component, although there are a large number

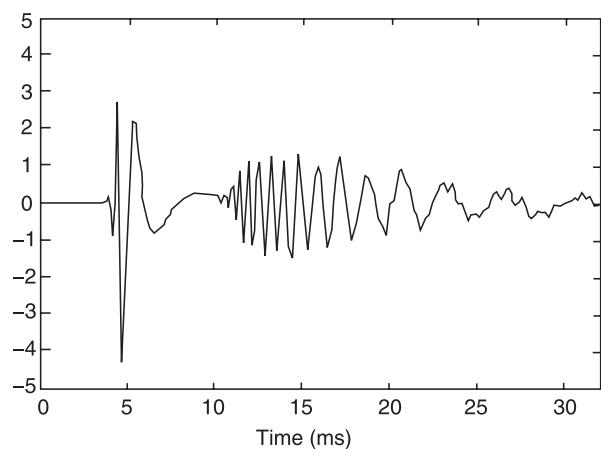

Figure 4 Impulse response data from beam with a semianechoic termination.

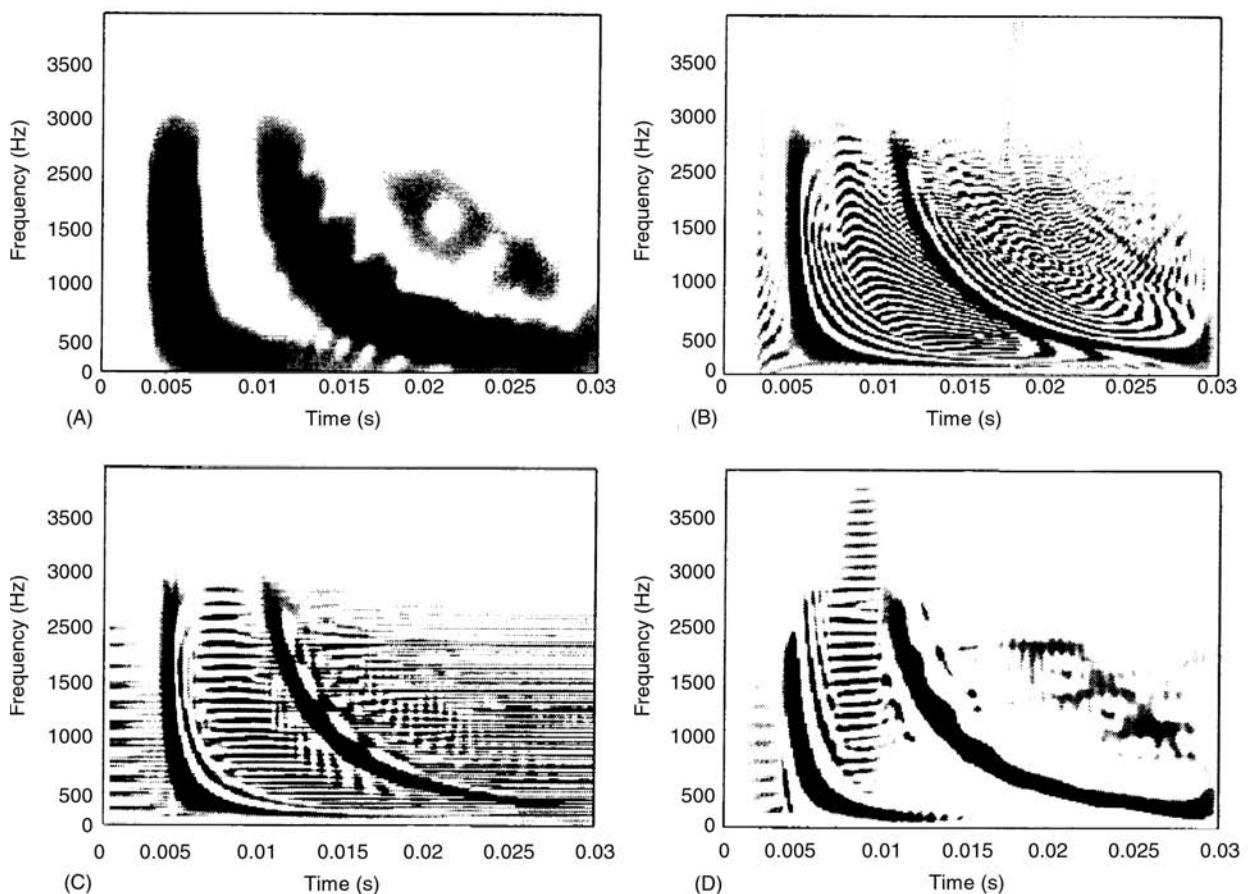

Figure 5 Bilinear time–frequency representations for data shown in **Figure 3**. (A) Spectrogram; (B) WWD; (C) CWD; (D) CKD.

of interaction terms present. In the CWD (shown in Figure 5C), these interaction terms are slightly reduced, with little loss of resolution. Finally, in the CKD (Figure 5D), the interaction terms are more heavily reduced, leaving the time–frequency curves as dominant features, but the loss of resolution required to achieve this is evident.

The second data set was collected by exciting a cantilever beam, near its root, and measuring the acceleration signal near its tip. The excitation used was band-limited white noise force input. These data were used to estimate the transfer function (inertance) between the excitation point and the measurement point using the classical $H_1(f)$ estimator. This transfer function was then used to compute the impulse response function, shown in Figure 6.

The impulse response of the beam contains many more components. It consists of an initial propagation delay, due to the finite time required for a disturbance to reach the measurement point from the excitation site. However, the character of wave propagation in the beam is such that high frequencies travel faster than low frequencies, i.e., the beam is dispersive. Thus, one anticipates that the onset of

each mode of vibration in the beam should be different, with the high-frequency modes being excited before the low-frequency modes. Such a phenomenon cannot be observed by examining either the impulse response or the FRF directly. This example demonstrates that evidence for such a phenomenon can be obtained from the time–frequency representation.

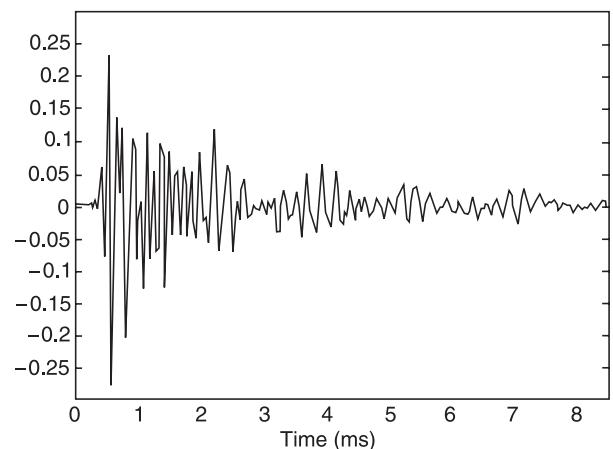

Figure 6 Impulse response data from cantilever beam.

Various time–frequency representations for a cantilever beam signal are shown in **Figure 7**. This signal contains many more components and so represents a difficult processing challenge. The spectrogram (**Figure 7A**) shows some structure. The frequency band centered near 4 kHz shows significant energy and there is evidence of packets of energy arriving at regular intervals. These packets of energy relate to the reflections arriving at measurement points. A similar effect can be seen in the frequency band near 8 kHz. The WVD, depicted in **Figure 7B**, is dominated by interaction terms and the signal details are almost completely obscured. In the CWD (**Figure 7C**), the interaction terms are reduced but the representation remains confused. The CKD (**Figure 7D**) conveys greater information about the signal. In the 4 kHz band the dispersion in the individual energy packets can be seen to exhibit its own dispersive character, with later arrivals exhibiting more dispersion than the earlier arrivals. In the higher-frequency band, near 8 kHz, the individual energy packets are smeared into a single component.

Summary

Time–frequency methods offer a convenient technique for representing the spectral content of a signal when that content varies as a function of time, i.e., when the signal is nonstationary. Basing a representation on the decomposition of a signal’s energy naturally leads to a bilinear (quadratic) representation. Such representations are characterized by the fact that the distributions commonly exhibit interaction terms that are located in counterintuitive locations in the time–frequency plane. These interaction terms can be reduced by the application of a two-dimensional filter. The reduction of interaction terms in this manner necessarily leads to a loss of resolution, but can be controlled so that some of the desirable properties of the original distribution are maintained.

By careful choice of the time–frequency representation one can obtain signal representations in which the underlying character of the signal is revealed.

Nomenclature

$A(f)$	Fourier transform of $a(t)$
$B(f)$	Fourier transform of $b(t)$
f	frequency variable
$h(t)$	arbitrary function
$P(t, f)$	time-frequency distribution
$r(\tau)$	instantaneous correlation function
$S(t, f)$	spectrogram
$x(t)$	signal
$X(f)$	Fourier transform of $x(t)$
$ X(f) ^2$	signal spectrum
$\delta(t)$	Dirac delta function
$\Phi(t, f)$	kernel function

TIRE VIBRATIONS

G D Shtehnauz and L T Charek, The Goodyear Tire Rubber Company, Akron, OH, USA

doi:10.1006/rwvb.2001.0069

Introduction

Tire vibration is an oscillatory motion of the whole tire or its parts with respect to a neutral (mounted and loaded) position on a vehicle or a test rig. Tires are the only parts of the vehicle that connect it to the road, providing support, isolation, traction, braking, and

steering. Each one of these functions involves developing, responding to, and transferring forces and moments between the road and the vehicle. Slow-changing or static forces, like vehicle weight, preload the tire, while fast-changing or dynamic forces, like road impacts or sudden braking, cause tire vibration.

In this article we discuss pneumatic tires, which are used on passenger cars, trucks, bicycles, tractors, and off-the-road vehicles. The common feature of these tires is that when installed on the wheel, they form a cavity containing a pressurized gas (mostly air). The pressurized gas preloads and stiffens the tire structure, while still maintaining enough flexibility to create a footprint on the road, which makes it

possible to carry the vehicle's load, while being able to develop and transfer the control forces and moments.

On passenger cars and trucks, the tire-wheel assembly is connected to the vehicle body through components of suspension, steering, and driving systems. The suspension system consists of springs, dampers, bushings, and connecting rods to isolate the vehicle further from the road disturbances. Bicycles, tractors, and off-the-road vehicles frequently do not have separate suspension systems, and tires function also as the suspension. **Figure 1** shows a schematic of the tire and suspension on a vehicle.

Tire vibration may be caused by: (i) road irregularities, e.g. texture, potholes, bumps; (ii) control actions of drivers, e.g. steering, accelerating, and braking; and (iii) tire-wheel assembly characteristics, e.g., nonuniformity, tread pattern, and imbalance. In response to excitation, tires vibrate with the whole vehicle in the frequency range of 0.5–3 Hz, tires vibrate with the suspension and steering systems at 10–30 Hz, and tires vibrate as a flexible body on a relatively rigid wheel at 30–300 Hz. To these we can add vibration of tire parts, such as tread lugs at 1000–4000 Hz, and vibration of the air in the cavity, starting from 150–200 Hz, depending on tire size.

Tire vibration response can be described as a combination of its natural modes, each with its own frequency, shape, and damping. Tire vibration cannot be avoided: the tire is supposed to flex along with the suspension, isolating the vehicle from the road, but the vibration can and should be controlled, to assure the optimal performance of a given vehicle. Tire vibration may be controlled by design or by changing tire boundary and operating conditions.

Tire vibrations are studied by testing and modeling of both free and constrained tire-wheel assemblies on special test rigs, as well as on vehicles. Knowledge of tire vibration characteristics is important in predicting, evaluating, and modifying tire features to obtain the desired on-vehicle performance.

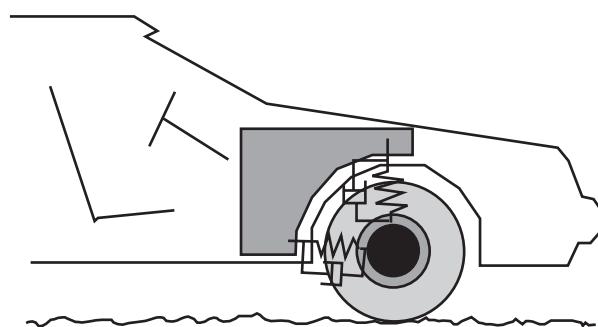

Figure 1 Tire, wheel, and suspension on vehicle.

Sources of Tire Vibration

The main sources of tire vibration are road irregularities, tire-wheel assembly imbalance, and tire-wheel nonuniformity. Drivers' inputs of accelerating, braking, and steering are of secondary importance.

Road Irregularities

Road irregularities can be continuous or discrete. The continuous ones relate to the texture and waviness of the road surface. The discrete ones are bumps, potholes, seams, and patches. The amplitudes and frequency content of the road-related excitation largely depend on the geometry of the road irregularities and the speed of the tire. In general, the waviness of the road will produce low-frequency (below 20 Hz) excitation, the surface texture will produce higher-frequency (above 100 Hz) continuous random excitation, and transient events will produce wide-band (0–2000 Hz) excitation.

Tire-Wheel Imbalance

A tire-wheel assembly can have imbalance, as a result of uneven mass or inertia distribution with respect to the assembly's center of mass (static imbalance) or axis of rotation (dynamic imbalance). Static imbalance will create centrifugal forces in vertical and longitudinal directions of the vehicle, while dynamic imbalance will create aligning and overturning moments with respect to the vertical and longitudinal axes. Frequency of imbalance-related excitation is once per revolution of the tire-wheel assembly, and it depends on vehicle speed and effective rolling radius of tire. At 60 mph for passenger tires, the frequency of imbalance-related vibration may vary from 8 to 12 Hz, depending on the tire size.

Tire-Wheel Nonuniformity

Both the tire and the wheel can show geometrical nonuniformity or run-out. A tire can also have stiffness variation, tread periodicity, and global and local mass irregularities. The tire-wheel nonuniformity produces periodic excitation, synchronous with the tire rotation in vertical, longitudinal, and lateral directions, as well as three moments about the vertical, longitudinal, and lateral axes. Nonuniformity-related excitation consists of harmonic components whose frequencies are multiples of the tire rotation frequency. Harmonics 1–10 typically produce tactile vibration, while higher harmonics related to tread periodicity can produce audible vibration.

Driver Inputs

Driver inputs that excite tire vibrations are accelerating the vehicle, braking, and steering maneuvers. Amplitude levels and frequency content of these inputs largely depend on the vehicle speed, and the severity of the driver's actions. Sudden accelerating and braking can produce excitation frequencies up to 200 Hz, while steering maneuvers can produce much lower excitation up to 4 Hz.

Tire–Vehicle Dynamics System

Tire Functions and Construction

Functionally, the tire is the only component that connects the vehicle to the road, providing support, traction, braking, and steering, and serving as a cushion against road irregularities. In passenger cars and trucks, the tire is a part of the vehicle suspension system. In tractors and off-the-road vehicles, the tire is the suspension.

Geometrically, the tire is a toroidal shell, attached to a relatively rigid wheel and stiffened by inflation pressure in the tire's inner cavity.

Physically, the tire is a complex engineering product. The main functional components of a tire are shown in Figure 2. Steel cable beads anchor the tire to the rim. An inner liner of rubber holds the pressurized gas in the cavity. Flexible sidewalls of fabric and rubber provide the cushion for a comfortable ride. Belts of high tensile strength maintain a flat footprint for good traction, braking, handling, and treadwear. Finally, a rubber tread provides firm contact with the road.

Dynamically the tire is a flexible, nonstretchable ring on an elastic foundation. The inertial properties of a tire are dominated by mass distribution of the tread and belts. Its stiffness is controlled by inflation pressure, but is also influenced by the load, tire shape, material properties, and design. Tire damping is a

combination of two mechanisms: viscous and hysteretic. Both the stiffness and damping of a tire depend on inflation pressure, load, and speed. A tire also acts as a nonlinear spring, softening with increased amplitudes but stiffening with increased frequency of excitation.

Vehicle and Suspension System

In its simplest form, the vehicle can be thought of as a rigid body on a suspension comprising a mass, spring, and damper. The tire can then be attached to a vehicle model as a mass and spring. In this fundamental approach, the tire/vehicle system exhibits four main rigid-body, or sprung-mass modes of vibration, and two suspension or unsprung-mass modes. The vehicle modes of bounce, pitch, roll, and yaw are shown in Figure 3A. With the exception of the yaw mode, the tire's contribution and participation in the rigid body modes is minimal, since its stiffness acts in series with the much softer suspension spring. However, in the case of the suspension modes, wheel hop and axle tramp, Figure 3B, the tire's mass and stiffness are key factors influencing the frequency of the suspension modes.

As the depth of study into tire/vehicle vibration increases, this simple representation must be replaced with more rigorous models in which the flexibility of the vehicle body/frame and local vehicle modes are included. Table 1 shows frequency ranges of the main tire-related vibration modes of a typical front-wheel-drive vehicle.

The frequencies of modes are typical for an independent front suspension, and may be different for the rear suspension, but the main point to make here is: there is a group of modes of the suspension system and tire in the range 10–100 Hz. These modes cannot be eliminated, but vibration response, resulting from a combination of these modes, can be reduced by adding damping to the system, or by shifting the modal frequencies by stiffness or inertia changes.

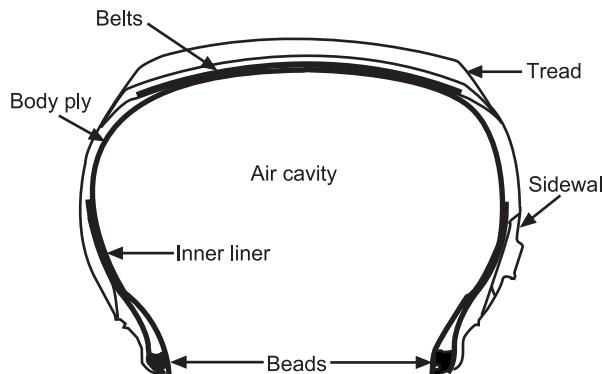

Figure 2 Main functional components of the tire.

Table 1 Tire-related vibration modes of a typical front-wheel-drive vehicle

Vibration mode	Frequency range (Hz)
Vehicle, bounce	1–1.2
Vehicle, pitch	1.2–1.5
Vehicle, roll	1.5–2.0
Vertical hop of suspension	12–16
Fore–Aft of suspension	14–22
Yaw of suspension	20–30
Tire on wheel first fore–aft	30–45
Tire vertical	65–100
Tire second fore–aft	75–110

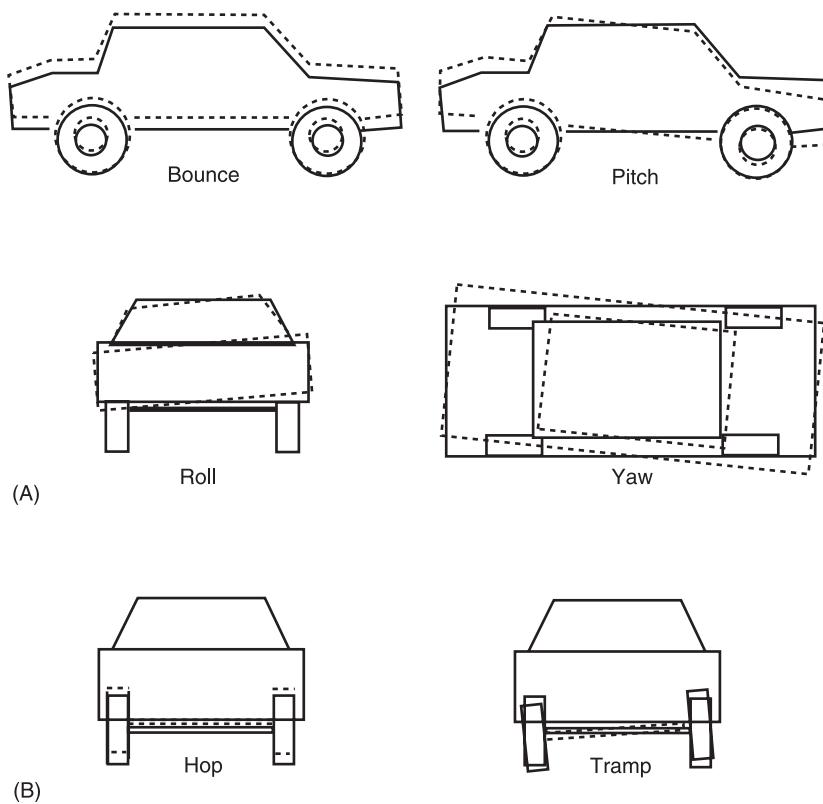

Figure 3 (A) Vehicle modes (sprung mass). (B) Suspension modes (unsprung mass).

In practice, not only is it necessary to separate tire-suspension modes from each other, but also from the modes of other vehicle components, which may be excited during vehicle operation.

Tire and Wheel System

In its simplest form, the tire and wheel assembly can be thought of as a mass on a spring attached to the ground in the vertical direction. This simple one-dimensional model is often used as a first-cut for predicting the fundamental suspension and rigid-body vehicle modes. However, as the frequency of interest increases, more detail is needed about the tire and wheel assembly.

The stiffness of the tire in the lateral and longitudinal directions must also be known and is usually obtained from tests. Tire stiffness in these two directions is found to be more sensitive to speed than is the vertical spring rate. The build-up of a cornering force as the tire rolls provides additional lateral stiffness and must be included in vehicle handling models.

For investigations involving vehicle ride, the lumped mass and spring representation of the tire is limited to frequency responses below 30 Hz. Above these primary vehicle and suspension frequencies the vibration of the tire is controlled by its mass and

stiffness distribution. In other words, the tire has to be represented as a flexible ring on an elastic foundation.

Tire Vibration Responses

Tire vibration responses include vibrations of the tire with the whole vehicle (0.5–3 Hz), tire vibrations with the vehicle's suspension and steering systems (10–30 Hz), and tire vibrations within the tire-wheel assembly itself (30–300 Hz). Special cases include vibrations of tread lugs, and air cavity resonance.

At the lower frequencies, 0.5–3 Hz, a tire vibrates as a spring and damper, participating in the vehicle's bounce, pitch, roll, and yaw motions. A Tire vibrates with the suspension and steering system in the range 10–30 Hz, participating in the vertical wheel hop, axle tramp, fore-aft, lateral, and steer modes. As a part of the tire-wheel assembly, the tire vibrates as a flexible ring, made up of the tread and belt package, elastically connected to the wheel and the road. The ring modes progress from the predominantly rigid body below 100 Hz, when the ring moves relative to the wheel in vertical, torsion, fore-aft, and steer directions, to the elastic modes above 100 Hz, where peaks and valleys are formed around the tire's circumference and across the tire's meridian.

Vibration modes of tires are characteristic displacement patterns, described by modal frequency, damping ratio, and mode shape. Each mode shape is the result of two waves traveling in opposite directions around the circumference of the tire and interfering with each other. In lab studies, the source of these waves might be a shaker attached to the tread-band.

By adjusting the frequency of the shaker, the wavelength of the travelling wave can be changed. When the wavelength, or an integer number of wavelengths matches the circumference of the tire, reinforcement occurs at the excitation point and the vibration pattern amplifies. The interference of the two opposing traveling waves results in the creation of a stationary mode shape pattern.

In practice, typical vibration response is a combination of several modes, but depending on excitation, some modes can dominate the response. Vibration modes of tires are influenced by the following conditions: tire-road contact (free or loaded), wheel axle mount (free, pinned, or fixed), and operating parameters (inflation pressure, load, and speed).

Vehicle Rigid-body Modes (0.5–3 Hz)

The tire flexes as a part of the vehicle corner spring, while the vehicle body is bouncing, pitching, rolling, and yawing. In most of these modes of vehicle vibration, the tire and the suspension spring work in series, and the resulting effective stiffness of the vehicle corner is calculated as follows:

$$k_e = \frac{k_s k_t}{k_s + k_t} \quad [1]$$

where:

k_e = the effective stiffness of the vehicle corner
 k_s = the stiffness of the vehicle suspension
 k_t = the stiffness of the tire

Dividing by the tire stiffness K_t , and remembering that the tire is 5–10 times stiffer than the suspension, shows that K_e is dominated by the suspension spring stiffness:

$$k_e = \frac{k_s}{1 + k_s/k_t} \quad [2]$$

The frequencies of vehicle rigid-body modes depend on the vehicle's inertia, location of its center of mass, and the positions of the wheel centers. For example, the pitch mode frequency f_p of a vehicle can be calculated as:

$$f_p = \frac{1}{2\pi} \sqrt{\frac{k_{ef}a^2 + k_{er}b^2}{I}} \quad [3]$$

where:

k_{ef} = effective front stiffness
 k_{er} = effective rear stiffness
 a = the distance from the front axle to the vehicle's center of mass
 b = the distance from the rear axle to the vehicle's center of mass
 I = the moment of inertia of the vehicle body with respect to the lateral axis crossing the center of mass.

Tire-Suspension Mods (10–30 Hz)

The tire, wheel, brake, attached elements of the driving and steering systems (unsprung mass), vibrate between the ground and the vehicle body (sprung mass). The tire and suspension spring work in parallel, and the tire, which is 5–10 times stiffer than the suspension spring, dominates the process. The frequency of the resulting wheel hop vibration is calculated by the following formula:

$$f_{hop} = \frac{1}{2\pi} \sqrt{\frac{k_t + k_s}{m_u}} \quad [4]$$

where:

k_t = the spring rate of tire
 k_s = the spring rate of suspension
 m_u = the unsprung mass

Rigid Ring Modes (>100 Hz)

The lowest-frequency tire modes are descriptively called rigid ring modes. These generally display a rigid-body motion of the belt-tread ring with respect to the wheel. These modes usually occur below 100 Hz. They represent translation and rotation with respect to the three axes and are named in accordance: first Vertical, first Lateral, first Steer and first Torsional (Figure 4).

Because of the global nature of the tire movement about the wheel, these rigid ring modes produce a significant force at the wheel. A spectrum of road data in Figure 5 shows peak spindle responses at the frequencies of two suspension modes (wheel hop and fore-aft) and two rigid ring modes (torsional and vertical).

Flexible Ring Modes (>100 Hz)

The next group of tire modes typically occurs above 100 Hz. They involve bending of the tread band in the

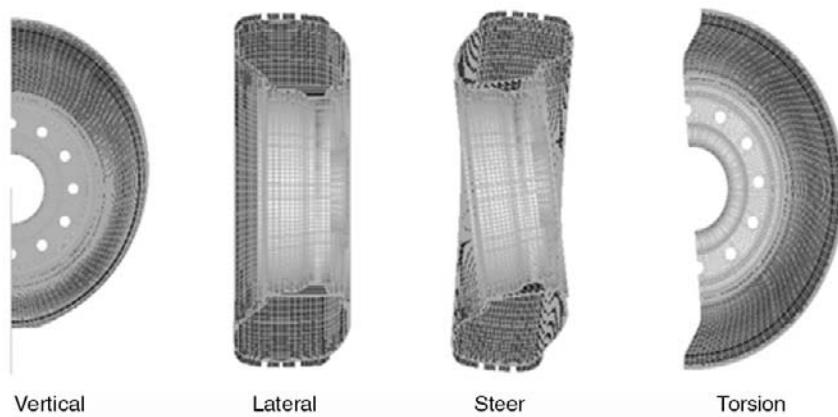

Figure 4 Rigid ring tire modes.

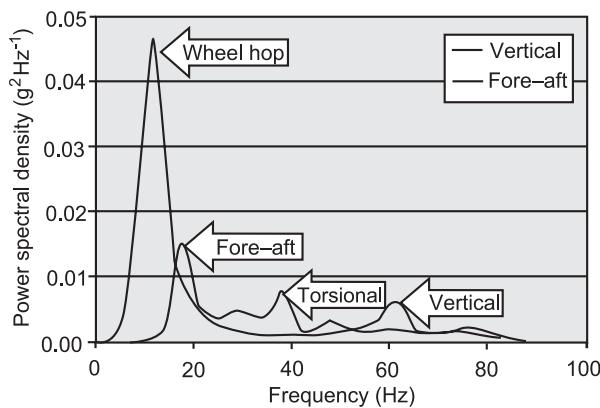

Figure 5 Vibration spectra of vehicle road response.

radial direction producing a series of peaks and valleys around the tire. Some of these modes are shown in Figure 6, and are identified by the number of full wavelengths around the tire. The lobe count increases by one approximately every 20-30 Hz, thus at 300 Hz, the tire will have as many as 10 or more lobes around the tread band.

The frequency of these modes can be found from the following general equation of a flexible ring on an elastic foundation, derived from the classical wave equation:

$$EI \frac{\partial^4 \xi}{\partial x^4} - N \frac{\partial^2 \xi}{\partial x^2} + k \xi = -m \frac{\partial^2 \xi}{\partial t^2} \quad [5]$$

where:

- ξ = the deflection of the ring vibration
- x = the independent circumference coordinate
- t = the time
- EI = the bending stiffness of the ring
- N = the axial preloading
- k = the stiffness of the elastic foundation
- m = the mass per unit length of the ring

Solving the wave eqn [5] we obtain the formula for the natural frequencies f_n of the elastic ring, as follows:

$$f_n = \frac{1}{2\pi R^2} \sqrt{\frac{EI n^4 + N R^2 n^2 + k R^4}{m}} \quad [6]$$

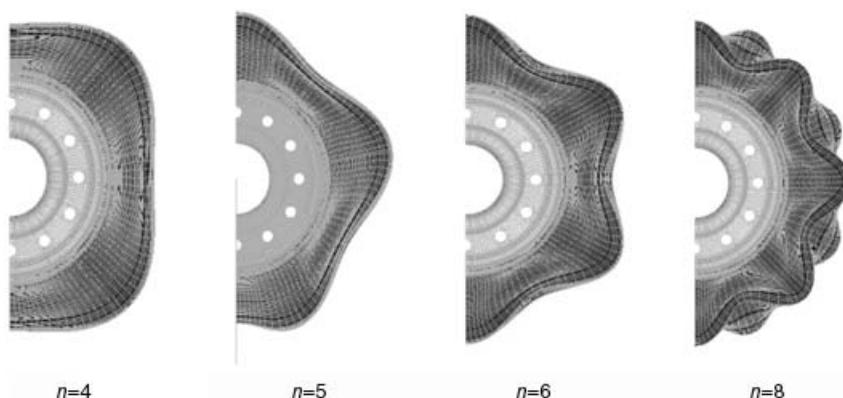

Figure 6 Flexible ring modes of tire.

where:

n = the mode number

R = the radius of the ring

Tire flexible ring modes are not significantly affected by the wheel boundary condition since they are symmetric about the wheel, resulting in little or no involvement of the wheel in the mode shapes. Because of this, flexible ring modes do not significantly amplify the road vibration transmitted to the vehicle as do the rigid ring modes. The frequencies of the rigid ring modes can be approximated from eqn [6], using the wave number $n = 0$.

While flexible ring modes may not significantly influence spindle vibration, they can impact the noise radiation pattern. Acoustic holography can be used to measure the noise radiation pattern of tires, as shown in Figure 7A. This noise radiation has the same pattern as the corresponding flexible ring mode, as measured by laser Doppler vibrometer, as shown in Figure 7B. In general, as the mode number increases,

the radiation efficiency decreases, making flexible ring modes less important to tire noise radiation at higher frequencies.

Cross-sectional (Bead-to-Bead) Modes (>100 Hz)

As vibration frequency increases above 100 Hz, the tire begins to act as a flexible membrane in the cross-sectional (meridian) plane in addition to the circumferential (equatorial) plane. This produces a series of peaks and valleys across the tire. A few of these modes are shown in Figure 8, and are identified by the number of half-wavelengths from bead to bead. The half-wavelength count, m , increases by one approximately every 100 Hz. Thus at 1000 Hz, the tire may have 10 or more half-wavelengths in its cross-section.

These cross-sectional modes, sometimes referred to as meridian modes, can influence the amount of vibration transmitted to the wheel. This is demonstrated in the sample of road data in Figure 9, where the peaks of 10, 350, 500, and 800 Hz are related to the $m = 3, 5, 7$, and 9 modes. Above 1100 Hz, the meridian modes lose their effect on noise generation.

First acoustic Cavity Mode (200–250 Hz)

The pressurized gas inside the tire not only provides the stiffness for the ring and cross-section modes, it also acts as the medium for the propagation of acoustic waves in the internal chamber of the tire-wheel assembly. This tire cavity can be thought of as an organ pipe wrapped into a circle. The length of this organ pipe can be approximated using the radius of the tire at mid-sidewall.

The frequency of the first tire acoustic cavity mode can be estimated using a basic equation of the fundamental frequency of the standing wave in the organ pipe, as follows:

$$f_c = \frac{c}{L_c} = \frac{c}{2\pi R_c} \quad [7]$$

where:

c = the speed of sound in the tire cavity gas

L_c = the effective length of the tire cavity

R_c = the effective radius of the tire cavity

The first acoustic cavity mode is typically in the range of 200–250 Hz, depending on the size of the tire. These acoustic modes are identified by the number of wavelengths around the tire. This wavelength count increases by one approximately every 200 Hz.

Because of the global and nonsymmetric nature of the first vertical and fore-aft acoustic cavity modes,

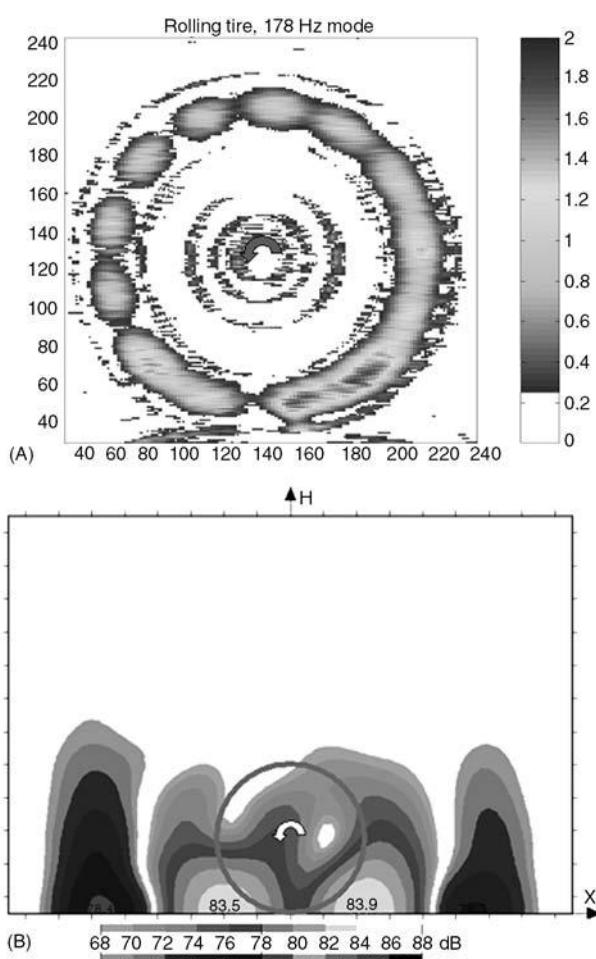

Figure 7 (A) Surface vibration map of a rolling tire. (B) Hologram of tire noise radiation.

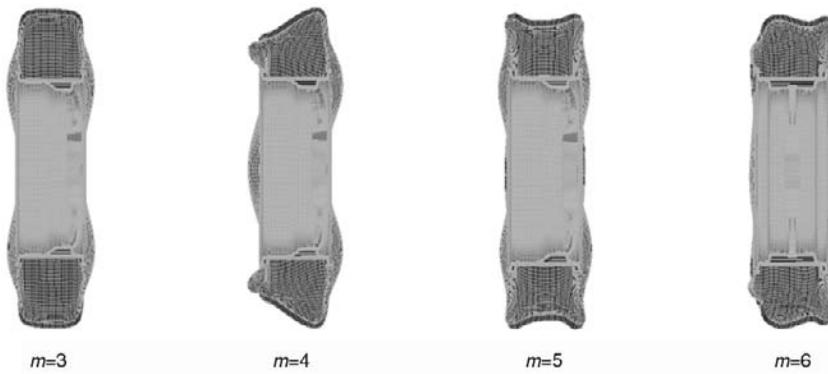

Figure 8 Meridian vibration modes of tire.

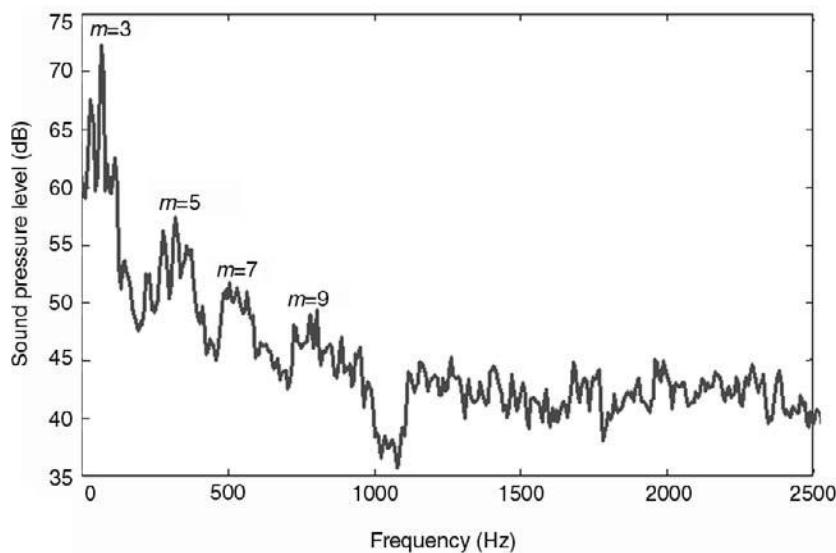

Figure 9 Contribution of vibration modes to tire noise.

these modes can produce significant spindle response, as seen in the lightly damped peaks around 230 Hz in **Figure 10**. This may be amplified if the air cavity mode is close to the wheel rocking mode, resulting in a highly tonal noise entering the vehicle cabin. The frequency of these peaks can be shifted by changing the gas in the tire, e.g., from air to helium.

Standing Wave

One interesting and potentially destructive tire vibration is the standing wave. This phenomenon can occur at high-speed operation of the loaded tire if the speed of the tire matches the speed of a displacement wave propagation in the tire (recall tire mode shapes are the result of traveling waves). At this critical speed, the footprint deflection serves to reinforce the mode shape, whose traveling wave speed matches that of the tire.

To help understand this, think of a string being excited laterally at one end. A wave can be observed traveling along the string. If an observer was able to slide a finger along the string just behind the wave, at the exact same speed as the traveling wave, he could in effect help push the wave along the string. If he goes slower or faster than the wave speed, he will destructively interfere with the traveling wave.

In the same way, the loaded spinning tire can be thought of as a stationary tire with the footprint traveling around it. When the speed of the footprint matches the speed of a traveling vibration wave, it will reinforce it. The result can be a standing wave at the trailing edge of the footprint.

The standing wave speed can be calculated for each mode number using the following equation:

$$v_n = \lambda f = \frac{2\pi R}{n} f \quad [8]$$

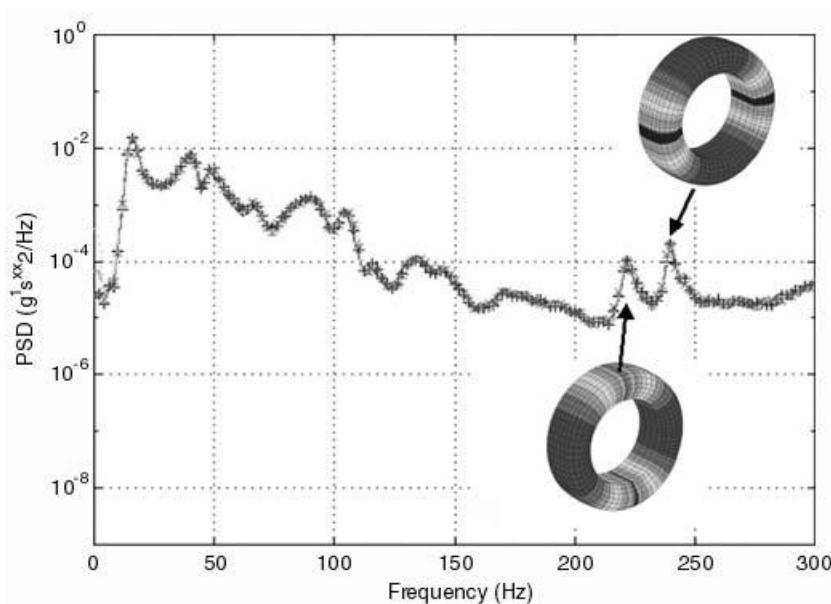

Figure 10 Acoustic cavity components of spindle vibration.

where:

v_n = the wave speed for mode n

R = the radius of the tire

λ = the wavelength

f = the frequency of mode n from eqn [6]

Applying this equation for $n = 1, 2, 3, \dots$ the slowest wave speed analytically is found to correspond to $n = 7 - 9$.

Experimentally, standing waves typically have a wavelength similar to that of the seventh to ninth ring mode. Tests on a loaded, rolling tire confirm that these tire ring modes typically have the lowest wave speeds and are the first ones to be matched by the 'traveling' footprint as tire speed is increased. The effects of reaching the critical speed and forming the standing wave are a sharp increase in rolling resistance, overheating of the tire, and even possible tire failure. This is why, based on the lowest critical speed, each tire has a maximum speed of operation, which should not be exceeded by the driver.

Table 2 summarizes vibration modes of a topical passenger tire, including mode descriptions frequencies, and related negative effects on passenger comfort, or tire.

Influence of Design and Operating Conditions on Tire Vibration Frequencies

While all tires have the same general mode shapes as described in the previous section, natural frequencies are determined by the tire design and applied operat-

ing conditions. Tire design includes both physical dimensions and internal construction. Operating conditions include load, inflation, and speed as well as boundary conditions at the spindle and footprint. Modal frequency studies conducted over a wide range of tires have established general trends on how each of these factors shifts the frequency of tire modes. Some of these trends follow.

Physical Dimensions: Size and Shape

Typically, increasing the size of a tire will lower its modal frequencies. There are two reasons for this: (i) a larger tire will likely have more mass, thus lowering its natural frequency, and (ii) a larger tire will have a longer wavelength for a given mode shape, which for

Table 2 Typical passenger tire vibration modes, and their effect

Vibration mode	Frequency (Hz)	Possible effect
Suspension/tire first vertical	12–16	Ride discomfort described as shake
Suspension/tire first fore-aft	14–22	Ride discomfort described as shake
Tire second fore-aft	30–45	Tactile vibration and audible rumble
Tire second vertical	65–100	Tactile vibration
Tire third fore-aft	75–100	Tactile vibration
Tire ring modes	100–1000	Increased noise radiation
Tire first cavity	200–250	Tonal interior noise
Meridian plane modes	100, 350, 500 ...	Interior noise and vibration
Standing wave	7–9th ring mode	Increased rolling resistance, reduced durability

a constant traveling wave speed, means a lower frequency. In addition to size, the tire cross-sectional shape or aspect ratio of section height to width also affects tire frequencies. Lowering the tire profile typically increases modal frequencies due to a reduction of mass and an increase in stiffness from the shorter sidewall.

Tire Construction

Without getting into the details of tire construction, there are some major components in a tire that can be adjusted to shift modal frequencies. Changing the body cord angle will shift the frequencies of most torsion and vertical-type modes, while having minimal effect on lateral modes. Increasing the number of body or belt plies also will increase frequencies, since their stiffening effect outweighs their mass effect. Because there are as many as 100 components in a tire, the designer has numerous design options to facilitate shifting specific tire modal frequencies as a means of optimizing the tire to a specific vehicle. The rule of thumb for this tuning process is to avoid the coincidence of tire modes with those of the vehicle.

Operating Conditions: Inflation, Load, and Speed

While tire design can be used to shift the modal frequencies of a tire, a far greater influence on modal frequencies have the tire's operating conditions. Tire inflation pressure has the highest influence on the modal frequencies. Increased inflation pressure can increase modal frequencies roughly $1\text{--}2 \text{ Hz lbf in}^{-2}$. The only exception to this is the first steer mode of the tire, which reduces in frequency with increase in inflation due to shortening of the footprint length.

Increased tire load typically has a stiffening effect on a tire, causing frequencies to increase slightly. The increased footprint length also reduces the free circumference of the tire, resulting in a shorter wavelength (higher frequency) for mode shapes involving the tread band.

Interestingly, speed has an effect on modal frequencies at the onset of tire rolling, whereby modal frequencies typically drop 5–10% compared to the nonrolling tire. A further increase in speed has a stiffening effect, which shifts the tire frequencies higher.

Boundary Conditions

The natural frequencies of a tire are also influenced by the boundary conditions at the axle and at the footprint. If the axle is rigid, which is often the case for lab test fixtures, the frequencies of the tire will be higher than when the tire is mounted on a compliant spindle such as on a car. Additional modes are also introduced with the added degrees-of-freedom of the vehicle's spindle.

The presence of the footprint will also dramatically change the modal frequencies of the tire. As with increased load, when the tire is placed in contact with the ground, the free circumference length of the tire is reduced. This results in shorter wavelength mode shapes, which mean higher frequency if one assumes constant wave speed. All these factors and their effect on tire modal frequencies need to be understood in order to predict the tire road performance from the lab data.

Putting Tire Vibration Knowledge into Practice

In addition to its roles of providing support for the vehicle and directional control for the driver, the tire also serves to isolate the vehicle and driver from the irregularities of the road. Road inputs excite a variety of tire, spindle, and vehicle responses. The goal of the tire design is to minimize these vibrations. This can best be achieved by knowing what the natural frequencies of the tire and vehicle are, how they are affected by the boundary and operating conditions on the car, and then minimizing the interaction or coupling of the tire modes with those of the car.

Determining Tire Natural Frequencies

Two approaches are available for identifying the natural frequencies of a tire: experimental measurement and analytical modeling. The experimental measurement can be as simple as hitting an unloaded, mounted tire with an instrumented hammer and measuring its response, or it can be as complex as exciting the loaded, rolling tire on a test fixture and measuring spindle and/or surface vibrations. Peak responses in these frequency response functions identify the modal frequencies. The mode shape associated with each frequency can be identified through modal survey techniques. The effects of boundary and operating conditions on these frequencies can then be used to determine from the lab data how the tire will perform on the vehicle.

The second approach for identifying tire natural frequencies is analytical modeling. Like testing, tire models can be as simple as a mass on a spring, or can be as complex as a finite element model using thousands of degrees-of-freedom to represent the detailed construction of the tire. Accurate performance predictions typically require the use of the finite element model approach. The results from these complex models are put into an efficient ‘modal model’, and are attached to a vehicle model to predict ride performance. Much research is underway to improve the accuracy of these models and their computational efficiency.

Minimizing Tire/Vehicle System Vibration

Once the vibration properties of the tire are known through experimental or analytical means, the critical and final step is to minimize vehicle vibration by optimizing the combined tire–vehicle system. This optimization is guided by the simple rule of separating the tire modes from the vehicle modes. When natural frequencies of the tire match those of the vehicle, mode coupling occurs and the response is magnified beyond that of the individual components.

For this reason, the fundamental car modes are generally grouped below the frequencies of the suspension modes. Front suspension mode frequencies are designed to be slightly different from those of the rear suspension. Tire modes, particularly those below 100 Hz, are shifted to avoid coincidence with natural frequencies of the steering wheel, passenger compartment cavity, frame, and body/roof panels.

Due to the complex interactions of the tire and vehicle, which are also affected by the boundary conditions at the spindle and the operating conditions encountered, this optimization process is a combined effort of the tire and vehicle engineers. This article has covered only the tire vibration side of the information and the equations used by the tire engineer in this tuning process. Similar information is required on the vehicle side to achieve a successful match of the tire and vehicle systems.

Nomenclature

c	speed of sound
f	frequency

EI	bending stiffness
I	inertia
k	stiffness
L	length
M	mass
R	radius
t	time
λ	wavelength
ξ	deflection

TOOL WEAR MONITORING

M Sidahmed, Université de Technologie de Compiègne, Compiègne, France

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0071

Controlled numerical center (CNC) machine tools in flexible manufacturing require the machining equipment to operate without human involvement. Online monitoring is then of importance to avoid machine unavailability and loss of product quality. Tool wear monitoring is a major factor in ensuring the quality of the machined products. Worn tools produce poor quality surfaces. Tool breakage can result in catastrophic failures resulting in significant down times and loss of productivity. Real-time and online sys-

tems process monitoring would improve the production considerably. A tremendous amount of work has been carried out, in order to develop reliable tool wear monitoring systems for various cutting processes (turning, drilling, and milling). Monitoring and diagnosis systems for industrial purposes have been available commercially since 1990, but they are still not widespread because they are often limited to specific machines and operating conditions.

The problem is made difficult by the physical complexity of the cutting process, the variable running conditions, and industrial constraints such as the online requirement or the costs of the sensors and monitoring systems.

Research and development has been carried out in various areas, discussed below.

Sensor Technology

We may distinguish two kinds of sensor technology that have been proposed to measure physical parameters useful for tool wear monitoring: first, direct methods which include: optical, radioactive and other methods, deliver a direct measure of the wear. They suffer from the difficulty of carrying out these techniques during the cutting operation. Secondly, indirect methods use sensors delivering signals related to the tool wear via signal processing or data analysis. 'Symptoms' related to the tool breakage or wear need to be determined. Several physical parameters have been used.

- Acoustic emission uses the fact that deformation, material removal, and the stress in the metal that occurs during the cutting operation generates acoustic waves at high frequencies (100 kHz to a few MHz) that may be amplified by specific piezoelectric sensors. Experience has shown good results when dealing with tool breakage. Wear monitoring is more difficult, even with advanced data analysis techniques.
- Force measurement is best related to the physical phenomena tool wear. Many researchers have investigated the dynamics of the cutting process, especially the relationship between components of the cutting forces and tool wear. This has led to various monitoring techniques, including model-based methods (observer methods), in order to separate the effects of the cutting operation from the effects of wear. Force measurement is, however, complex to implement, especially on machines that have already been built.
- Vibrations are increasingly used when associated with advanced signal processing techniques. The cutting process generates forces, and indeed vibrations, that may be measured more easily than the forces with nonintrusive sensors. Models associated with the operating conditions (feed, and depth of cut) are slightly more difficult to derive.
- Spindle currents and power were found to be sensitive to the torque variations and then to the cutting process (force variations) and finally to the tool wear.

Data Analysis Techniques

Various methods have been applied with varying success. Most of the methods used in the diagnostics of rotating machines may be applied for tool wear monitoring. The main problems are due to the changing of operating conditions inherent in the machine tools. To overcome these problems, pattern recognition analysis techniques are used (neural networks,

fuzzy diagnostic techniques). Signal properties involve the response of structures (including sensors) whose dynamic properties are not easy to predict. They are excited by periodic (sometimes intermittent as in milling) forces. Their spectral content is therefore quite complex.

Physical Modeling

Research is continuing on dynamic modeling of the cutting process. Progress in automatic control and diagnostic techniques allows us to deal with complex nonlinear models. The interest in such an approach is to be able to derive monitoring systems which take account of the operating conditions directly connected to the machine tool controller. The vibration process to be modeled is different from the one geared to the dynamic properties of the machine tool structure. There the possibility of instability (known as chatter) is of interest.

TRANSDUCERS FOR ABSOLUTE MOTION

K G McConnell, Iowa State University, Ames, IA, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0103

Often it is inconvenient to measure motion and/or forces relative to a fixed reference, for the fixed reference may not be available, as in the case of vibration and forces in a rocket launch vehicle. This need to measure these quantities without a fixed reference has led to the development of seismic instruments. The general model and parameters that govern the mechanical behavior of these instruments are presented first. Then, this model is extended to describe the behavior of seismic displacement transducers, velocity transducers, acceleration transducers, and force and pressure transducers. The fact that force and pressure transducers respond to external vibration as well as force and/or pressure is often overlooked both in practice and in the literature. In this entry, force and pressure transducers are classified as seismic instruments so that this potential sensitivity to vibration motion is clear for all users.

General Model

The general elements of the two-degree-of-freedom model that make up a seismic instrument are shown in Figure 1. There is a seismic mass, m , a base mass, m_b , an external force, $F(t)$, that is applied to the seismic mass, and an external force, $F_b(t)$, that is applied to the base mass. The instrument is constructed so that the seismic mass motion, $y(t)$, and the base mass motion, $x(t)$, are different due to the instrument's structural stiffness, k , and damping, c .

The free-body diagram in Figure 2 shows the forces that act on the seismic mass when it is assumed that $y > x$ and $\dot{y} > \dot{x}$. Newton's second law gives the differential equation of motion for the seismic mass in two different forms:

$$m\ddot{z} + c\dot{z} + kz = f(t) - m\ddot{x} \quad [1]$$

and:

$$c\dot{z} + kz = f(t) - m\ddot{y} \quad [2]$$

where $z = y - x$ and its derivatives represent the relative motion between the seismic mass and the base.

It is clear that the relative motion is dependent on the type of excitation relative to the transducer characteristics. In eqn [1], the external force is altered by the seismic mass inertia force due to base acceleration ($m\ddot{x}$), while in eqn [2] the external force is altered by the seismic mass inertia force due to seismic mass acceleration ($m\ddot{y}$). These two equations will be used to develop the behavior of each type of seismic sensor.

Seismic Displacement Sensor

Eqn [1] is used to describe the behavior of a seismic displacement sensor when the external force, $f(t)$, is assumed to be zero. This is generally true since the seismic mass is covered to protect it from all external forces, with the exception of gravity force, mg . For illustration purposes, assume that the base motion is sinusoidal and given by:

$$x = X_o e^{j\omega t}, \dot{x} = j\omega X_o e^{j\omega t}, \text{ and } \ddot{x} = -\omega^2 X_o e^{j\omega t} \quad [3]$$

where X_o is the magnitude of the base motion and $j = \sqrt{-1}$. For sinusoidal excitations, the responses will be harmonic with values dependent on frequency ω . Hence, in the following equations, the frequency ω (or the normalized frequency r) will be mixed with time domain expressions to indicate that the time domain responses depend on their frequency content. The corresponding relative motion, $z(t)$, at frequency ω becomes:

$$z(t) = Z_o e^{j\omega t} \quad Z_o(\omega) = H(\omega)X_o(\omega) \quad [4]$$

where $H(\omega)$ is the transducer's mechanical frequency response function (FRF) that is given by:

$$H(\omega) = \frac{m\omega^2}{k - m\omega^2 + j\omega c} \quad [5]$$

$H(\omega)$ is seen to alter both the magnitude and phase of the relative motion, $z(t)$, compared to the input base motion, $x(t)$, at each frequency ω . $H(\omega)$ can be written in a dimensionless form as:

$$H(r) = \frac{r^2}{1 - r^2 + j2\zeta r} = \frac{r^2}{\sqrt{(1 - r^2)^2 + (2\zeta r)^2}} e^{-j\phi} \quad [6]$$

where $\omega_n = \sqrt{k/m}$ is the natural frequency, $\zeta = c/2\sqrt{km}$ is the dimensionless damping ratio, $r = \omega/\omega_n$ is the dimensionless frequency ratio, and $\tan(\phi) = (2\zeta r)/(1 - r^2)$ is the phase angle of the output motion $z(t)$ relative to the input motion $x(t)$.

The magnitude and phase from eqn [6] are plotted in Figure 3 for three values of damping ratio ζ (0.05, 0.50, and 0.650). It is clear from the magnitude plot

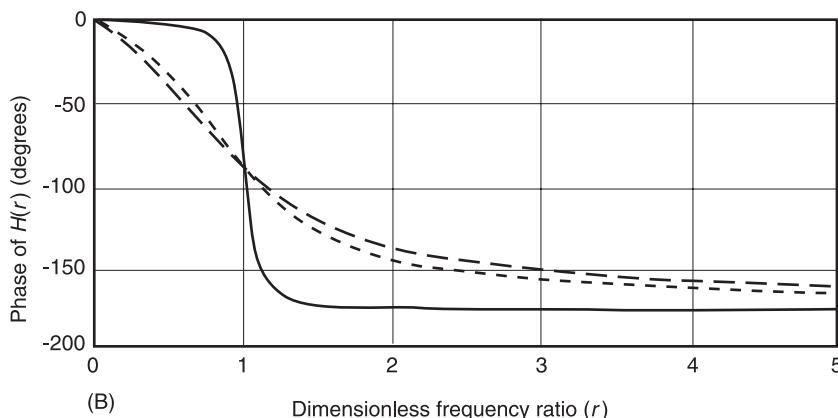

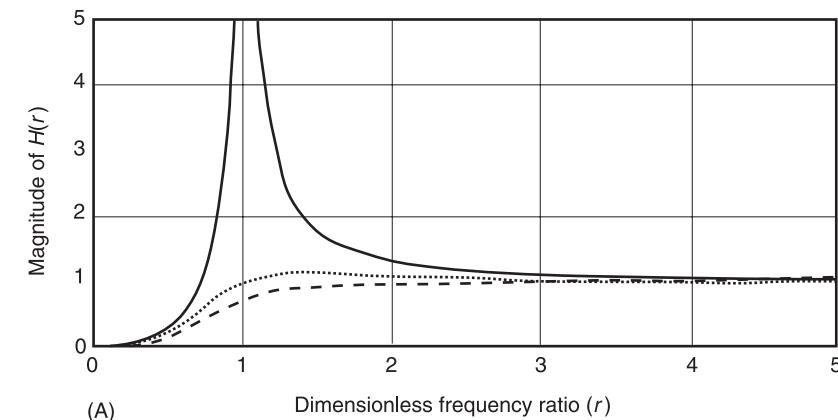

Figure 3 (A) Magnitude and (B) phase vs dimensionless frequency ratio frequency response function $H(r)$ for a displacement-type of seismic transducer for three damping ratios of 0.05 (continuous line), 0.50 (dotted line), and 0.65 (dashed line).

that the frequency ratio must be greater than 2 if the magnitude is to be reasonably correct. It is also clear that a damping ratio of approximately 0.650 gives the best magnitude results. The phase plot shows that the lightly damped curve gives the most correct phase angles at the lower frequencies while the more heavily damped response will have significant phase errors for frequency ratios approaching a value of 5. The physical meaning of these curves is that the seismic displacement transducer works by having the seismic mass essentially remain stationary while the base moves back and forth relative to it. This means that the relative motion z is the same as the base motion. The conditions required are that $r \ll 1$ and the phase angle $\phi \approx 180$ deg. To achieve this goal, the instrument must have a low natural frequency, soft springs, a large seismic mass, and a large rattle space for the relative motion. The sensor used to measure the relative motion is usually either a strain gauge or a linear voltage differential transformer. All of these requirements lead to a relatively large and massive transducer that is severely limited by the lowest frequency that can be measured.

Seismic Velocity Transducers

The seismic velocity transducer is the same as a seismic displacement transducer except that the sensing element is a velocity-sensitive electromagnetic sensor. Then, the time derivative of eqn [4] gives:

$$\begin{aligned} \dot{z}(t) &= j\omega Z_o e^{j\omega t} \\ j\omega Z_o &= H(\omega)(j\omega X_o) = H(\omega)\dot{x}(t) \end{aligned} \quad [7]$$

where $H(\omega)$ is the same as given by eqn [6] above. It is clear that if $r \gg 1$ and $\phi \approx 180^\circ$, then eqn [7] shows that $\dot{z}(t) \approx -\dot{x}(t)$. The seismic velocity transducer suffers from the same large size and mass as the seismic displacement transducer.

Seismic Accelerometer

The seismic accelerometer has the same transducer model given by eqn [4], which can be rewritten as:

$$\begin{aligned} z(t) &= \frac{-m(-\omega^2 X_o)}{k - m\omega^2 + j\omega} e^{j\omega t} = H_a(\omega)a_o e^{j\omega t} \\ &= \left[\frac{H_a(r)}{\omega_n^2} \right] a_o e^{j\omega t} \end{aligned} \quad [8]$$

where $a_o = \omega^2 X_o$ is the magnitude of the sinusoidal acceleration. The accelerometer's mechanical FRF, $H_a(\omega)$, has two main parts: $1/\omega_n^2$ and $H_a(r)$. The $1/\omega_n^2$ term shows how the relative motion, z ,

decreases with increasing natural frequency so that high natural frequency shock accelerometers ($f_n \approx 200$ kHz) have approximately 10 times lower sensitivity than general-purpose accelerometers ($f_n \approx 60$ kHz). Hence, the general rule is that higher natural frequency accelerometers are significantly less sensitive than lower natural frequency accelerometers of approximately the same physical size.

The accelerometer's mechanical FRF, $H_a(r)$, is given by:

$$H_a(r) = \frac{1}{1 - r^2 + j2\zeta r} \quad [9]$$

where the dimensionless frequency ratio r and damping ratio ζ are defined above. The magnitude and phase characteristics of eqn [9] are shown in Figure 4. It is seen that the magnitude and phase are nearly constant at unity and 0° for values of $r < 0.20$ for the case of lightest damping. The maximum magnitude error is about 5% when $r = 0.20$ in this case. When the damping is about 0.650, the phase shift is nearly linear with frequency for values of $r < 1.0$ and the magnitude is nearly unity ($\pm 5\%$) up to $r = 0.72$. Often a great deal of fuss is made over this fact that 65–70% damping gives the best FRF. The problem with this concept is that it is difficult to achieve the required amount of damping that is basically temperature-independent and add little to the mass of the transducer. It is desirable to have a very high natural frequency with small damping since the usable frequency range is about 0.20 of the natural frequency. This means that the spring must be very stiff and the seismic mass must be small. In this frequency range, eqn [8] shows that the output motion z is related to the acceleration by:

$$z(t) = \frac{-ma(t)}{k} = \frac{-a(t)}{\omega_n^2} \quad [10]$$

Eqn [10] clearly shows that the relative motion is directly dependent on the inertia force divided by the transducer's spring constant, k . These terms combine to show that sensitivity decreases with the square of the natural frequency, ω_n .

Seismic Force Transducers

Seismic force transducers are governed by eqns [1] and [2] where it is desired to measure the external force, $f(t)$, that acts on the seismic mass, m . It is clear from these two equations that the relative motion, $z(t)$, depends on both inputs, $f(t)$, and an inertial force term. These inertial terms depend on the seismic mass m and either the seismic acceleration \ddot{z} or the base acceleration \ddot{x} . The seismic mass, m , often depends on the force transducer application since

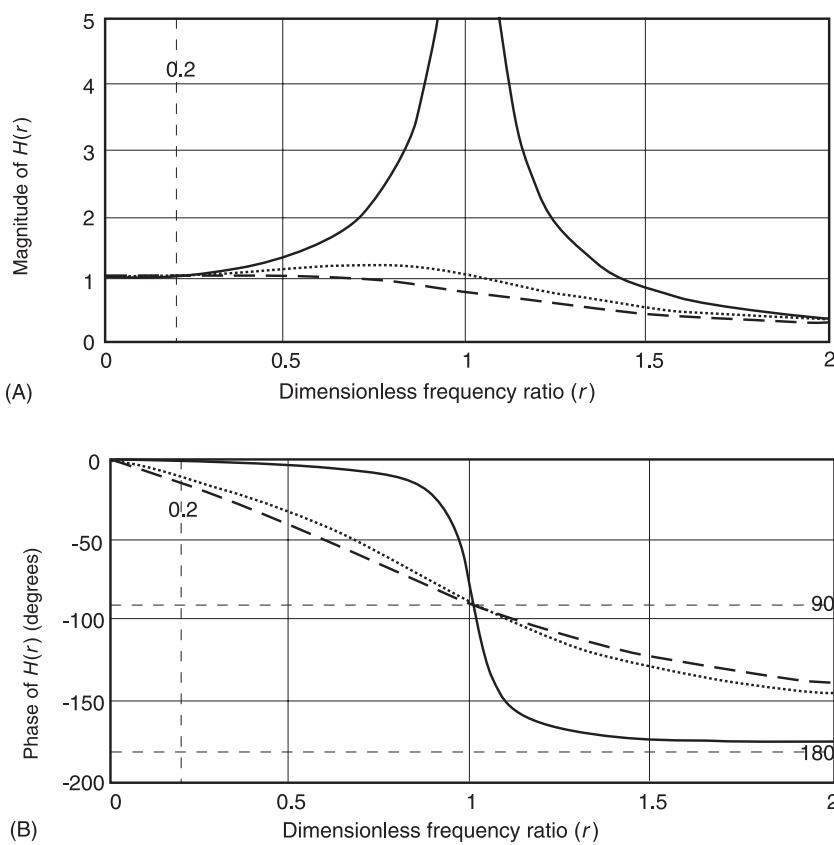

Figure 4 Accelerometer and force transducer mechanical FRF showing (A) magnitude and (B) phase characteristics as a function of dimensionless frequency ratio r for dimensionless damping ratios of 0.05 (continuous line), 0.50 (dotted line), and 0.65 (dashed line).

mounting bolts and mounting hardware are often used. Consequently, this inertial force contamination term can vary from application to application. Eqn [1] also shows that the transducer has a resonance similar to that of accelerometers, as shown in Figure 4. Hence, force transducers are limited to about 0.20 of the transducer's natural frequency as installed since the natural frequency is affected by a change in seismic mass that occurs in many applications. Eqn [2] shows that the transducer actually measures the difference between the applied force and the inertial force; i.e., $f(t) - m\ddot{y}$. Hence, signal contamination is always present and is most important when dealing with light-weight structures.

Pressure Transducers

The pressure transducer has the same mechanical model as the force transducer when $f(t)$ is replaced by $\{Ap(t)\}$ where A is the effective area and $p(t)$ is the pressure time history. In this case the seismic mass also includes some of the contact fluid so this sensor's dynamic characteristics are application-dependent where there is little fluid inertial effect with gases and significant fluid inertial effects with liquids.

Typical Sensors

Three different sensors – capacitive, piezoelectric, and strain gauge – are used to measure the relative motion, z , in accelerometers. The most common sensor used in accelerometers and force and pressure transducers is the piezoelectric type since it provides for good sensitivity, small size, high stiffness and natural frequency, and stable sensitivity. These sensors can be used over a wide range of temperatures as well as nuclear radiation environments. Manufacturers should be consulted about uses in extreme temperature and nuclear radiation applications. The second most popular sensor is the strain gauge that is used for accelerometers, force transducers, and pressure transducers. The capacitive sensor is used primarily in accelerometers and microphone-type pressure transducers.

Piezoelectric Sensor Model

The piezoelectric sensor is commonly used in accelerometers, pressure, and force transducers since it provides for good sensitivity, small size, high stiffness and natural frequency, and stable sensitivity. This

article is concerned with the piezoelectric sensor, its general characteristics that are of interest to the user, and the types of circuits that are commonly employed with this sensor.

General Model

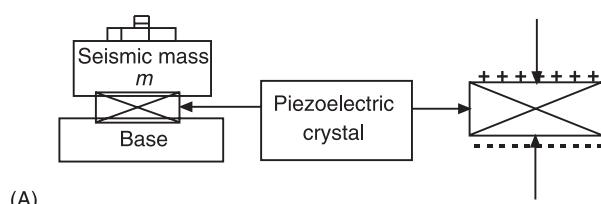

Piezoelectric material occurs naturally in the form of quartz and is also made synthetically by shocking certain ceramic materials. It is used in two different basic designs, as shown in Figure 5. The compression design in Figure 5A is used in both load cells and accelerometers where the crystal is cut so that it generates an electrical charge when exposed to a change in compressive strain. This design is sensitive to base strains. The shear design is shown in Figure 5B, where the crystal is cut so that it generates an electrical charge when it is under shear strain deformation. In either design, the amount of charge generated, q , with units of picocoulombs, is directly proportional to the amount of relative motion, z , between the crystal's support ends so that:

$$q = S_z z \quad [11]$$

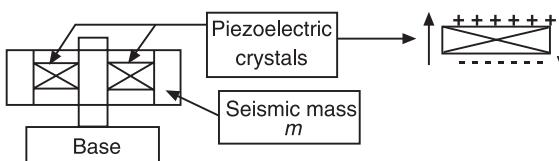

where S_z is the displacement charge sensitivity with units of pcb/unit displacement. When the relative motion solution to eqn [1] is substituted into eqn [11], we obtain the steady-state frequency domain solution for each frequency ω to be given by:

$$\begin{aligned} q(\omega) &= \frac{S_z}{k} \left[\frac{F(\omega) - m\ddot{X}(\omega)}{1 - r^2 + j2\zeta r} \right] \\ &= H(r) [S_{qf} F(\omega) - S_{qa} A(\omega)] \end{aligned} \quad [12]$$

where:

(A)

(B)

Figure 5 Basic piezoelectric transducer design. (A) Compression design used in both force transducers and accelerometers; (B) shear design, used only in accelerometers.

$$S_{qf} = \frac{S_z}{k} \quad [13]$$

is the force charge sensitivity in pcb/unit of force

$$S_{qa} = \frac{mg}{k} S_z \quad [14]$$

is the acceleration charge sensitivity in pcb/g

$$A(\omega) = \frac{\ddot{X}(\omega)}{g} \quad [15]$$

is the base acceleration in g's

$$H(r) = \frac{1}{1 - r^2 + j2\zeta r} \quad [16]$$

is the transducer's mechanical FRF, r is the dimensionless frequency ratio (ω/ω_n) and ζ is the dimensionless damping ratio. Eqns [11] and [12] clearly show how the mechanical force $F(\omega)$ and base acceleration $A(\omega)$ are converted into an electrical charge. Now, it is required to show how the charge is measured.

Basic Charge Circuit

The basic charge generator circuit is shown in Figure 6 where the charge generator is shown as a q in a circle. Piezoelectric crystals have very high internal resistance which have little effect on system performance so that no internal resistor is shown. The piezoelectric sensor has capacitance C_t , the connecting cable has capacitance C_c , and the amplifier has input capacitance C_a . These three capacitance are in parallel so that the equivalent circuit consists of the charge generator and a single capacitance of C that is given by:

$$C = C_t + C_c + C_a \quad [17]$$

This circuit is connected to three different types of amplifiers that are called voltage follower, charge amplifier, and built-in voltage follower.

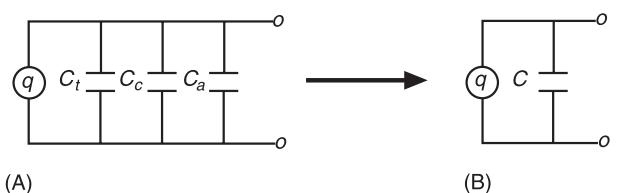

Figure 6 Equivalent piezoelectric sensor circuit showing (A) all capacitors and (B) reduced equivalent circuit where q is the charge generator.

Voltage Follower

The voltage follower is modeled as shown in Figure 7A by using an operational amplifier (called an op-amp) connected in the voltage follower mode where the output is connected to the negative input ($-$). This circuit presents a very high input impedance to the charge generated. Usually resistor R has a large value and is connected in parallel with the capacitor C to give a specific input resistance on the order of 10–100 M Ω . The differential equation governing this circuit is given by:

$$\dot{e}_o + \frac{e_o}{RC} = \frac{\dot{q}}{C} = \frac{S_q}{C} H(r) [\dot{f} \text{ or } \dot{a}] \quad [18]$$

for either a force transducer or an accelerometer. It is clear from eqn [18] that the corresponding voltage sensitivities are given by:

$$S_f = \frac{S_{qf}}{C} \quad \text{and} \quad S_a = \frac{S_{qa}}{C} \quad [19]$$

The steady-state solution to eqn [18] in the frequency domain is given by:

$$E_o(\omega) = [S_f \text{ or } S_a] H(r) \left[\frac{jRC\omega}{1 + jRC\omega} \right] [F(\omega) \text{ or } A(\omega)] \quad [20]$$

where $j = \sqrt{-1}$. The transducer's mechanical characteristics are contained in $H(r)$ and its low-frequency ($jRC\omega$) electrical characteristics are contained in the bracketed term. The voltage sensitivity (S_f or S_a) and the RC time constant are dependent on cable capacitance C_c in this type of circuit. The RC time constant controls the low-frequency response, as shown in Figure 7B and 7C, where the magnitude and the phase are plotted as a function of $RC\omega$. In

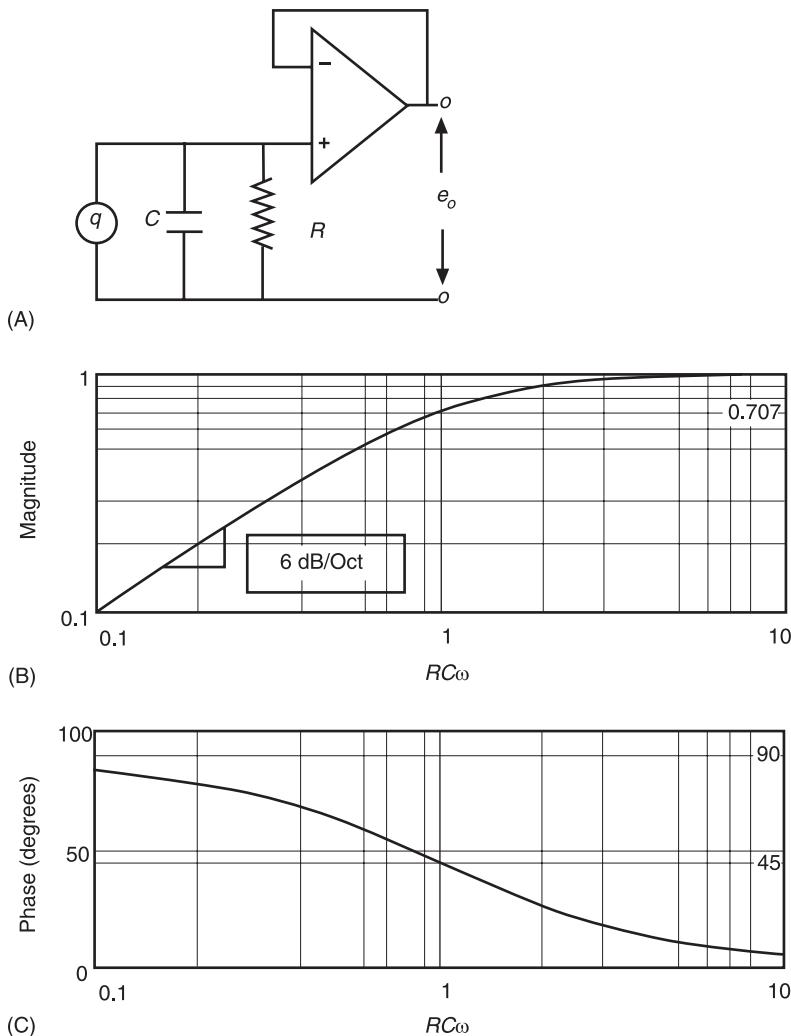

Figure 7 Voltage follower-type piezoelectric circuit (A) and low-frequency characteristics (B) magnitude and (C) phase as a function of $RC\omega$.

Figure 7B, the magnitude is attenuated with a slope of 6 dB/octave below $RC\omega = 0.5$, is down 30% and has a phase shift of 45° when $RC\omega = 1.0$. When $RC\omega = 5.0$, the attenuation is 2% and the phase shift is 11.3° . Hence, the time constant variation between data channels can cause both absolute and relative measurement errors (in magnitude and/or phase) at frequencies below $RC\omega = 10$ depending on the measurement situation.

Charge Amplifier

The charge amplifier was developed to overcome some of the problems associated with the voltage follower, such as sensitivity and low-frequency performance being dependent on cable capacitance. Charge amplifier characteristics are modeled by using two operational amplifiers, as shown in Figure 8. The transducer and its connecting cable are modeled as a charge generator q and total capacitance C . The first op-amp has both capacitance C_f and resistance R_f feedback components. The second op-amp is a voltage inverter with gain of $(1/\lambda)$. The equivalent capacitance controlling this circuit is given by:

$$C_{eq} = C_f \left[1 + \frac{C}{C_f G} \right] \quad [21]$$

where G is the open-loop gain of the first op-amp. Since this gain is on the order of 100 000 or more, it is evident that the effective capacitance is the feedback capacitance so long as C is less than a specified amount for each feedback capacitance, C_f . For this instrument, the voltage sensitivity is given by:

$$S_v = \frac{S_q}{\lambda C_f} = \frac{S_q^*}{C_f} \quad [22]$$

where it is clear that the voltage sensitivity can have standardized values like 10 mV g^{-1} or 100 mV N^{-1}

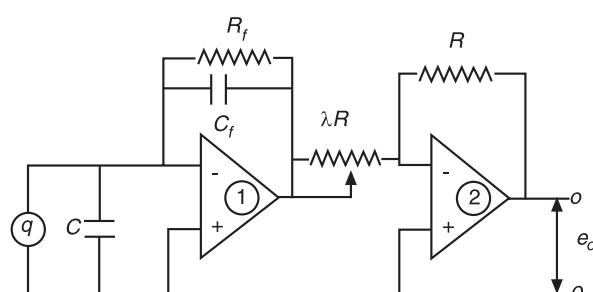

Figure 8 Charge amplifier model using two op-amps. Reproduced with permission from Dally JW, Riley WF and McConnell KG (1993) *Instrumentation for Engineering Measurements*, 2nd edn. New York: John Wiley.

when the value of λ is adjusted to be numerically equal to the actual transducer sensitivity, S_q . The charge amplifier has several advantages, such as:

- The time constant is controlled by the charge amp's feedback elements $R_f C_f$ that are independent of the transducer capacitance.
- Charge and voltage sensitivities can be standardized by use of the gain, λ .
- A wide range of voltage and time constants are available by changing the feedback capacitance, C_f .

Built-in Voltage Follower

The built-in voltage follower can be modeled as shown in Figure 9A. The voltage follower, capacitance, C , and resistance, R , are built into the transducer itself. The voltage follower's output is coupled through capacitance, C_1 , to the data-recording device with input resistance R_1 . Analysis of this circuit shows that there are two time constants, $T = RC$ and $T_1 = R_1 C_1$, where $T(R \text{ and } C)$ and C_1 are fixed by the instrument manufacturer while T_1 is determined by the user, since R_1 is dependent on the recording instrument employed. For this case, the input-output frequency domain solution is given by:

$$E_o(\omega) = \frac{S_q}{C} H(r) \left[\frac{jRC\omega}{1 + jRC\omega} \right] \left[\frac{jR_1 C_1 \omega}{1 + jR_1 C_1 \omega} \right] \times \{F(\omega) \text{ or } A(\omega)\} \quad [23]$$

where it is evident that two different time constants, the mechanical response function, $H(r)$, the transducer's charge sensitivity, S_q , and the internal capacitance, C , are involved in describing its dynamic behavior. The effect of dual time constants is shown in the magnitude vs $RC\omega$ in Figure 9B and phase vs $RC\omega$ in Figure 9C when $T_1 = 10T$. In this case, the magnitude has a slope of 12 dB/oct below $RC\omega = 0.1$, and a slope of 6 dB/octave above $RC\omega$ above 0.1. As the values of $RC\omega$ approach unity, the curve begins to match the curves for a single time constant system. The magnitude and phase values for both a single and double time constant system ($T_1 = 10T$) are compared in Table 1. In this table, it is seen that 3% magnitude error occurs around $RC\omega = 4.0$ while a 2% magnitude error occurs around $RC\omega = 5.0$. The error is about 0.5% at $RC\omega = 10.0$.

Strain Gauge and Capacitance Sensors

The strain gauge type of sensor is often used in accelerometers, pressure transducers, and force transducers while the capacitive sensors are often used in

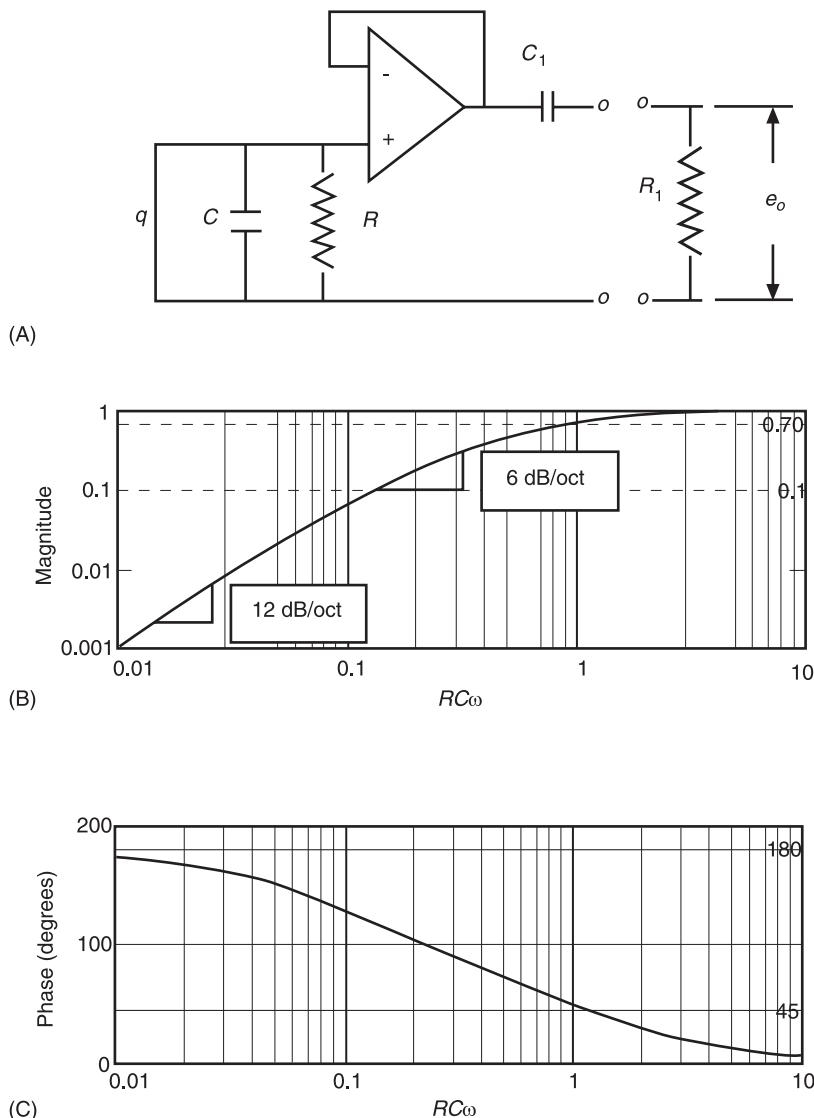

Figure 9 Built-in voltage follower circuit (A) and low-frequency characteristics (B) magnitude and (C) phase as a function of $RC\omega$. Reproduced with permission from Dally J W, Riley W F and McConnell K G (1993) *Instrumentation for Engineering Measurements*, 2nd edn. New York: John Wiley.

microphones, pressure transducers, and some accelerometers. In this section, the primary characteristics of these sensors are reviewed.

General Strain Gauge Model

The strain gauge is based on the linear variation of resistance in a wire or metal film with strain. This linear variation is called the gauge factor or gauge sensitivity, S_g and is defined as:

$$S_g = \frac{\Delta R/R}{\varepsilon} \quad [24]$$

where R is the nominal gauge resistance, ΔR is the change in resistance, and ε is the material strain. The

gauge factor ranges from 2 to 4 for common strain gauge alloys.

Wheatstone bridge The constant-voltage Wheatstone bridge is shown in Figure 10 and consists of four resistors, R_1 , R_2 , R_3 , and R_4 , a DC supply voltage, E_s that is connected between nodes A and C, and an output voltage, e_o between nodes B and D. This bridge is said to be balanced when the output voltage, e_o , is zero. This balanced condition requires that:

$$R_1 R_3 = R_2 R_4 \quad [25]$$

Consider the case when each resistor changes by an amount of ΔR_1 , ΔR_2 , ΔR_3 , and ΔR_4 , respectively.

Table 1 Comparison of low-frequency characteristics for single and dual time constant systems when $T_1 = 10T$

$RC\omega$	Single time constant		Dual time constants $T_1 = 10T$	
	Magnitude	Phase (°)	Magnitude	Phase (°)
0.1	0.0995	84.3	0.0704	129
1.0	0.707	45.0	0.704	50.7
4.0	0.970	14.0	0.970	15.5
5.0	0.981	11.3	0.980	12.5
10.0	0.995	5.71	0.995	6.28

Then the change in the output voltage e_o is given by:

$$\Delta e_o = \frac{r}{(1+r)^2} \left[\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} + \frac{\Delta R_3}{R_3} - \frac{\Delta R_4}{R_4} \right] E_s \quad [26]$$

where $r = R_2/R_1$. In a typical transducer application, four active gauges with equal resistances are employed so that $r = 1.0$. It is important to note that the Wheatstone bridge has good temperature compensation when the gauges are temperature-compensated. In addition, the ΔR s due to temperature are seen to cancel out in eqn [26] if each gauge has the same ΔR_T due to change in temperature. The output voltage can be given in terms of the individual gauge strains if it is assumed that each gauge has the same gauge factor, S_g , so that:

$$\frac{\Delta e_o}{E_s} = \frac{S_g}{4} [\varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4] = \frac{S_g}{4} [\eta \varepsilon] \quad [27]$$

where η usually ranges from 2 to 4 dependent on the transducer design in placing the strain gauges and assuming that the strain measured in each gauge is in proportion to ε , the largest strain measured. The overall transducer sensitivity is obtained when it is assumed that the strain ε is proportional to the transducer's relative motion z from eqn [8]. Then, the frequency domain output voltage becomes:

$$\begin{aligned} \frac{\Delta e_o(\omega)}{E_s} &= \frac{S_g}{4} H(r) [K_f F(\omega) \text{ or } K_a A(\omega)] \\ &= H(r) [S_f F(\omega) \text{ or } S_a A(\omega)] \end{aligned} \quad [28]$$

where the K_x s are the transducer's structural proportionality constants and $H(r)$ is the transducer's mechanical FRF. The voltage sensitivity units are usually (mV/volt/unit force) for S_f and (mV/volt/unit acceleration) for S_a . The values of these sensitivities is very small and the excitation voltage, E_s , is limited by strain gauge heat dissipation to be on the order of 1–10 V. Consequently, the transducer must be con-

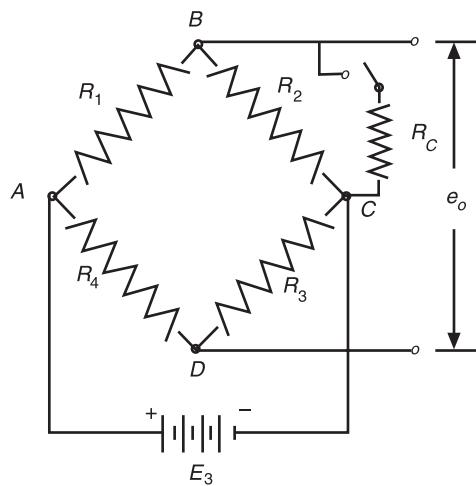

Figure 10 Basic elements of a Wheatstone bridge circuit for strain gauge sensors used in force and acceleration transducers. Reproduced with permission from Dally JW, Riley WF and McConnell KG (1993) *Instrumentation for Engineering Measurements*, 2nd edn. New York: John Wiley.

nected to an amplifier with considerable gain on the order of 1000 or more in order to have an acceptable signal level for recording purposes. These strain gauge amplifiers usually have DC or zero-frequency response. However, the user is warned that most data-recording devices from oscilloscopes to digital data acquisition systems can be either DC- or AC-coupled. When AC-coupled, the low-frequency behavior is identical to that of the piezoelectric transducer with a single RC time constant. Hence, the user must be aware of how the instrumentation system is set up when dealing with low (usually below 10 Hz) frequencies.

Calibration The calibration of a strain gauge-based sensor is achieved by switching the calibration resistor, R_c , between points B and C of the bridge. This resistance causes a change in resistance in arm R_2 that is given by:

$$\frac{\Delta R_2}{R_2} = S_g \varepsilon_c = \frac{-R_2}{R_2 + R_c} \approx \frac{-R_2}{R_c} \quad [29]$$

where R_c is usually much larger than R_2 . This resistance change is related to the strain sensed by strain gauge. Once the transducer's voltage sensitivity, S_v , is established through direct calibration against a standard, then a standard precision resistance of, say, 250 k Ω can be used to simulate a given calibration force, F_c , or calibration acceleration, a_c . Through this means, the variations in excitation voltage and amplifier gain are automatically accounted for.

The Capacitive Sensor

The basic geometric arrangement for the capacitive sensor is shown in Figure 11, where the surface motion to be measured is grounded, the sensor is located a distance h from the surface of interest, the sensor has a diameter d , and is connected to appropriate electronic circuits. The capacitance, C , in picofarads (pf) for this geometry where $h < d/4$ is given by:

$$C = \frac{kKA}{h} \quad [30]$$

where $A = \pi d^2/4$ is the sensor's area, K is the dielectric constant (1.0 for air), and k depends on units used (0.225 for in and 0.00885 for mm). The electrical impedance Z for a capacitor is given by:

$$Z = \frac{1}{jC\omega} \quad [31]$$

where ω is the frequency applied to the capacitance sensor by the sensing electronics. It can be shown that the sensor sensitivity can be expressed in terms of the ratio of the change in impedance Z to the change in position h so that:

$$S = \frac{\Delta Z}{\Delta h} = \left| \frac{1}{Ch\omega} \right| = \left| \frac{1}{kKA\omega} \right| \quad [32]$$

This sensitivity is limited to $h < d/4$ and the temperature range of 40–1600°F (40–870°C) when the gap medium is air. Then, an impedance bridge type of circuit is used to measure the change in capacitance with gap motion, h .

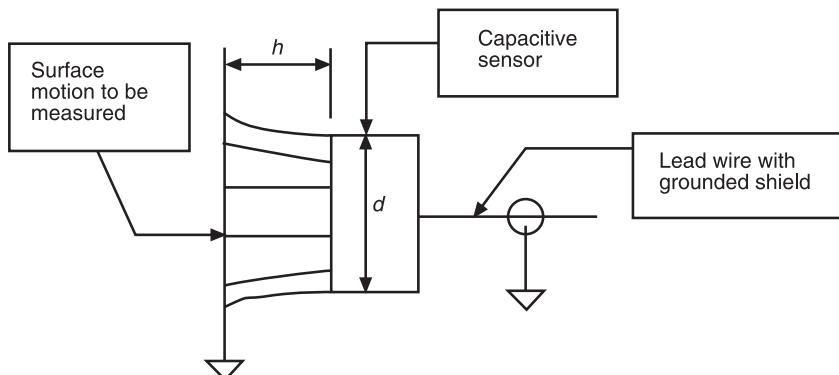

Figure 11 Schematic of capacitive sensor. Reproduced with permission from Dally JW, Riley WF and McConnell KG (1993) *Instrumentation for Engineering Measurements*, 2nd edn. New York: John Wiley.

Measuring Angular Accelerations

Often the angular motion of a structure is of interest. In situations with very low frequencies and significant amplitudes of motion, the angle can be measured using potentiometer-type devices. Only since the mid-1980s has a successful single-unit angular accelerometer been developed. In this section, two different methods of measuring angular acceleration are discussed.

Two-accelerometer Method

The arrangement for the two-accelerometer method is shown in Figure 12A, where two accelerometers are attached $2l$ apart on a rigid bar. From the kinematics diagram of Figure 12B and the concept of rigid-body

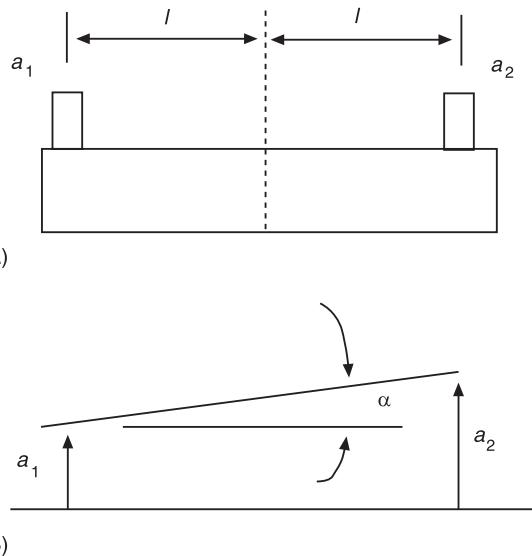

Figure 12 (A) Two accelerometers mounted on a rigid bar and (B) acceleration kinematics diagram showing geometric relationship between linear and angular acceleration.

relative acceleration, the frequency domain angular acceleration $\alpha(\omega)$ is given by:

$$\begin{aligned}\alpha(\omega) &= \left[\frac{1}{2l} \right] [A_2(\omega) - A_1(\omega)] \\ &= \left[\frac{1}{2l} \right] \left[\frac{E_2(\omega)}{S_2 H_2(\omega)} - \frac{E_1(\omega)}{S_1 H_1(\omega)} \right]\end{aligned}\quad [33]$$

where S_1 and S_2 are the transducer voltage sensitivities, $H_1(\omega)$ and $H_2(\omega)$ are the transducer input–output FRFs that include both mechanical and electrical characteristics, and $E_1(\omega)$ and $E_2(\omega)$ are the measured voltages in the frequency domain. It is clear from eqn [33] that the two accelerometers must be carefully matched in magnitude and phase at each frequency of interest. This matching of dynamic characteristics at low frequencies can be a serious problem unless careful attention is paid to matching time constants. Even when the transducers are carefully calibrated and matched, the subtraction of two large signals can easily lead to significant signal noise dependent on the signal-processing methods employed. The successful application of these concepts is no easy matter.

Combined Linear and Angular Accelerometer

A schematic of the combined linear and angular accelerometer is shown in **Figure 13**. This unit consists of two piezoelectric beams called 1 and 2 and mounted on a center post. The center of the beam is the common connection through the center post, while each surface connection is labeled A, B, etc. When the base has a linear acceleration of a_y , as shown in **Figure 13A**, the top sides A and B of beams 1 and 2 have a positive charge generated while the bottom sides C and D have a negative charge generated as shown. When the base has an angular acceleration α_z , as shown in **Figure 13B**, beam 1 has a negative charge on side A and a positive charge on side C while beam 2 has a positive charge on side B and a negative charge on side D. It can be shown that the frequency domain output voltage for beam 1 is given by:

$$E_1(\omega) = H_1(\omega) [S_{1y}A_y(\omega) - S_{1z}\alpha_z(\omega)] \quad [34]$$

and for beam 2 is given by:

$$E_2(\omega) = H_2(\omega) [S_{2y}A_y(\omega) + S_{2z}\alpha_z(\omega)] \quad [35]$$

Eqns [34] and [35] show that addition should give the linear acceleration while subtraction of E_1 from E_2 should give the angular acceleration, provided that certain terms cancel out. The addition gives:

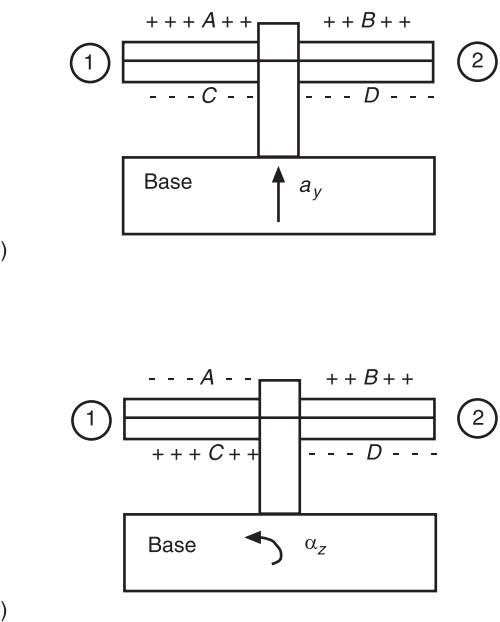

Figure 13 Schematic of combined linear and angular accelerometer using two piezo-beams. (A) Charge generated for positive linear acceleration a_y . (B) Charge generated for positive angular acceleration, α_z . Reproduced with permission from Daily JW, Riley WF and McConnell KG (1993) *Instrumentation for Engineering Measurements*, 2nd edn., New York: John Wiley.

$$\begin{aligned}E_a &= [H_1 S_{1y} + H_2 S_{2y}] A_y + [H_2 S_{2z} - H_1 S_{1z}] \alpha_z \\ &\cong S_a A_y\end{aligned}\quad [36]$$

while subtraction gives:

$$\begin{aligned}E_a &= [H_2 S_{2y} - H_1 S_{1y}] A_y + [H_2 S_{2z} + H_1 S_{1z}] \alpha_z \\ &\cong S_a \alpha_z\end{aligned}\quad [37]$$

if it is assumed that H_1 and H_2 are unity. Eqn [4] is valid so long as $(H_2 S_{2z} - H_1 S_{1z} = 0)$ and $(H_1 S_{1y} + H_2 S_{2y} = S_a)$. Similarly, eqn [37] is valid so long as $(H_1 S_{1y} - H_2 S_{2y} = 0)$ and $H_2 S_{2z} + H_1 S_{1z} = S_z$. In both cases, the desired signal comes from terms that are additive while there is a need to balance out the subtractive terms in order to make the transducer work properly over a broad range of frequencies. This is why the addition and subtraction interface electronics must be matched to the transducer and are not interchangeable with other linear angular accelerometer units. These transducers are very efficient when both linear and angular motion must be measured at the same point. In addition, the mass of these units is low compared to using two accelerometers and a rigid bar.

Servo Accelerometers

These are force-balance transducers that incorporate a feedback control circuit, as shown in **Figure 14**. A

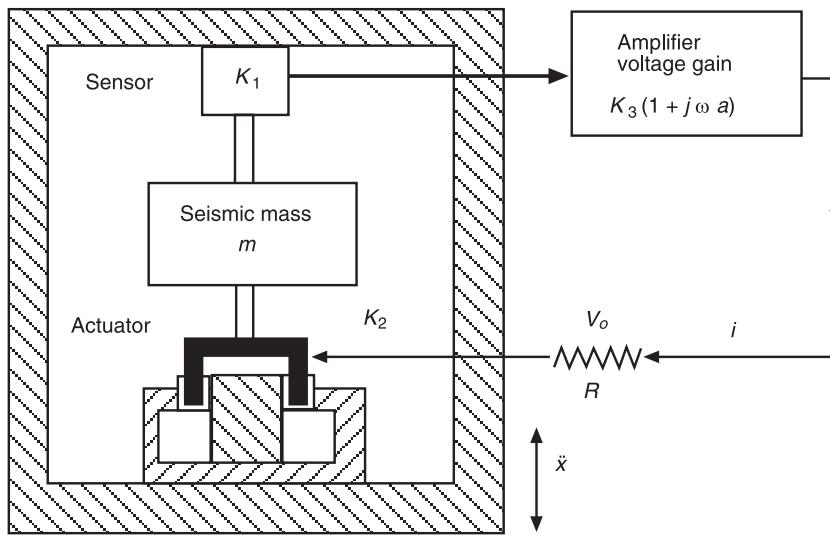

Figure 14 Schematic of servo accelerometer showing main elements of seismic mass, relative motion sensor, amplifier, and electromagnetic force actuator.

balancing force is applied to the seismic mass, m , via the electromagnetic actuator in order to maintain near-zero relative motion, z . The balance force is directly proportional to current i and is measured as a voltage drop, V_o , across resistor R , as shown. The relative motion z is measured with sensitivity $K_1(\text{Vm}^{-1})$, the electromagnetic actuator has force sensitivity $K_2(\text{NA}^{-1})$, and the amplifier has a voltage gain of $K_3(\text{VV}^{-1})$. The actuator back electromotive force sensitivity is also $K_2(\text{V/m s}^{-1})$. These transducers usually have a mechanical spring with stiffness k and some mechanical damping, c . The transducer's input-output FRF is given by:

$$H_a(\omega) = \frac{V_o(\omega)}{\ddot{X}(\omega)} = \frac{K + j\omega}{K_2\omega_n^2} \left[\frac{1}{1 - r^2 + 2\zeta r} \right] \quad [38]$$

where:

$$b = Ka + K_2^2 \quad [39]$$

with units of (N ohm s m^{-1}) is due to the feedforward time constant α and the force actuator's electromagnetic constants, K_2 :

$$K = K_1 K_2 K_3 \quad [40]$$

is the system overall electrical stiffness (N ohm m^{-1}) :

$$r = \frac{\omega}{\omega_n} \quad [41]$$

is the dimensionless frequency ratio:

$$\omega_n = \left[\frac{k + K/R}{m} \right]^{1/2} \quad [42]$$

is the transducer's natural frequency, and:

$$\zeta = \frac{c + K_2^2/R + Ka/R}{2m\omega_n} \quad [43]$$

is the dimensionless damping ratio. It is clear that the mechanical stiffness, k , and damping, c , are not critical and can be zero since the electrical parameters can be used to control the operating characteristics. While the servo accelerometer is more complicated, massive, and larger than the other types, it has the advantages of very high sensitivities and resolution on the order of micro-g's, very linear behavior, and small cross-axis sensitivity. They are well suited for making low-level acceleration measurements in the DC to 100 Hz frequency range.

Transient Response

Transient signals often contain a broad range of frequencies. Consider the two 10 ms pulses shown in Figure 15A. The magnitude of the transient frequency spectra for each pulse is shown in Figure 15B. While both pulses have the same time duration, it is seen that they have dramatically different frequency content. Both pulses have significant low-frequency components since the pulse part of the time history is only positive and the signal is zero elsewhere. This means that the measurement system must be able to measure these low frequencies, which is a problem for

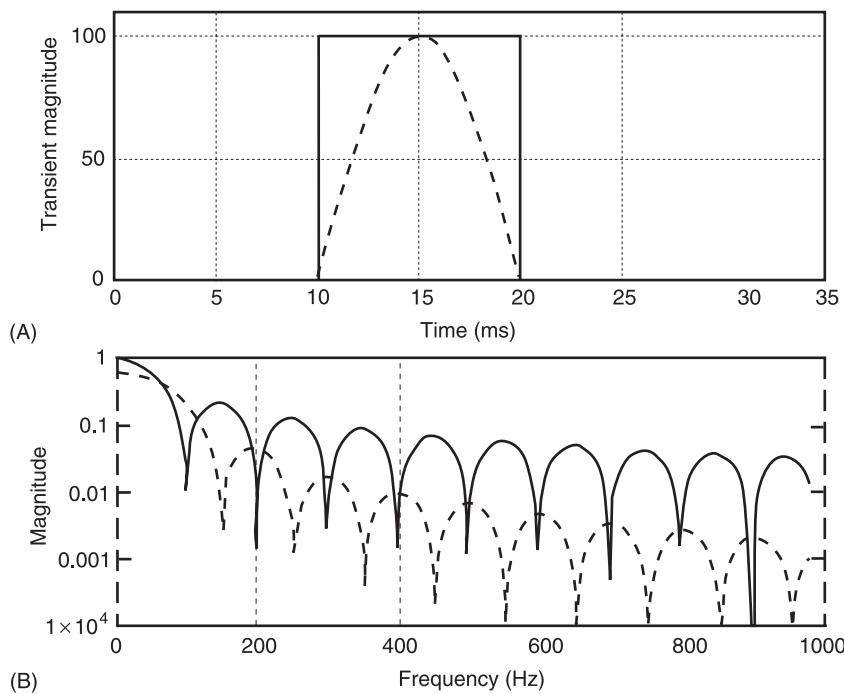

Figure 15 (A) Continuous line: square and dashed line: half-sine transient time histories, and (B) their corresponding transient frequency spectra to illustrate different frequency content in a 10 ms pulse.

the piezoelectric type of sensors as well as the AC coupling feature of many recording instruments. The square pulse has significant frequency components above 1 kHz while the half-sine has frequency components that are less than 1% of the maximum low-frequency value at 1 kHz. Consequently, the step type of pulse requires a much higher transducer natural frequency if there is to be a faithful reproduction of the input. We shall examine the electrical and natural frequency limits on making transient measurements in this section.

Mechanical Response

The mechanical limits can be easily understood by examining the response to a ramp hold-type of transient, as shown in Figure 16A, where the ramp duration is t_o s and the step height is a_o . The mechanical response to this ramp is broken down into two parts, one during the ramp and one after the ramp height is achieved. The undamped transducer response is used here since the resulting errors are conservative. The undamped relative motion during the ramp is given by:

$$\frac{z}{z_o} = \frac{t}{t_o} - \frac{\sin(\omega_n t)}{\omega_n t_o} \quad [44]$$

for $0 < t < t_o$ where z_o is the reference motion for the transient input of a_o . For $t > t_o$, the response is given by:

$$\begin{aligned} \frac{z}{z_o} &= 1 - \left[\frac{\sin(\omega_n t) - \sin(\omega_n(t-t_o))}{\omega_n t_o} \right] \\ &= 1 - \frac{D \sin(\omega_n(t-\beta))}{\omega_n t_o} \end{aligned} \quad [45]$$

where the magnitude for the oscillations about the hold position is given by:

$$D = \sqrt{2(1 - \cos(\omega_n t_o))} \quad [46]$$

and the shift angle β is given by:

$$\tan(\beta) = \frac{\sin(\omega_n t_o)}{\{1 - \cos(\omega_n t_o)\}} \quad [47]$$

The first term of eqn [44] is a linear ramp while the second term shows an oscillation about this linear ramp with an amplitude of $1/(\omega_n t_o)$. The maximum error at time t_o is $\sin(\omega_n t_o)/(\omega_n t_o)$. Whenever $(\omega_n t_o)$ is a multiple of π the error is zero at time t_o . However, from eqn [46], it is seen that $D = 0$ only when $(\omega_n t_o)$ is an even multiple of π . As a general rule, the transducer

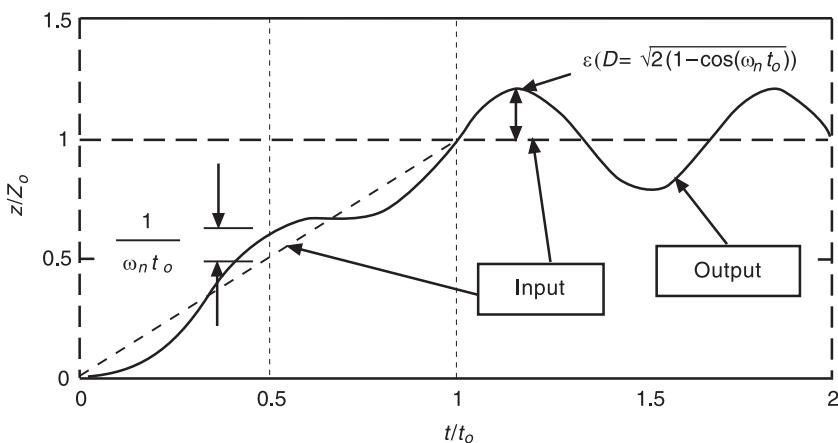

Figure 16 Input and response to ramp hold-type of transient when $t_o = 1.57$. Reproduced with permission from Dally JW, Riley WF and McConnell KG (1993) *Instrumentation for Engineering Measurements*, 2nd edn. New York: John Wiley.

will reasonably match the ramp-type signal with little overshoot if the ramp duration is $t_o < 5T$, where T is the transducer's mechanical natural period. If this rule is applied to the half-sine pulse shown in **Figure 15A** where the ramp time is 5.0 ms, then the transducer's natural frequency should be greater than 1.0 kHz. **Figure 15B** shows that the frequency components above 1.0 kHz are less than 0.1% of the largest frequency components near 0 Hz. Now consider the limiting case when $(\omega_n t_o \approx 0)$ in eqns [46] and [47] so that $D \cong (\omega_n t_o)$ and $\beta \cong \pi/2$. Then eqn [45] gives the response as:

$$\frac{z}{z_o} = 1 - \cos(\omega_n t) \quad [48]$$

which is the well-known undamped step response function that shows traditional transducer ringing at the transducer's natural frequency. Hence, whenever

the transducer's natural frequency shows up in the measurement, the transient ramp is too steep or sharp for the transducer to respond and describe that ramp. Use of the $t_o = 5T$ rule prevents this from happening for either rapid increases or decreases in the measured variable.

RC Time Constant Effects

The RC time constant effects for the rectangular pulse are shown in **Figure 17**. The rectangular transient pulse $x(t)$ can be represented by two step functions $u(t)$ separated by t_1 as:

$$x(t) = u(t - t_o) - u(t - t_o - t_1) \quad [49]$$

where the first pulse begins at time t_o and the second unit step begins at $(t_o + t_1)$. The solution to this input is given by:

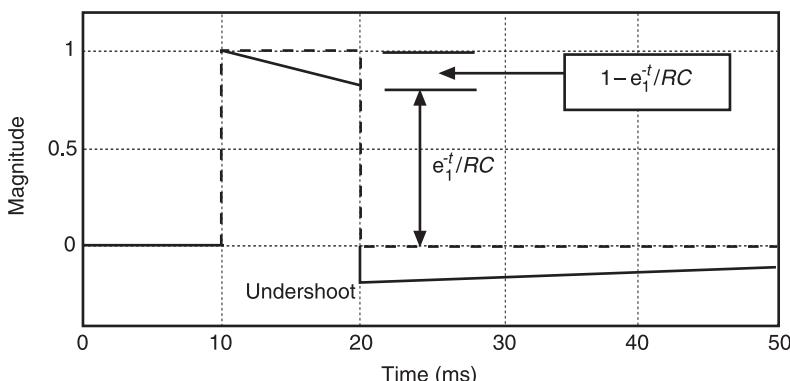

Figure 17 Electrical response of a piezoelectric sensor to a square pulse of duration $t_1 = 10.0$ ms and $RC = 50$ ms. Continuous line, response; dashed line, square input. (Reproduced with permission from Dally JW, Riley WF, and McConnell KG (1993), *Instrumentation for Engineering Measurements*, 2nd edn. New York: John Wiley.)

$$z(t) = u(t - t_o)e^{-(t-t_o)/RC} - u(t - t_o - t_1)e^{-(t-t_o-t_1)/RC} \quad [50]$$

and is shown in Figure 17. We see that both magnitude of the top and undershoot errors at the pulse's end is given by:

$$\text{Error} = 1 - e^{-t_1/RC} \approx \frac{t_1}{RC} \quad [51]$$

for small values of the ratio of (t_1/RC) . This ratio is 0.20 for the case illustrated, which is about the limit of the accuracy of eqn [51]. The presence of significant undershoot indicates that the RC time constant is too small for the duration of the transient being measured. Table 2 gives some guidance for the required time constant for three different transient shapes. The built-in voltage follower-type of piezoelectric sensor has dual time constants. It can be shown that the effective time constant T_e for this case is given by:

$$T_e = \frac{T_1 T_2}{T_1 + T_2} \quad [52]$$

It is obvious from eqn [52] that, when the larger time constant is greater than 10 times the smaller time constant, the smaller time constant controls the low-frequency characteristics as far as transient measurements are concerned.

Typical Accelerometer and Force Transducer Characteristics

The previous sections have delineated the mechanical and electrical characteristics of accelerometers and force transducers as separate items. In this section, we present some typical overall characteristics for these transducers when connected to either a charge amplifier or a built-in voltage follower-type of amplifier. In addition to the characteristics shown here, there are models designed to work in cryogenic and high-temperature applications. These characteristics are typical for either shear or compression design. Contact specific vendors for additional information. Several web addresses are provided for the convenience of the reader.

Accelerometers

Accelerometers for use with charge amplifiers are given in Table 3, while those supplied with built-in

Table 2 Time-constant requirements to limit error

voltage followers are given in **Table 4**. The general trend is for high-sensitivity transducers to have more mass and lower natural frequencies when compared to the general-purpose and high-frequency (shock) type of accelerometers. The damping is generally low (0.5–5%) for these piezoelectric-based transducers.

The characteristics of several piezoresistive accelerometers are given in **Table 5**. The same general trends for sensitivity, transducer mass, and natural frequency are observed. There are two major differences. First, the frequency response goes to DC (0 Hz) on the low end of the frequency scale. Second, there is a significant amount of damping for two of the transducers.

Force Transducers

Force transducer characteristics are shown in **Table 6** for general purpose, impact, and force ring types. The three transducers shown in **Table 5** are quite similar in terms of characteristics. The reader should be aware that the force ring type of transducer sensitivity can depend on bolt size and material as well as how the load is transmitted to the load cell. In addition, there are penetrating force transducers, force links,

and press monitoring types of transducers. As a general rule, all of these transducers use the basic compression design: a design that is usually sensitive to base strains and bending moments. Consequently, the user needs to be aware that signal contamination is possible if either significant bending moments or base strains are present in a given application.

TRANSDUCERS FOR RELATIVE MOTION

G E Maddux, Tipp City, OH, USA

$$x_{2/1} = x_2 - x_1 \quad [2]$$

K G McConnell, Iowa State University, Ames, IA, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0102

General Considerations

We need to consider what we mean by fixed references. Transducers measure the relative motion between two objects or surfaces in sensing motion. Consider the situation shown in **Figure 1**. Here, we want to measure the motion of surface or object 2 relative to surface or object 1. Let the absolute fixed reference position of the base be x_1 and surface 2 be x_2 . The sensor measures the position of surface 2 relative to surface or object 1. Hence, from the geometry of **Figure 1** we have:

$$x_2 = x_1 + x_{2/1} \quad [1]$$

which can be rearranged to give relative motion as:

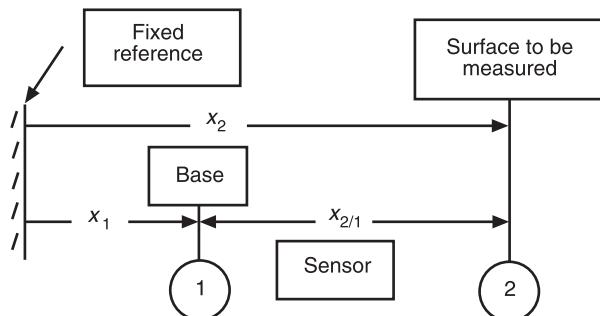

Figure 1 Geometry showing sensor placement relative to surface to be measured, 2, and instrument base position, 1, relative to the fixed reference position.

If x_1 is a constant, then the changes in the relative motion, $x_{2/1}$, will be the same as the changes in the absolute motion, x_2 . While this is a very simple concept, it is often overlooked when applying sensors with fixed references, since it can happen that x_1 is not constant due to vibration of the sensor support. Unfortunately, the sensor measures only the relative motion $x_{2/1}$ and cannot distinguish whether x_1 or x_2 is the source of the signal.

This article is concerned with displacement and velocity sensors that are designed to measure motion with respect to a fixed reference. These sensors include four different displacement sensors and two different velocity transducers. The displacement sensors are capacitive, eddy current types, linear voltage differential transformer (LVDT), and strain gauges. The velocity sensors are electromagnetic and laser.

The articles **Transducers for absolute motion** and **Seismic instruments, environmental factors** deal with seismic instruments that make displacement, velocity, acceleration, and force measurements without a fixed reference. In all cases, the concept of relative motion between a base and the moving surface, as outlined in **Figure 1**, is used.

Displacement Sensors

Capacitive Displacement Sensors

A capacitive sensor has two plate or flat surfaces, called sensor head and target plate, as shown in **Figure 2**. These two surfaces are separated by an air gap of thickness x to form the two sides of a flat plate capacitor with capacitance C given by:

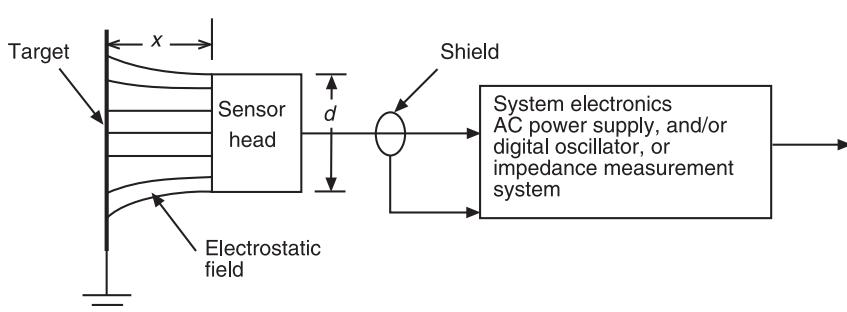

Figure 2 Capacitor sensor without guard ring where electrostatic field edge effects distort linear range. Note that either the target or the sensor head must be fixed.

$$C = \frac{kKA}{x} \quad [3]$$

where C is the capacitance in picofarads (pF), A is the sensor area ($\pi d^2/4$) for a circular plate of diameter d , K is the relative dielectric constant for the gap medium (unity for air), and k is the proportionality constant: 0.00885 for mm dimensions, or 0.225 for inch dimensions. When there is relative motion between the head and the target by an amount of Δx , the new capacitance is given by:

$$\Delta C + C = \frac{kKA}{x + \Delta x} \quad [4]$$

From eqn [4], we find that the change in capacitance divided by the original capacitance gives:

$$\frac{\Delta C}{C} = -\frac{\Delta x/x}{1 + \Delta x/x} \quad [5]$$

The impedance Z due to capacitance is given by:

$$Z = \frac{1}{jC\omega} \quad [6]$$

where $j = \sqrt{-1}$ and ω is the AC power supply frequency driving the electric field. Then, if we divide the change in impedance ΔZ by the original impedance Z , we obtain:

$$\frac{\Delta Z}{Z} = \frac{\Delta x}{x} \quad [7]$$

when eqns [3], [4], and [6] are used with eqn [5]. Eqn [7] shows that the change in impedance is directly proportional to the change in position. Hence, from eqn [7], the capacitive sensor sensitivity S (ohm mm^{-1} or ohm in^{-1}) becomes:

$$S = \frac{\Delta Z}{\Delta x} = \left| \frac{Z}{x} \right| = \left| \frac{1}{\omega k A} \right| \quad [8]$$

For a given gap medium, this sensitivity is seen to depend on plate area A and power supply excitation frequency ω . We would like to make both area A and frequency ω as small as possible in order to improve sensitivity. While eqn [8] implies a linear relationship, experience shows that the transducer is linear so long as $0 < x < d/4$ for a circular sensor head, as shown in Figure 2.

However, if a guard ring is employed, as shown in Figure 3, the range of linearity is doubled so that $0 < x < d/2$. Hence, there is a practical tradeoff of limits that must be satisfied on transducer size versus the displacement to be measured. Similarly, the lowest value of the excitation frequency ω is limited by the frequency of the displacement that is to be measured. The sensitivity stability requires ω to be constant so that a digital oscillator is often used. Several different types of electronic circuits are used to implement eqn [8] that range from DC and AC-type circuits to tuned capacitive-inductive circuit to build an FM oscillator-type circuit where the frequency is controlled by the sensor capacitance and a fixed inductance.

Capacitance sensors have a number of advantages. First, it can be used with nearly any material with a resistivity less than $100 \Omega \text{cm}^{-2}$. Second, it can withstand large shock loads in the order of 5000 g. Third, it is noncontacting. Fourth, it can be used over a wide range of temperatures that range from 20°C to 870°C (68°F to 1600°F) when air is the gaseous medium between plates.

Eddy Current Sensors

Eddy current probes are noncontacting displacement sensors used extensively as gap detectors. Eddy currents are local electric currents induced in the

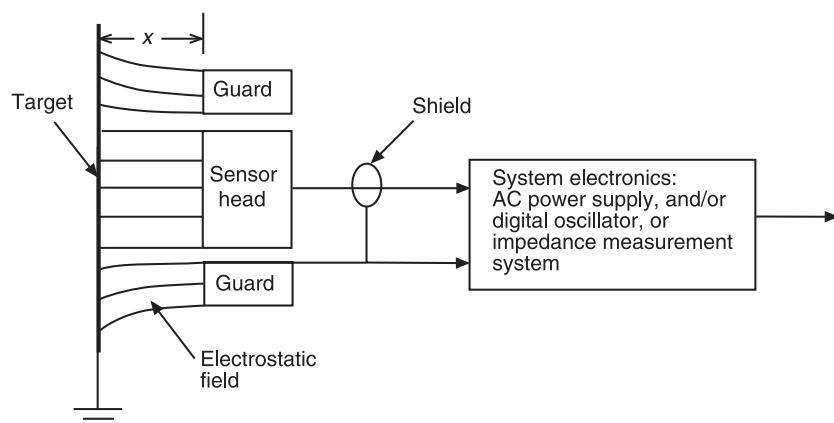

Figure 3 Capacitor sensor with guard ring to improve linearity range.

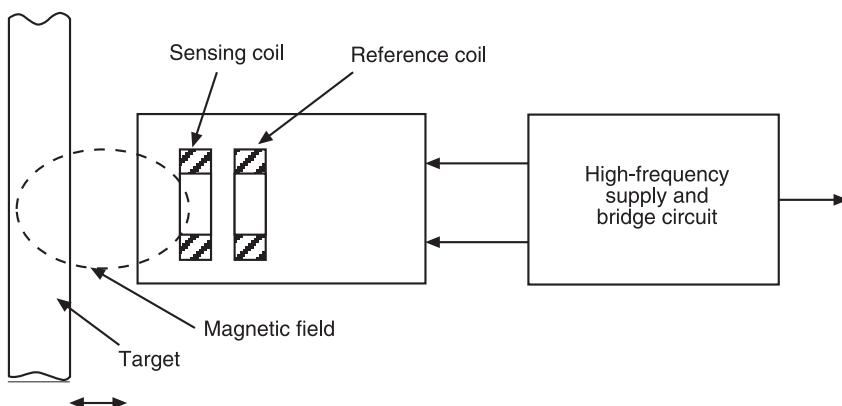

Figure 4 Schematic of eddy current sensor.

conducting target material by a time-varying magnetic field, as shown in **Figure 4**. The eddy currents generate an opposing magnetic field, resulting in a change in the induction of the sensing coil inductance. This inductance change is then measured by appropriate instrumentation.

For high-frequency excitation (say, of the order of MHz), the eddy currents are mostly at the surface of the target. Highly conductive materials like gold, copper, and aluminum are the most sensitive. Non-conducting targets can then be monitored if a metal foil is attached to it.

The sensor can be calibrated within specific tolerances to be linear in the generating range, typically from $80\text{ }\mu\text{m}$ to 1 mm. The sensitivity itself is material-dependent; unless this sensitivity is known for the specific material at hand, calibration will be necessary.

Rotating shaft vibrations are often monitored with such sensors, as shown in **Figure 5**. Many large rotating machines have built-in eddy current sensors that monitor the relative shaft-bearing vibrations in order to determine machine health.

Linear Variable Differential Transformer (LVDT)

The LVDT is well suited to measure displacements that range from ± 0.00001 in (± 0.000254 mm) in a

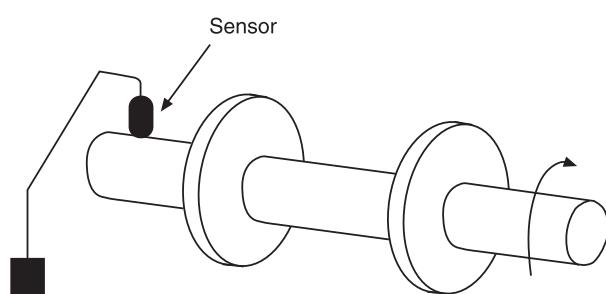

Figure 5 Schematic of eddy current sensor monitoring a rotating shaft.

± 0.050 in (± 1.25 mm) full-scale LVDT to ± 10.0 in (± 254 mm) full-scale in a large-displacement LVDT. The construction of a LVDT is shown in **Figure 6** where there are three coils wound around a common cylindrical core. The center coil is called the primary winding and is driven by a sinusoidal voltage. The other two coils are called secondary windings and are connected in series so that their voltages add to zero when the coupling core is at the null or balanced position. When the core is displaced in one direction or the other relative to its neutral or null, or central position, a phase-sensitive linear voltage is generated when within the linear range of the instrument. The core is usually made from a uniformly dense nickel-iron alloy that is carefully annealed to obtain excellent magnetic permeability.

The LVDT has a number of distinct features due to its principles of operation and construction. When the core is properly supported, there is no friction between the sensing elements. This makes the LVDT an excellent choice for creep or low-friction type of testing. The mechanical life is controlled by the core support system so it can have an infinite fatigue life if properly designed. The magnetic sensing circuit gives a theoretical infinite resolution characteristic that is only limited by the readout electronics. This infinite resolution is enhanced by the essentially frictionless response. The null repeatability is extremely stable due to the stability of the magnetic coupling principle that is employed. This null position is most affected by temperature changes that cause thermal expansion or contraction to occur. This high stability makes the LVDT ideal for use with high-gain closed-loop control systems. Finally, the input and output circuits are electrically isolated from one another so that excitation ground and signal ground are totally independent from one another.

The sensitivity of the LVDT depends on the excitation voltage, the resistance of the secondary windings, and the circuits connected to these windings, and the

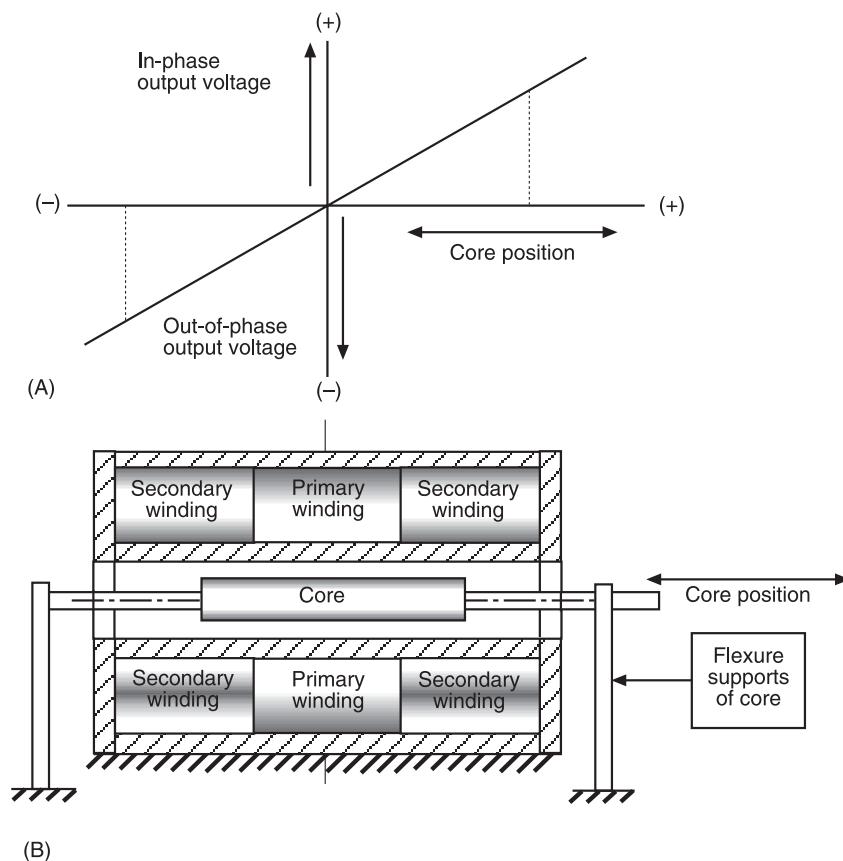

Figure 6 (A) Output voltage vs core position of linear variable differential transformer (LVDT). (B) Cross-section of LVDT showing primary winding, secondary windings, and core position.

frequency of excitation. These sensitivities are usually given in terms of $\text{mV in}^{-1} \text{V}^{-1}$ of excitation (or $\text{mV mm}^{-1} \text{V}^{-1}$ of excitation) at a specified frequency and amplifier impedance.

A modern development of the LVDT is called DCDT where all electronics such as the excitation voltage and signal demodulator are built into the transducer case. The DCDT simply requires a DC voltage like +7 or +14 V to be applied to the input terminals. The demodulator output voltage is proportional to the displacement and can be connected directly to the data-recording system as long as the data-recording input impedance is greater than a certain minimum resistance. In these cases, the sensitivity is then given simply as mV in^{-1} or mV mm^{-1} . Table 1 gives some typical characteristics.

Velocity

Electromagnetic Sensors

The electromagnetic sensor measures the relative velocity between the base side and the moving side by using Lenz's law. Typical construction is shown in

Figure 7, where a wire coil is wound around a carrier structure that slips over the magnetic core in the gap between the core and the outside magnetic circuit. This construction is identical to audio speakers and even light-weight head phones. Lenz's law relates the

Table 1 Typical LVDT and DCDT specifications:

(A) AC (LVDT) excitation 3.0 V _{rms} at 2.4 kHz		Sensitivity

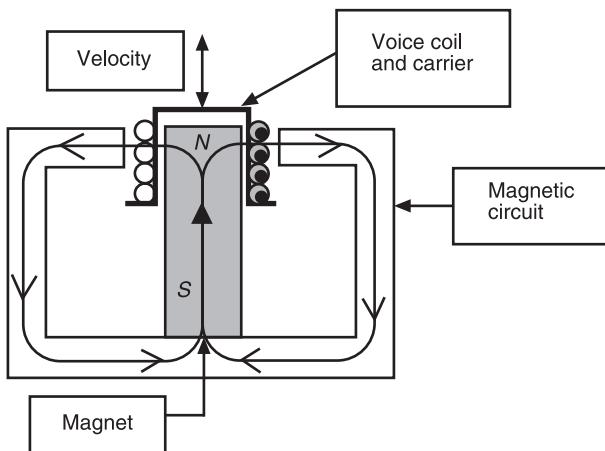

Figure 7 Cross-section of an electromagnetic sensor showing magnet and voice coil elements.

voltage generated (sometimes called back electromotive force or bemf) to the magnetic field strength B by:

$$E = (B\lambda n)v = K_v v \quad [9]$$

where $B = d\phi/dx$ = field strength, ϕ is the field flux, λ is the coil length per coil, n is the number of coils, K_v is the instrument's voltage sensitivity, and v is the coil velocity.

The electromagnetic sensing circuit is shown in Figure 8 where there is a voltage generator described by eqn [9], the sensing coil's inductance, L , and resistance, R_c , recording instrument's input impedance, R , which is usually only a resistance, and current i . The output voltage is E_o that appears across the recording instrument's input resistance, R . The differential equation describing this circuit is given by:

$$E_o = K_v v = \frac{L}{R} \dot{E} + (1 + \beta) E_o \quad [10]$$

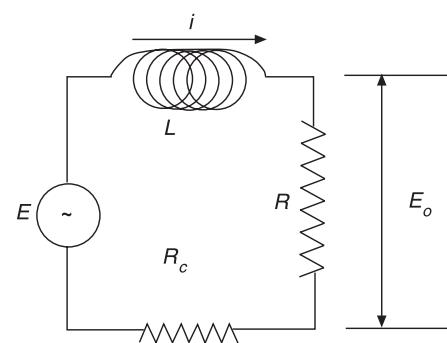

Figure 8 Equivalent electromagnetic sensor showing voltage generator, voice coil inductance, L , and resistance, R_c , instrument input resistance, R , output voltage, E_o , and circuit current, i .

where $\beta = R_c/R$ is the circuit resistance ratio. Since R_c is usually on the order of a few ohms and R should be on the order of $100\text{ k}\Omega$, the value of β is very small and can be neglected. Then, when the velocity is sinusoidal and is given by $v = v_0 e^{j\omega t}$, the corresponding transducer frequency response function becomes:

$$\frac{E_o}{S_v v_0} = \frac{1}{1 + j\omega T} \quad [11]$$

where $T = (L/R)$ is the transducer's time constant and S_v is the voltage sensitivity in volts or mV per unit of velocity. It is evident that $K_v = S_v$ when β is small. Figure 9 shows a plot of a typical frequency response function of an electromagnetic sensor, as described by eqn [11]. The time constant, T , is assumed to be equal to 0.001 s in this case. It is seen that there is little magnitude or phase error in the measured signal so long as $\omega < 100.0\text{ rad s}^{-1}$. Between $100 < \omega < 1000\text{ rad s}^{-1}$, it is seen that the magnitude is reduced and the phase angle changes dramatically. In fact, the magnitude is reduced by 3 dB (0.707) and the phase shift is 45° when $\omega = 1000\text{ rad s}^{-1}$. The

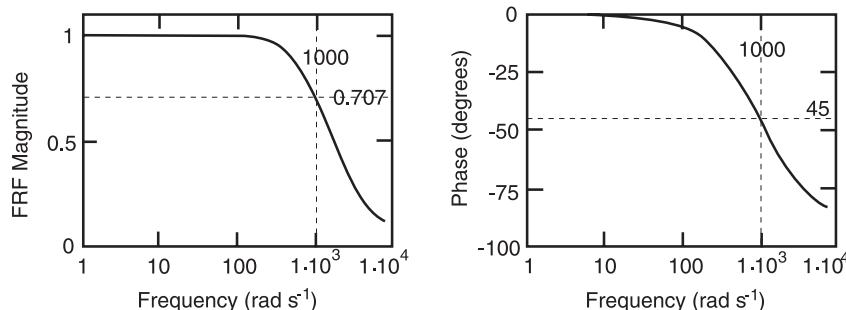

Figure 9 Magnitude and phase of typical electromagnetic sensor as function of frequency ω when the transducer time constant $T = 0.001\text{ s}$.

ability of this ideal instrument to measure velocities with frequency content above 1000 rad s⁻¹, is generally unacceptable. Hence, it is important for the user to be aware of transducer frequency limitations; particularly with this instrument, since the user is the one who selects the value of R when the instrument is connected to the recording instrument.

The Laser Doppler Vibrometer

The device used most often for measuring the velocity of a vibrating object with respect to a fixed reference system is the laser Doppler vibrometer (LDV). An outgrowth of the laser Doppler velocimeter used for gas and fluid flow measurement, it has undergone significant development in the past few years and is marketed in many countries around the world. This success is due in part to improved electrooptic technologies and to the implementation of the personal computer or workstation. The LDV is also popular because it is easy to use. One merely points the LDV laser beam at a location where a vibration measurement is required and the data can be viewed immediately and recorded for additional processing later.

Computer-controlled optical scanning and data acquisition provide for the beam to be directed

rapidly at an array of locations on a structure vibrating at resonance, pausing at each for a few milliseconds to take and store data and then graphically display the mode shape on a monitor. The scanning laser Doppler vibrometer (SLDV) can capture and display a complicated resonant mode shape in seconds that would require the use of thousands of accelerometers and lengthy data processing to duplicate. The SLDV can be used for objects ranging from a few square millimeters up to several square meters.

Operating Principles

The LDV is made possible by the coherent properties of laser light. Figure 10A shows one complete cycle of a HeNe beam with amplitude (A_0) and wavelength (λ) of 0.6328 μm. With the speed of light (c) being approximately 300×10^6 m s⁻¹, the frequency, λ/c , is about 4.74×10^{14} Hz (2.98×10^{15} rad s⁻¹). If two coherent beams, each of amplitude A_0 are combined, the resulting waveform will have twice the amplitude (Figure 10B). If one of the beams is shifted in phase (ϕ) by π rad before combination, the two beams will cancel each other out (Figure 10C). All optical detectors produce a signal that is proportional to intensity, which is the square of the amplitude (Figure 10D).

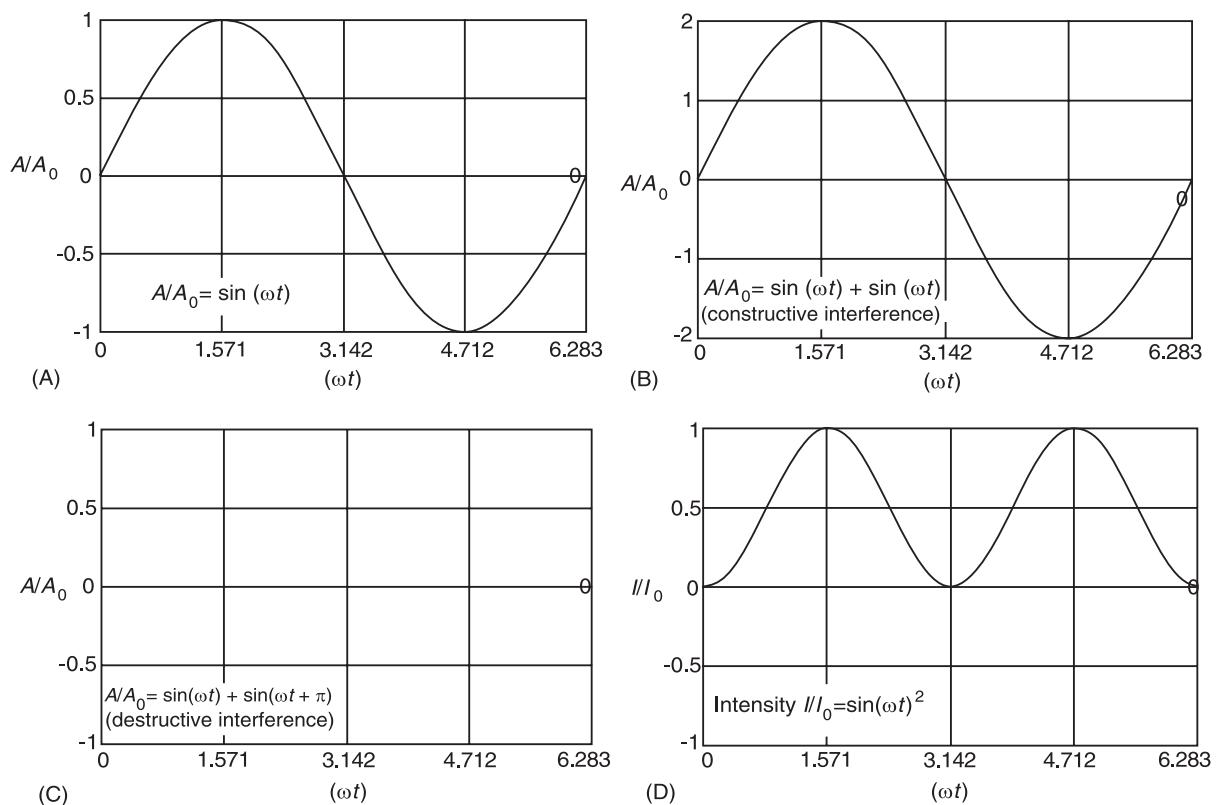

Figure 10 (A) Output from HeNe laser. (B) Superposition of two coherent beams. (C) Superposition of two completely out-of-phase coherent beams. (D) Result of using a square law detector.

One type of LDV uses a version of the Michelson interferometer (Figure 11). The laser light beam is divided into two beams by beam splitter (BS). One beam travels to the vibrating object, returns back along the same path, and is reflected downward by the splitter. Since it contains information about the vibrating surface, it is known as the signal beam. The other, called the reference beam, passes to a stationary mirror, is reflected downward, and is combined with the signal beam. Any change between reference and signal beam path lengths will cause an interference that is observed as a change in intensity at the detector. Each time the point on the structure moves an amount equal to half the wavelength of the laser light used, the intensity will undergo one full cycle from light to dark to light. The frequency of this fluctuation, f_D , is called the Doppler frequency and is related to the velocity, v , of the point on the structure by:

$$f_D = 2v/\lambda \quad [12]$$

where λ is the wavelength of the laser light. If the structure is moving at a constant velocity of 1 m s^{-1} and a HeNe laser is used ($\lambda = 0.6328\text{ }\mu\text{m}$), $f_D = 3.174\text{ MHz}$. Since the frequency of the reference beam is $4.74 \times 10^8\text{ MHz}$, this is a very small increase (or decrease, depending upon the direction of the velocity) to detect. Since the best frequency measurement capability of even the newest detectors is less than 10^3 MHz , some additional approach is required.

When the shifted frequency is combined with the reference frequency, a time-dependent interference or beat frequency results which, when reaching the photodetector, produces an output signal that contains observable information about the velocity, v . Unfortunately, because detectors measure intensity

instead of amplitude, they do not discriminate between positive and negative velocities. If the structure is vibrating, this signal is frequency-modulated. In some LDV designs a technique called homodyning is used to decode the information in the combined signal and reference beams. This method uses electronic processing and is usually performed outside the interferometer loop.

Optical Heterodyning

Another solution to the problem of velocity sign is to introduce a slight frequency shift in the reference beam using an electrooptic device such as a Bragg cell. To do this, a different type of interferometer, a modified Mach-Zender configuration, is used (Figure 12). The Bragg cell is inserted in the reference beam leg. The Doppler frequency generation is the same as with the Michelson interferometer. The Bragg cell produces a known frequency shift in the reference beam, such that the combined reference and object beam contains three frequencies: the original reference, the Doppler signal beam, and the Bragg cell frequency. When there is no vibration present, the output of the detector is a steady function of the Bragg cell frequency. When vibration is present, it is sensed as a frequency modulation of that signal. The output from the detector is electronically demodulated in a variety of ways, depending upon the manufacturer, to produce an output voltage that is proportional to the instantaneous velocity of the structure. The introduction of the constant frequency shift is called heterodyning.

A thorough mathematical treatment of the above processes is beyond the scope of this article and the reader is referred to current symposia papers, manufacturers' literature and the Further reading section for greater detail.

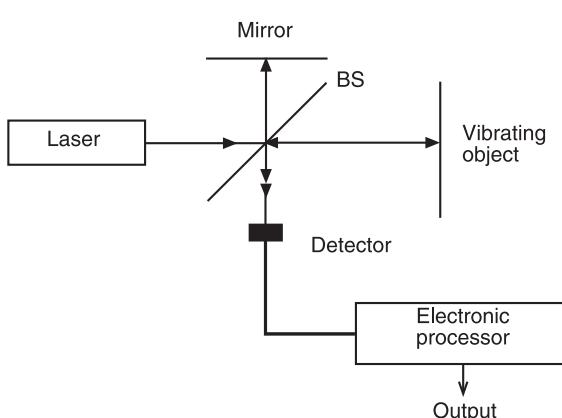

Figure 11 Michelson interferometer configuration. BS, beam splitter.

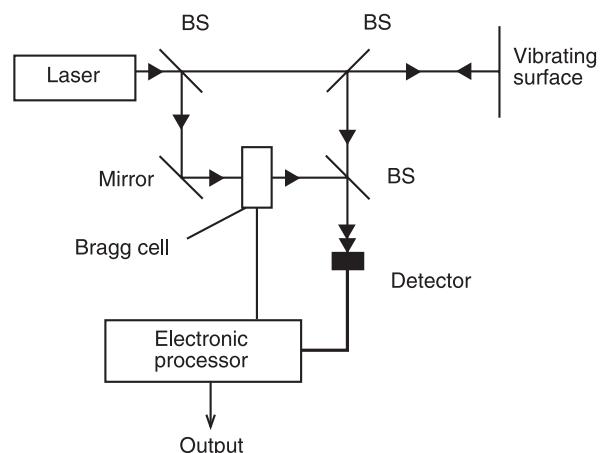

Figure 12 Modified Mach-Zender interferometer. BS, beam splitter.

Choosing an LDV

When choosing which of the many commercial LDVs to use, there are some technical factors that need to be considered.

Surface effects Unlike conventional interferometers, the LDV relies on focusing the interrogating beam to a point so that the return beam, which is actually a radiating speckle field due to diffraction effects at the surface, completely fills the aperture of the detector with as few speckles as possible. In practice, surfaces will range from nearly specular (mirror-like) to totally diffuse. Some LDV systems are very tolerant of variations in surface conditions, while others require the use of retroreflective coatings to provide usable signals. If vibration is to be measured at high temperatures, this becomes an important consideration, since the surface may undergo physical changes that affect the return signal. Most high-temperature metals require no surface treatment below 1800°C. High-temperature composite materials have been tested up to 800°C using ceramic beads as a retro-reflecting coating.

Effect of coherence Some LDVs must be located no more than a few centimeters from the vibrating

structure; others have been used as far away as 200 m. When a multimode laser is used in an LDV, it is usually recommended that the vibrating structure be located at some integer multiple of the laser cavity length away to improve the quality of the data.

Filter effect Most commercial LDVs use some form of electronic filtering to optimize the quality of the output signal. If the user is interested in measuring not only the velocity of the structure but also its vibrational phase, the manufacturers' specifications must be closely examined. It is also an important consideration when measuring the response to broadband random excitation.

Operating Range

Figure 13 represents one way that the useful range of an LDV is displayed, showing the limits for velocity, displacement, frequency, and acceleration. This illustration is not for any particular LDV but is indicative of what is found in the manufacturers' literature.

Environmental Considerations

If measurements are made using the LDV in the presence of sound pressure levels greater than 130 dB, consideration must be given to designing an

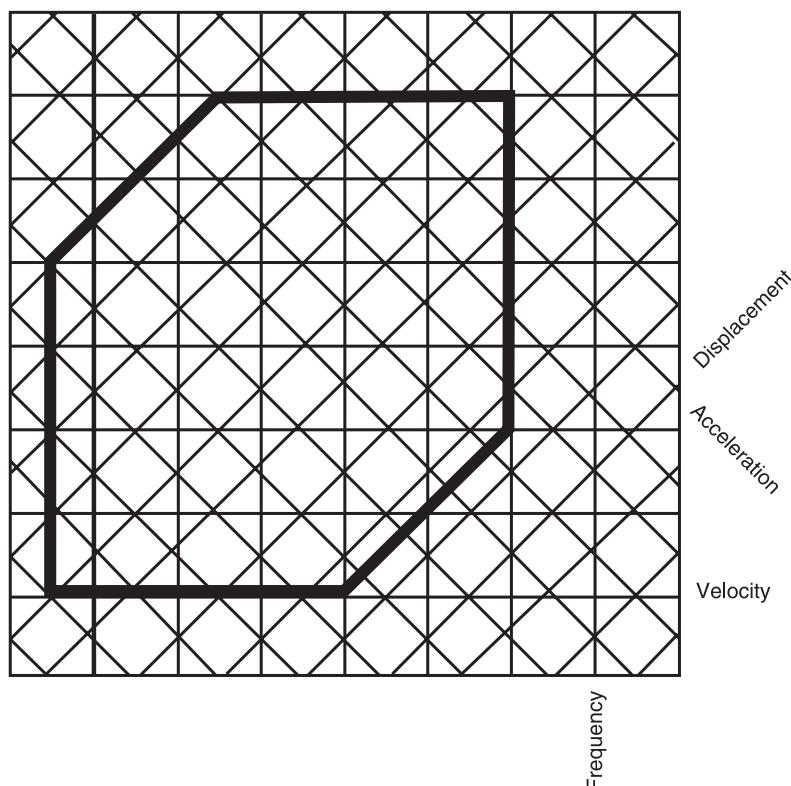

Figure 13 Usable range chart.

acoustic shield for the instrumentation. Since this is not a common use of the LDV, there is very little information available from the manufacturers as to what is a safe level.

Other LDV Devices

Some LDVs have two measurement beams, so that the difference in velocity between two moving points can be measured.

The previous discussions have been related to measuring the velocity normal to a surface. There are commercial LDVs designed specifically for measuring the velocity of rotating bodies and in-plane vibrations.

Diode lasers and fiberoptic interferometers are being incorporated into commercially available systems.

TRANSFORM METHODS

S Braun, Technion – Israel Institute of Technology,
Haifa, Israel

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0158

General

Mathematical transforms are main tools of disciplines dealing with signal and system. Analysis (and synthesis) in the transform domain complements the one of time domain, and often has specific advantages.

The existence of (direct) transforms as well as of their inverse enables to switch back and forth between both domains. The information in both domains is thus equivalent, even if the type of presentation is markedly different.

The transform relation is here denoted by a double arrow. A capital letter (*L* for Laplace, *Z* for *Z*-transform and *F* for Fourier) shows the transform at hand, and a superscript of $[]^{-1}$ denotes the inverse transform. Upper case letters will be used for transforms domains, and lower case letters for the time domain. For example, for the Laplace transform:

$$\begin{aligned} X(s) &= L[x(t)] \\ x(t) &= L^{-1}[X(s)] \\ x(t) &\longleftrightarrow X(s) \end{aligned}$$

Some transforms are geared to continuous signals and systems, for instance the Laplace and Fourier transforms; others, like the *Z*-transform and discrete Fourier transform are geared to discrete ones.

The dynamics of linear, lumped parameter, continuous systems are modeled by linear differential equations, those of discrete systems by difference equations. The response of such systems to an excitation signal is given (with zero initial conditions) by the convolution of the input and the system's impulse response. One important property of these transforms relates to the operation of convolution: the transform of the convolution equals the product of the transforms. Applying the transform then results in a set of algebraic equations, as opposed to differential or difference ones. Analytical solution then necessitates the solving of algebraic equations. This is one reason why transform methods prevail in many theoretically oriented texts.

Another aspect is that of computability. The possibility of computing Fourier transform numerically via the efficient fast Fourier transform (FFT) algorithm has practically revolutionized signal processing. Fourier methods thus are central to spectral analysis and system identification tasks in the area of vibration engineering.

In what follows, some general aspects of Laplace, Z and Fourier transforms are given. A more detailed exposition of Fourier methods follows. This includes Fourier series and integral transforms, the discrete Fourier transform and the FFT algorithm.

The Laplace Transform

These are given by:

$$X(s) = \int_{-\infty}^{\infty} x(t) \exp(-st) dt \quad [1a]$$

and

$$x(t) = \frac{1}{2\pi j} \int_{\sigma-j\infty}^{\sigma+j\infty} X(s) \exp(st) ds \quad [1b]$$

$$s = \sigma + j\omega$$

The integral will converge for the majority of signals typical of engineering applications, but not necessarily for all of them. Associated with the transforms is a region of convergence (ROC). It is only with such an association that an inverse transform can be defined uniquely.

A unilateral transform is used for causal signals, usually encountered in vibration engineering:

$$X(s) = \int_0^{\infty} x(t) \exp(-st) dt \quad [2]$$

Properties

Some important properties of the Laplace transform are given below. Given that $x(t) \leftrightarrow X(s)$:

- Linearity:

$$a_1 x_1(t) + a_2 x_2(t) \longleftrightarrow a_1 X_1(s) + a_2 X_2(s) \quad [3a]$$

and generally:

$$L \left[\sum_i a_i x_i(t) \right] \longleftrightarrow \sum_i a_i L[x_i(t)] \quad [3b]$$

- Time shift:

$$x(t - t_0) \longleftrightarrow \exp(-st_0) X(s) \quad [4]$$

- Scaling:

$$x(at) \longleftrightarrow \frac{1}{|a|} X\left(\frac{s}{a}\right) \quad [5]$$

- Differentiation:

$$\frac{d^n}{dt^n} x(t) \longleftrightarrow s^n X(s) + \sum_{i=1}^n s^{i-1} \frac{d^{n-i}}{dt^{n-i}} x(t)|_{t=0^+} \quad [6]$$

- Integration:

$$\int_{-\infty}^t x(\tau) d\tau \longleftrightarrow \frac{X(s)}{s} + \frac{1}{s} \int_{-\infty}^{0^+} x(\tau) d\tau \quad [7]$$

- Convolution:

$$x_1(t) \otimes x_2(t) \longleftrightarrow X_1(s) X_2(s) \quad [8]$$

- Multiplication:

$$x_1(t) x_2(t) \longleftrightarrow X_1(s) \otimes X_2(s) \quad [9]$$

One important application concerns the solving of linear differential equations of the type:

$$\sum_{k=0}^N a_k \frac{d^k}{dt^k} y(t) = \sum_{k=0}^M b_k \frac{d^k}{dt^k} x(t) \quad [10]$$

Applying the laws of linearity and differentiation (eqns [3] and [6]) with zero initial conditions results in:

$$\sum_{k=0}^N a_k s^k Y(s) = \sum_{k=0}^M b_k s^k X(s) \quad [11]$$

The resulting algebraic equation is often easy to solve for analytical cases with closed form solutions.

The important notion of a ‘transfer function’ can now be defined as:

$$H(s) = \frac{Y(s)}{X(s)} = \frac{\sum_{k=0}^M b_k s^k}{\sum_{k=0}^N a_k s^k} = \frac{B(s)}{A(s)} \quad [12]$$

Another characterization of systems is via their impulse response. Mathematically this is the response to a Dirac function $\delta(t)$. It is straightforward to show that:

$$L[\delta(t)] = 1 \quad [13]$$

And hence the response:

$$Y(s) = H(s) \quad [14a]$$

$$y(t) = L^{-1}[H(s)] \quad [14b]$$

An additional description of the system is that of the zero/poles. The transfer function $H(s)$ of many physical systems is described by a ratio of rational polynomials in s . The values of s for which the nominator equals zero are then the zeros of the system. Those at which the denominator equals zero are the poles:

$$\begin{aligned} A(s) &= \prod_{k=1}^N (s - z_k) \\ B(s) &= b_m \prod_{k=1}^M (s - p_k) \\ H(s) &= \frac{B(s)}{A(s)} \end{aligned} \quad [15]$$

As will be presented later, the frequency response function (FRF) of a system is given by:

$$H(j\omega) = H(s)|_{s=j\omega} \quad [16]$$

i.e., by evaluating H on the $s = \sigma + j\omega$ contour.

Inversion of the Laplace Transform

While the general expression [1] necessitates an integration in the complex plane, simpler techniques often suffice. Tables of Laplace transforms can obviously be used for many cases. One important case concerns transfer functions where the nominator and denominator of $H(s)$ are rationale polynomials in the variable s . Inversion can then be done by fraction expansion using the method of residuals:

$$X(s) = \frac{B(s)}{A(s)} = \sum_{k=1}^N \frac{A_k}{s - p_k} \quad [17]$$

and the transform of each component can be shown to equal:

$$\frac{A_k}{s - p_k} \longleftrightarrow A_k \exp(p_k t) \quad [18]$$

The decomposition by the residual, a standard method well-documented in any mathematical text on Laplace transform, is slightly more complicated for the case of multiple poles.

Example We analyze a classic single-degree-of-freedom (SDOF), second-order system, composed of a mass, spring and damper (**Figure 1A**):

$$x(t) \longleftrightarrow X(s)$$

Applying the Laplace transform and assuming zero initial conditions:

$$ms^2 X(s) + csX(s) + kX(s) = P(s)$$

The transfer function:

$$\begin{aligned} H(s) &= \frac{X(s)}{P(s)} \\ &= \frac{1/m}{s^2 + (c/m)s + (k/m)} = \frac{1/m}{s^2 + 2\zeta\omega_n s + \omega_n^2} \end{aligned}$$

with $\omega_n = (k/m)^{1/2}$ the undamped natural frequency in rad s^{-1} :

$$\zeta = \frac{c}{2(mk)^{1/2}} \text{ the damping ratio}$$

The system poles:

$$s^2 + 2\zeta\omega_n + \omega_n^2 = 0$$

$$s_{1,2} = -\zeta\omega_n \pm j\omega_n(1 - \zeta^2)^{1/2} = -\zeta\omega_n \pm j\omega_d$$

with ω_d the damped natural frequency.

The impulse response: Rearranging $H(s)$, and looking at Laplace transform tables:

$$\begin{aligned} h(t) &= L^{-1}[H(s)] = L^{-1}\left[\frac{1}{m\omega_d} \frac{\omega_d}{(s + \zeta\omega_n)^2 + \omega_d^2}\right] \\ &= \frac{1}{m\omega_d} \exp(-\zeta\omega_n t) \sin(\omega_d t) \end{aligned}$$

The frequency response function:

$$H(j\omega) = H(s)_{s=j\omega} = \frac{1/m}{\omega_n^2 - \omega^2 + j2\zeta\omega\omega_n}$$

A specific numerical example, with $m = 0.1 \text{ kg}$, $k = 1000 \text{ N m}^{-1}$ and $c = 1 \text{ N s m}^{-1}$ is shown in Figure 1 (where the frequency is in Hz). The corresponding natural undamped frequency is $f_0 = 19.5 \text{ Hz}$, $\zeta = 5$ percent, and the poles $-5.0000 \pm j99.8749$.

Z-transforms

This is given by:

$$X(z) = \sum_{n=-\infty}^{\infty} x(n)z^{-n} \quad [19a]$$

$$x(n) = \frac{1}{2\pi j} \int X(z)z^{n-1} dz \quad [19b]$$

The integral will converge for certain regions of the complex variable z . Associated with the transform (19) is an ROC. It is only with such an association that an inverse transform can be defined uniquely.

A unilateral transform is often used for causal signals:

$$X(z) = \sum_{n=0}^{\infty} x(n)z^{-n} \quad [20]$$

Properties

Some important properties of the Z transform are given below:

- Linearity:

$$\left. \begin{aligned} a_1x_1(n) + a_2x_2(n) &\leftrightarrow a_1X_1(z) + a_2X_2(z) \\ Z\left[\sum_i a_i x_i(n)\right] &= \sum_i a_i Z[x_i(n)] \end{aligned} \right\} \quad [21]$$

- Time shift (for the unilateral case, eqn [20]):

$$x(n - n_0) \leftrightarrow z^{-n_0}X(z) \quad [22]$$

- Time reversal:

$$x(-n) = X(1/z) \quad [23]$$

- Convolution:

$$x_1(n) \otimes x_2(n) \leftrightarrow X_1(z)X_2(z) \quad [24]$$

One important application concerns the solving of linear difference equations of the type:

$$\sum_{k=0}^N a_k y(n-k) = \sum_{k=0}^M b_k x(n-k) \quad [25]$$

Applying the laws of linearity and time shift (eqns [21] and [22]) results in:

$$\sum_{k=0}^N a_k z^{-k} Y(z) = \sum_{k=0}^M b_k z^{-k} X(z) \quad [26]$$

The resulting algebraic equation is often easy to solve for analytical cases with closed form solutions.

The important notion of a discrete transfer function can now be defined as:

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{l=0}^M b_l z^{-l}}{\sum_{k=0}^N a_k z^{-k}} \quad [27]$$

which is of course a linear time invariant system.

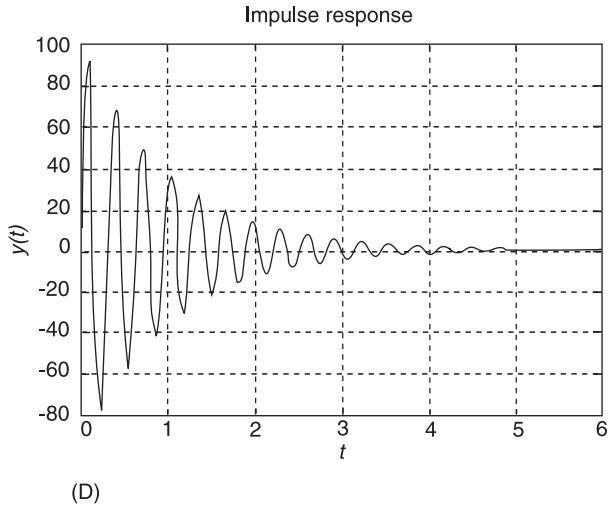

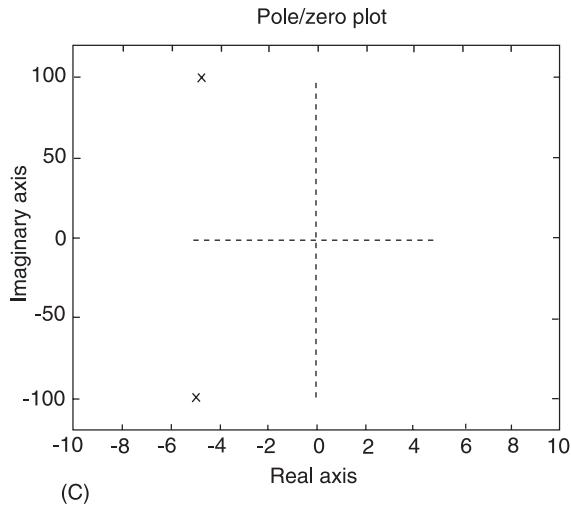

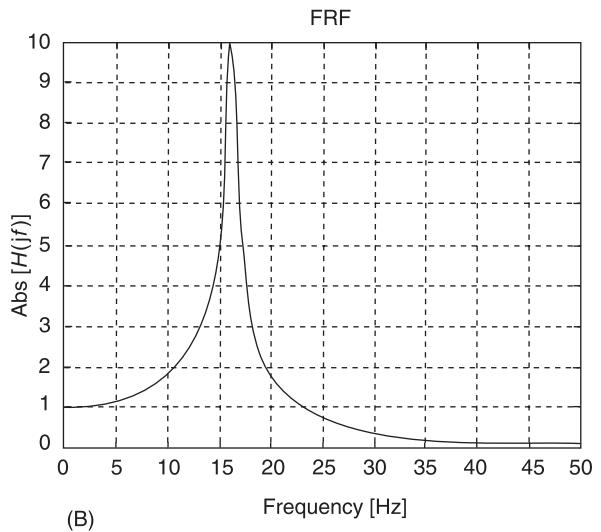

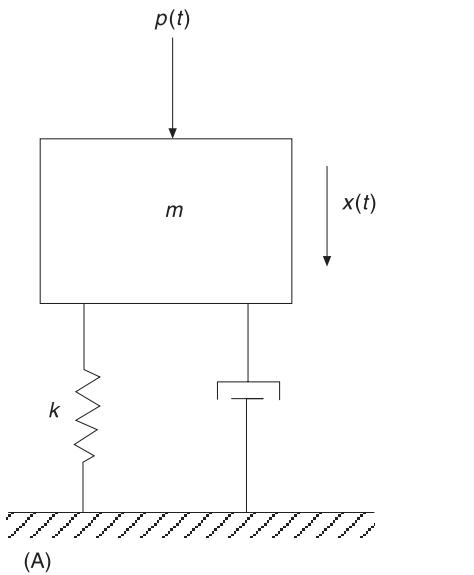

Figure 1 (A) Mass–spring–damper system. (B) Frequency response function (FRF). (C) Pole/zero plot (only poles exist). (D) Impulse response.

Another characterization of systems is via their impulse response. Mathematically, this is the response to a Dirac function $[\delta(n)]$. It is straightforward to show that:

$$Z[\delta(n)] = 1 \quad [28]$$

And hence the response:

$$\begin{aligned} X(z) &= H(z)Z[\delta(t)] = H(z) \\ x(n) &= h(n) = Z^{-1}[H(z)] \end{aligned} \quad [29]$$

An additional description of the system is that of the zero/poles. The transfer function $H(z)$ of many linear time-invariant systems that is described by a ratio of rational polynomials in z . The values of z for which the nominator and denominator equals zero, are then z_k , the zeros and p_k , poles of the system:

$$H(z) = b_m \frac{\prod_{k=j}^M (z - z_k)}{\prod_{k=1}^N (z - p_k)} \quad [30]$$

The frequency response of a discrete system is given by:

$$H(j\phi) = H(z)|_{z=j\phi} \quad [31a]$$

$$\phi = \omega \Delta t \quad H(j\omega) = H(z)|_{z=\exp(j\omega \Delta t)} \quad [31b]$$

i.e., evaluating $H(z)$ on the $z = \exp(j\omega \Delta t)$ contour, with Δt the sampling interval. Note that this FRF is a continuous function of the frequency. It is also periodic with $2\pi/\Delta t$.

Inversion

While the general expression [19] necessitates an integration in the complex plane, simpler techniques often suffice. One important case concerns transfer functions where the nominator and denominator of $H(z)$ are rational polynomials in the variable z . Inversion can then be done by fraction expansion by the method of residuals:

$$X(z) = \sum_{k=1}^N \frac{A_k}{1 - p_k z^{-1}} \quad [32]$$

and the transform (for the causal case) of each component can be shown to equal:

$$\frac{A_k}{1 - p_k z^{-1}} \leftrightarrow A_k z_k^n u(n) \quad [33]$$

where $u(n)$ is the unit step function.

Comparing the descriptions of continuous and discrete systems, we can observe the similar types of descriptions available, namely transfer functions, impulse responses, poles/zeros and FRFs.

Example The following recursive difference equation simulates a SDOF system having $f_n = 40$ Hz:

$$\begin{aligned} y(n) &= b_0 x(n) + b_1 x(n-1) + b_2 x(n-2) \\ &\quad - a_1 y(n-1) - a_2 y(n-2) \end{aligned}$$

with:

$$\begin{aligned} a_1 &= -1.7217, \quad a_2 = 0.938, \\ b_0 &= 0.0580, \quad b_1 = 0.1161, \quad b_2 = 0.0580 \end{aligned}$$

Applying a Z transform and solving the algebraic equations for:

$$H(z) = \frac{Y(z)}{X(z)}$$

results in:

$$H(z) = \frac{0.058 + 0.1161z^{-1} + 0.058z^{-2}}{1 + 1.7217z^{-1} - 0.9538z^{-2}}$$

Zeros and poles are computed by equating numerator and denominator polynomials to zero:

$$\begin{aligned} z_k &= -1 \pm j(0) \\ p_k &= 0.8608 \pm j0.4613 \end{aligned}$$

For data sampled at intervals of $\Delta t = 5$ ms, the FRF is:

$$H(z)_{z=j\omega\Delta t} = \frac{0.058(j\omega\Delta t)^2 + 0.1161(j\omega\Delta t) + 0.058}{(j\omega\Delta t)^2 + 1.7217(j\omega\Delta t) + 0.9538}$$

and the results (with frequency in Hz) are shown in Figure 2.

Fourier Transforms

These have similarities to the Laplace transform, evaluated for the special case of:

$$s = j\omega$$

$$x(t) \leftrightarrow X(j\omega)$$

$$X(j\omega) = \int_{-\infty}^{\infty} x(t) \exp(-j\omega t) dt \quad [34a]$$

$$x(t) = \int_{-\infty}^{\infty} X(j\omega) \exp(-j\omega t) dt \quad [34b]$$

The transform is complex, and often presented in polar form via a modulus and phase:

$$X(j\omega) = |X(j\omega)| \angle \phi(\omega) \quad [34c]$$

The convergence thus may not always exist for cases where the Laplace one does. Some signals may not satisfy the requirement of being absolutely square integrable, i.e.,

$$\int_{-\infty}^{\infty} |x^2(t) dt| < \infty$$

For some signals, the use of impulses in the Fourier transform may have to be used to enable its use in actual problems. In spite of this limitation, the

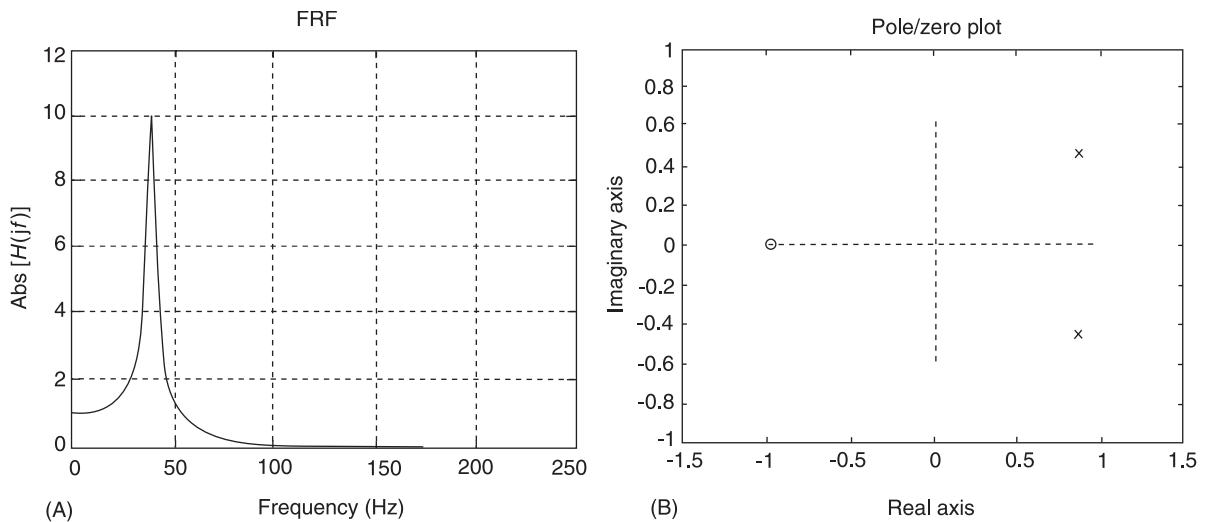

Figure 2 (A) Discrete system-FRF. (B) Pole/zero plot.

Fourier transform is widely used in signal and system analysis. One of its most appealing aspects is the physical interpretation of the domain transform: the time domain signals are transformed to the frequency domain. The frequency ‘content’ of a signal is an intuitively appealing description in many engineering applications.

Another advantage is the availability of efficient computational procedures. These are based on the FFT, a cornerstone of today’s signal processing.

Thus signal and system analysis draws consistently on methods based on the Fourier transform. The actual tool used depends on the signal characteristics. The following describes the various existing Fourier tools in some detail, the tools used for specific signal types being:

- >Fourier transform (FT) (sometimes called the Fourier integral transform, and sometimes Fourier integral) – for continuous aperiodic (transient) signals;
- Fourier series (FS) – for continuous periodic signal;
- discrete Fourier series (DFS) – for discrete periodic signals;
- discrete Fourier transform (DFT) – for discrete aperiodic signals.

Fourier Transform

These were given by [34]. The frequency in Hz is sometimes preferred as a variable, resulting in:

$$X(f) = \int_{-\infty}^{\infty} x(t) \exp(-j2\pi ft) dt \quad [35]$$

- Linearity:

$$\begin{aligned} a_1x_1(t) + a_2x_2(t) &\leftrightarrow a_1X_1(j\omega) + a_2X_2(j\omega) \\ F\left[\sum_i a_i x_i(t)\right] &= \sum_i a_i F[x_i(t)] \end{aligned} \quad [36]$$

- Time shift:

$$F[x(t - t_0)] = \exp(-j\omega t_0)X(j\omega) \quad [37]$$

- Scaling:

$$F[x(at)] = \frac{1}{|a|}F\left[X\left(j\frac{\omega}{a}\right)\right] \quad [38]$$

- Differentiation:

$$F\left[\frac{d}{dt}x(t)\right] = j\omega X(j\omega) \quad [39]$$

- Integration:

$$F\left[\int_{-\infty}^t x(t) dt\right] = \frac{1}{j\omega}X(j\omega) \quad [40]$$

- Convolution:

$$F[x_1(t) \otimes x_2(t)] = X_1(j\omega)X_2(j\omega) \quad [41]$$

- Products, modulation:

$$F[x_1(t)x_2(t)] = X_1(j\omega) \otimes X_2(j\omega) \quad [42]$$

- Parseval's law:

$$\begin{aligned} \int_{-\infty}^{\infty} |x(t)|^2 dt &= \frac{1}{2\pi} \int_{-\infty}^{\infty} |X(j\omega)|^2 d\omega \\ &= \int_{-\infty}^{\infty} |X(f)|^2 df \end{aligned} \quad [43]$$

The energy is invariant under the FT, and can be computed in either domain.

The properties are similar to those of the Laplace transform, but physical insight can be gained. Practical implications often follow and some of these are now addressed.

Linearity The superposition indicated by [36] implies that the contribution to each frequency range may be investigated independently for each signal component.

Time shift A pure delay does not affect the modulus of the transform. The phase however is shifted proportionally to the frequency.

Differentiation/Integration These operations weigh the modulus of the transform proportionally or inversely to the frequency (with a positive or negative 90° shift in phase).

Scaling This property has important practical implications. Compressing a signal in the time domain ($a > 1$) results in a spread in the frequency domain, and vice versa. Short impulses thus occupy a wide frequency range. Time duration and bandwidth (BW) are thus inversely proportional.

The duration in the time domain, T_{DUR} , and spread in the frequency domain BW, can be defined in various ways. One possibility is through a normalized second moment as:

$$T_{DUR} = \left[\frac{\int_{-\infty}^{\infty} t^2 x^2(t) dt}{\int_{-\infty}^{\infty} x^2(t) } \right]^{1/2} \quad [44a]$$

$$BW = \left[\frac{\int_{-\infty}^{\infty} \omega^2 |X(j\omega)|^2 d\omega}{\int_{-\infty}^{\infty} |X(j\omega)|^2 d\omega} \right]^{1/2} \quad [44b]$$

but the inverse relation between these two remains for other possible definitions.

Example We will take a Gaussian signal, for which the closed-form expression will result in:

$$x(t) = K_1 \exp \left(-\frac{t^2}{2\sigma^2} \right) \leftrightarrow K_2 \exp \left(-\frac{\sigma^2 \omega^2}{2} \right) \quad [45]$$

where K_1 and K_2 are chosen so as to satisfy Parseval's law.

To see the effect of compressing the time duration, using $\sigma = 1$, we use the scaling property [38], the results being shown in Figure 3 (for $a = 1$ and $a = 3$). The implication is of utmost practicality: the shorter the transient, the wider the frequency bandwidth of the signal.

By analogy with eqns [10]–[14], a differential equation will be transformed to an algebraic one by application of a FT. Eqn [10] will be transformed to

$$\begin{aligned} \sum_{k=0}^N a_k(j\omega)^k Y(j\omega) &= \sum_{k=0}^M b_k(j\omega)^k X(j\omega) \\ H(j\omega) &= \frac{\sum_{k=0}^M b_k(j\omega)^k}{\sum_{k=0}^N a_k(j\omega)^k} \end{aligned} \quad [46a]$$

which could also have been obtained directly by substituting $s = j\omega$ into $H(s)$, eqn [12]. Obviously we also have:

$$\begin{aligned} h(t) &\leftrightarrow H(j\omega) \\ h(t) &= F^{-1}[H(j\omega)] \end{aligned} \quad [46b]$$

A convenient interpretation of $H(j\omega)$ is that of a system gain. Exciting a linear system by an harmonic input of frequency ω_1 , will result in an harmonic output with the same frequency (in the steady state condition). The gain will be $H(j\omega_1)$, and the phase shift the phase of $H(j\omega_1)$.

Real time signals In most engineering applications, time signals will be real. This results in some symmetries in the FT. Intuitively it should be obvious that only when some symmetries in the frequency domain exist will the imaginary parts of eqn [34b] cancel. Specifically we have:

$$X(-j\omega) = X^*(j\omega) \quad [47]$$

where * stands for the complex conjugate.

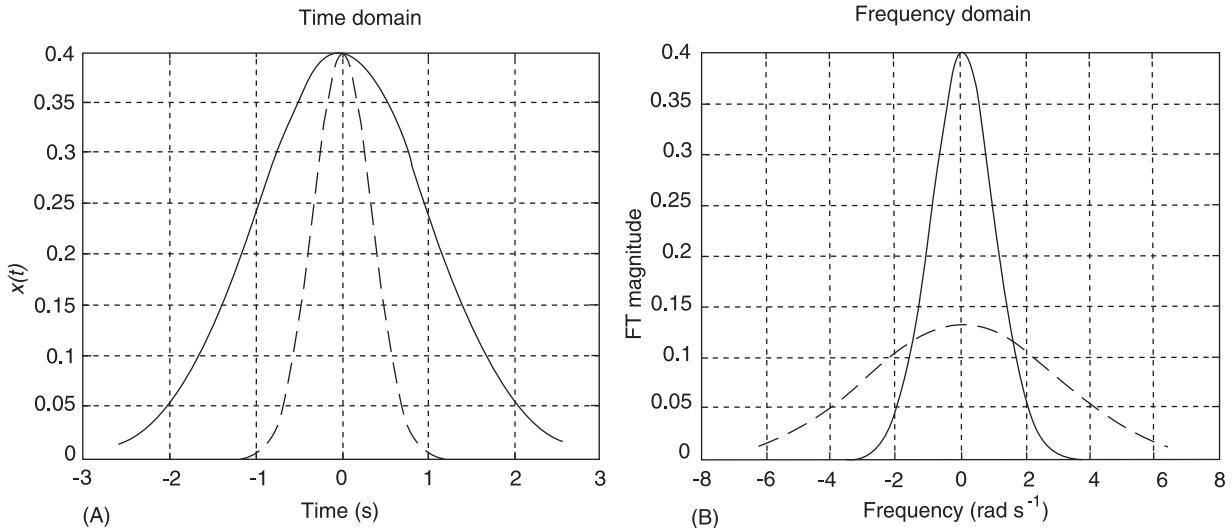

Figure 3 (A) Time domain. (—) original, (---) compressed. (B) Frequency domain. (—) original, (---) compressed.

We finally address the transform of periodic signals. Impulses in the transform are needed in such cases:

$$\begin{aligned} x(t) &= x(t + T_p) \quad \omega_0 = \frac{1}{T_p} \\ X(j\omega) &= 2\pi \sum_k X(k)\delta(\omega - \omega_0) \end{aligned} \quad [48]$$

indicating that the contribution in the frequency domain is concentrated at discrete frequencies.

Fourier Series

A periodic signal:

$$x(t) = x(t + T_p)$$

can be decomposed into a Fourier series:

$$x(t) = \sum_{k=-\infty}^{\infty} C(k) \exp(j2\pi k f_0 t), \quad f_0 = \frac{1}{T_p} \quad [49a]$$

$$C(k) = \frac{1}{T_p} \int_{T_p}^x x(t) \exp(-j2\pi k f_0 t) dt \quad [49b]$$

A Fourier series synthesis is obviously possible, generating a periodic signal by the superposition of harmonic components. Borrowing terms from music theory, $k = 1$ defines the fundamental component, while higher k values define the harmonics. If a

truncated series is used, a minimization of the mean square error between the signal and the summation is achieved.

The series will converge if:

$$\frac{1}{T_p} \int_{T_p} |x(t)|^2 < \infty \quad [50]$$

except at discontinuities where overshoots and oscillations may occur. Equations [49] show a two-sided decomposition. The use of negative indices, and hence negative frequencies, is mainly a mathematical convenience, resulting in a compact presentation (and also closer to the FT representation). A one-sided presentation is also possible.

Symmetries in $C(k)$ exist for $x(t)$ a real signal, namely:

$$C(-k) = C^*(k) \quad [51]$$

Figure 4 shows the first few terms of a Fourier series and the partial sums for a square wave signal. The convergence can already be noticed, as well as the overshoot and oscillations around the discontinuities.

Discrete Fourier Series

Computational schemes can only be applied to discrete signals, and the continuous signals acquired by measurements are thus digitized.

The DFS is the Fourier tool suitable for decomposing discrete periodic signals of the form:

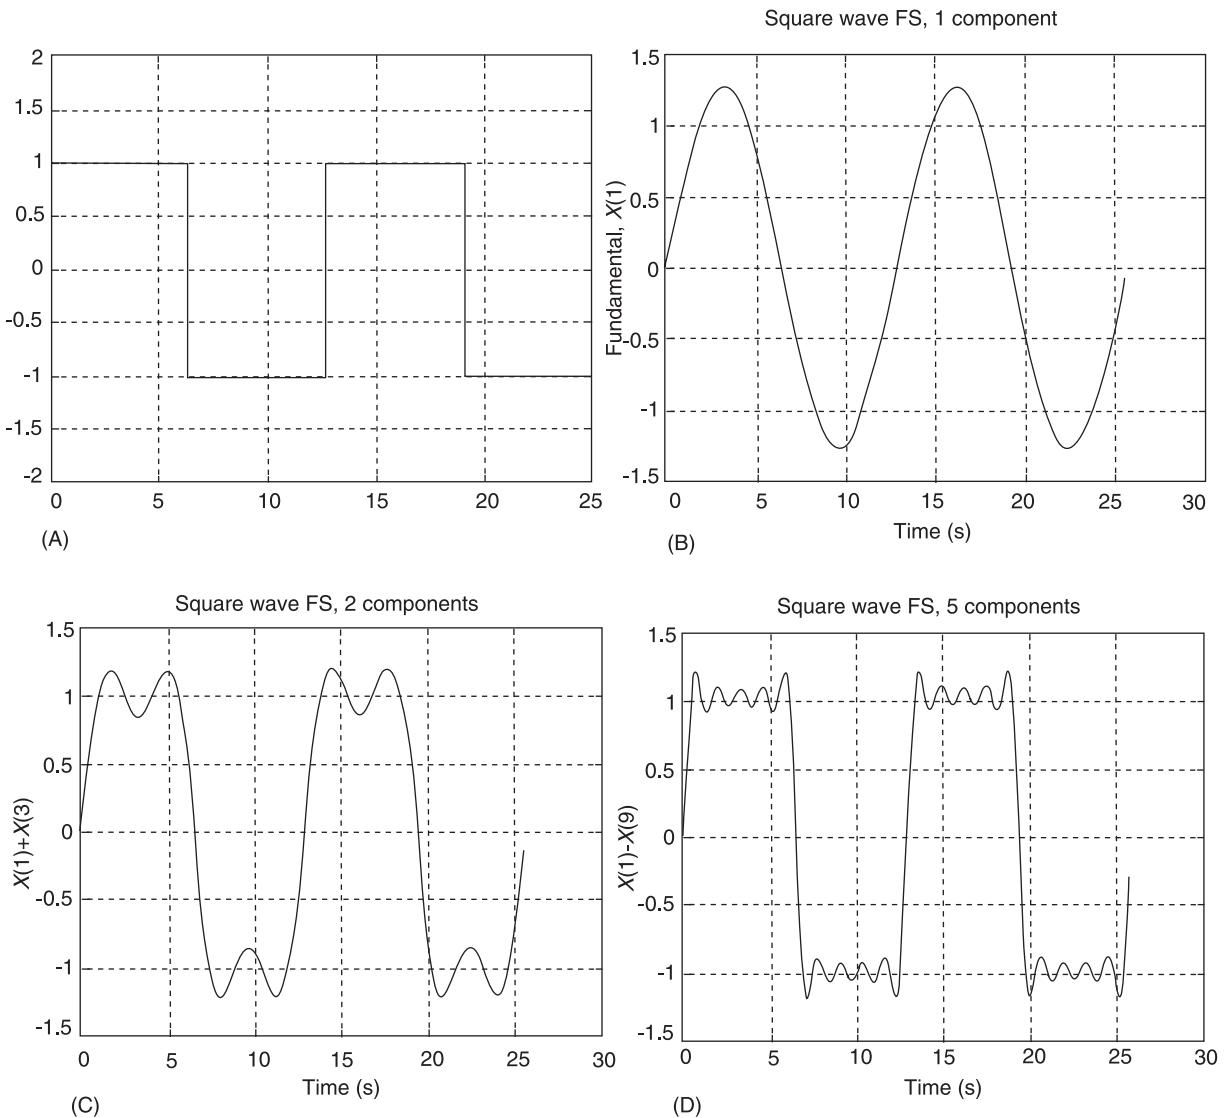

Figure 4 (A) Periodic signal (square). (B) Fundamental Fourier series component. (C) First three Fourier series components (second zero). (D) First nine components Fourier series components.

$$x(n) = x(n + N) \quad [52a]$$

The decomposition is:

$$x(n) = \sum_k X_{\text{DFS}}(k) \exp(j2\pi kf_0n); \quad f_0 = \frac{1}{N} \quad [52b]$$

with:

$$X_{\text{DFS}}(k) = \frac{1}{N} \sum_n x(n) \exp(-j2\pi kf_0n) \quad [52c]$$

We note that the transform given by eqns [52] can be manipulated in a computer, giving exact results.

The FS is a decomposition suitable for continuous periodic signal, the DFS for discrete periodic ones. The discretization however imposes a periodicity in the frequency domain (Figure 5), and it is easy to show that:

$$X_{\text{DFS}}(k) = X_{\text{DFS}}(k + N) \quad [53]$$

and the sum [52c] is computed over N points. The transform described next is actually the one usually computed. The DFS itself, if computed, will be based on the DFT (see below, eqn [57]).

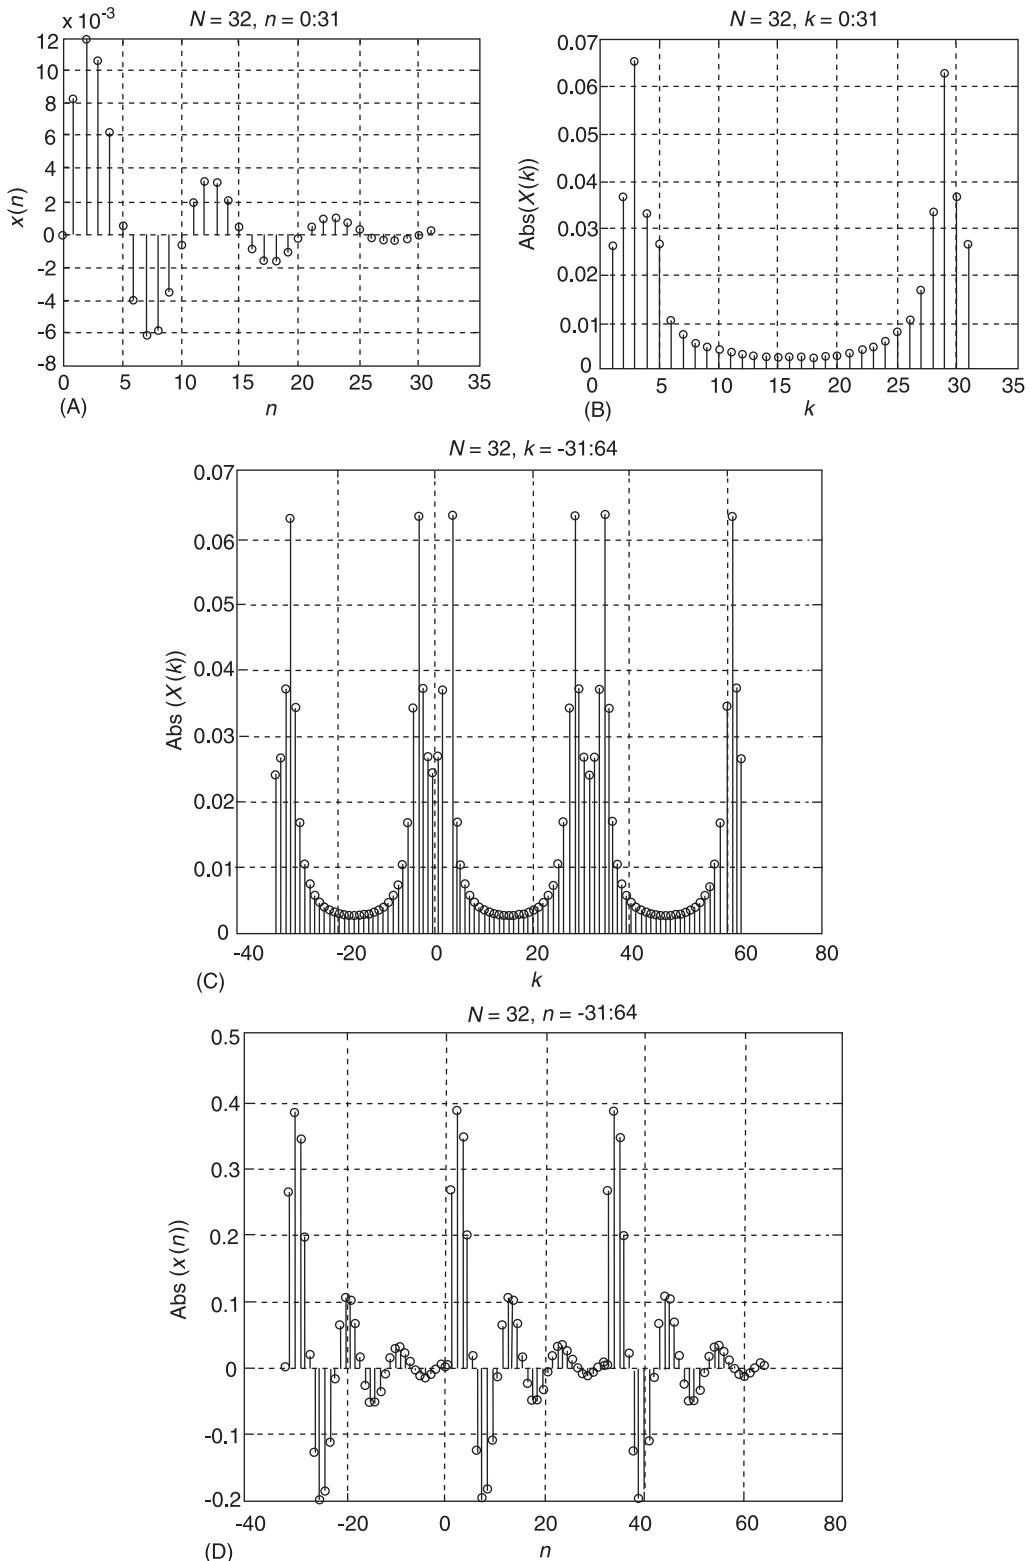

Figure 5 (A) Discrete periodic time domain sequence, single period. (B) Discrete Fourier series. (C) Discrete periodic time domain sequence. (D) Discrete Fourier series, periodic extension.

The Discrete Fourier Transform

This is the actual transformation computed in the majority of Fourier-based signal processing methods.

It is actually a transformation from one N point (complex) sequence into another N point (complex) sequence in another domain:

$$\left. \begin{aligned} X(k) &= \sum_{n=0}^{N-1} x(n) \exp(-j(2\pi/N)nk) \\ x(n) &= \frac{1}{N} \sum_{k=0}^{N-1} X(k) \exp(j(2\pi/N)nk) \end{aligned} \right\} [54]$$

and in the majority of applications n and k would be time and frequency indices. It is often convenient to look at (54) as an approximation of the continuous FT with the following:

$$\begin{aligned} dt &\rightarrow \Delta t = 1 \\ df &\rightarrow \Delta f \\ f &\rightarrow k\Delta f \\ t = i\Delta t \\ \int &\rightarrow \sum \\ \Delta f &= \frac{1}{N\Delta t} \end{aligned} [55]$$

where Δf and Δt are the discrete frequency and time steps, Δt being dictated by the sampling frequency. The transformation, like most signal processing basic expressions, is normalized with $\Delta t = 1$, and the frequency range then being $-\frac{1}{2} + \frac{1}{2}$. Equation [54] is the one implemented in standard signal processing software routines.

For a discrete transform approximating the FT and finite Δt to retain engineering units, EU, we modify [54] to:

$$\left. \begin{aligned} X(k\Delta f) &= \Delta t \sum_{n=0}^{N-1} x(n) \exp(-j(2\pi/N)nk) \\ x(i\Delta t) &= \frac{1}{N\Delta t} \sum_{k=0}^{N-1} X(k\Delta f) \exp(j(2\pi/N)nk) \end{aligned} \right\} [56]$$

where Δt is the sampling interval and Δf the computational frequency step (eqn [55]). The expression [56] would be implemented only in dedicated (usually commercial) instrumentation/analysers. The approximation to the FT deteriorates when aliasing occurs due to too large Δt .

When extending the indices n and k in [55] beyond N points, a periodicity in N will be noticed. Except for a factor of N , we may interpret [54] as ‘the

transform between one period of a periodically sequence $x(n)$ to one period of a periodically sequence $X(k)$ ', i.e., those described by the DFS. Thus we also have the relation:

$$X(k) = N X_{\text{DFS}} \quad [57]$$

The implied peridicity in $X(k)$ enables us to give additional interpretation to the indices k and n :

$$\left. \begin{aligned} X(-k) &= X(N - k) \\ x(-n) &= x(N - n) \end{aligned} \right\} [58]$$

and the region of $k = N/2 + 1, \dots, N - 1$ can be interpreted as one of negative frequencies.

Two more specific indices have a special interpretation:

For $k = 0$, eqn [54] shows that:

$$X(k) = \sum_{n=0}^{N-1} x(n) \quad [59]$$

except for a factor of N , this is the average (or DC component) of $x(n)$:

$$X_{\text{DC}} = \frac{1}{N} \sum_{n=0}^{N-1} x(n) \quad [60]$$

which is intuitively obvious as the zero frequency component is one of DC.

For $k = N/2$, we have a frequency of:

$$f = k\Delta f = \frac{N}{2} \frac{1}{N\Delta t} = \frac{1}{2\Delta t} = f_{\text{NYQUIST}} \quad [61]$$

which corresponds to the Nyquist frequency (see **Data acquisition**), the maximum frequency range compatible with the sampling process.

While [54] is a transformation between two complex sequences, signals acquired are usually real. This imposes symmetries on $X(k)$ as:

$$X(-k) = X^*(k) \quad [62]$$

Figure 6, showing absolute value of $X(k)$ of a real signal, summarizes the above properties. We note the interpretation of a negative frequency region as well as the symmetries. The more conventional way of presenting positive and negative frequency region is shown in **Figure 6C**, which can be easily obtained from **Figure 6B** by a shifting operation.

Parseval's law of equal energies in the time and frequency domain holds (eqn [63]):

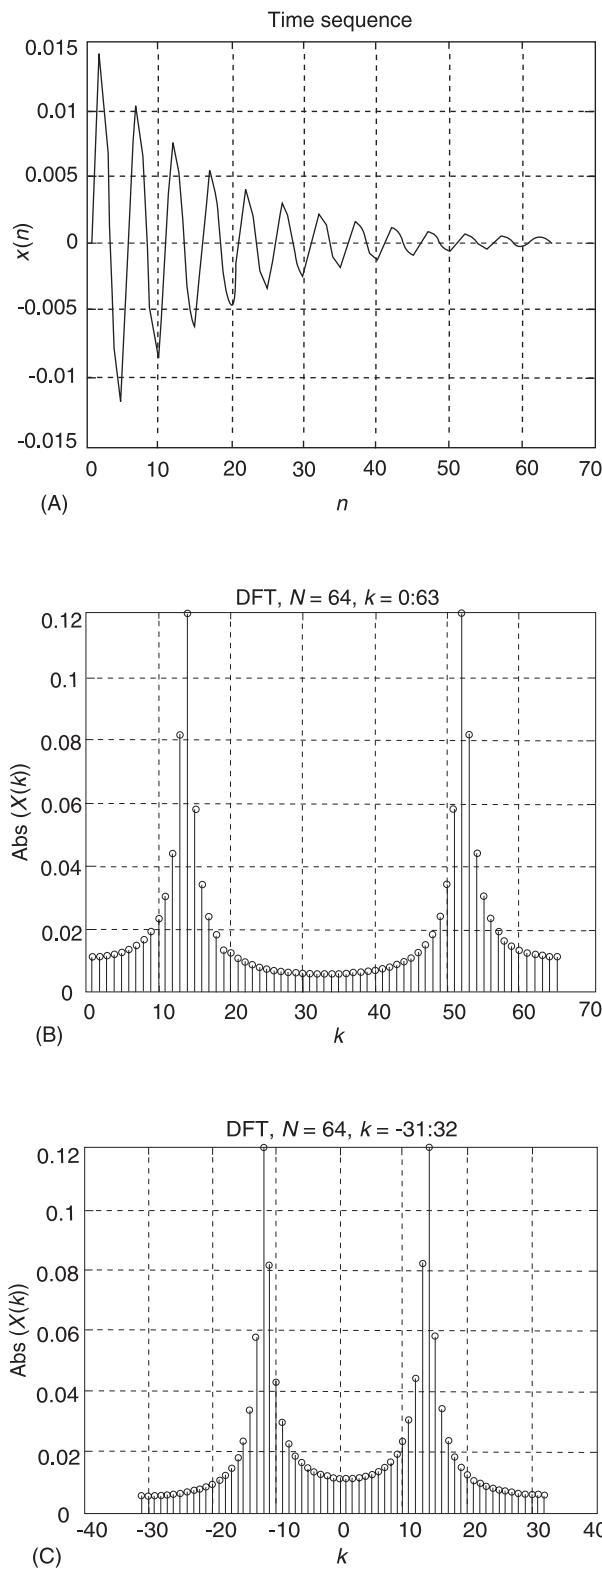

Figure 6 (A) Discrete time signal. (B) DFT. (C) DFT, negative frequencies shifted to left half plane.

$$\sum_n x^2(n) = \frac{1}{N} \sum_k |X(k)|^2 \quad [63]$$

The Fast Fourier Transform (FFT)

This is an extremely efficient algorithm for the computation of the DFT (and its inverse). The name FFT has in many aspects become synonymous with that of the DFT, and the literature often refers to phrases like ‘presented is the FFT of ...’. The FFT takes advantage of symmetries involved in the DFT computations, to achieve efficiency.

The name FFT actually refers to a large family of algorithms, each one geared to different situations. For vibration signals, we would use a FFT from a real sequence (in time) to a complex one (in frequency). Complex-to-complex algorithms are also available.

The length \$N\$ of the sequences to be transformed will affect the efficiency. For small (PC and commercial analyser) machines, a power of 2 length is usually preferred (and the only one available in the dedicated analyzers). The term ‘Radix M’ is sometime used, and ‘Radix 2’ FFT hence refers to an algorithm where the number of analyzed points is:

$$2^M \quad \text{where } M \text{ is an integer} \quad [64]$$

i.e., \$N = 32, 64, 128, \dots\$, but Radix 8 FFTs are sometimes used by practitioners.

As a result of possible requirements on the number of samples \$N\$, various computing variations are sometimes built into commercial software. Zeros are sometimes appended to the sequence in order to achieve a length of a power of 2. We note that the appending of zeros will not affect the result of the summation for \$X(k)\$ as per:

$$X(k) = \sum_0^{n1-1} x(n) \exp \left(-j \frac{2\pi}{N} \right)^{nk} + \sum_{n1}^N 0 \exp \left(-j \frac{2\pi}{N} \right)^{nk} \quad [65]$$

Sometimes a straight DFT computation (with the loss of efficiency) may be performed for arbitrary length sequences.

The implementation for an inverse DFT is very similar to that of the forward FFT, and is usually available in all FFT packages. Some algorithms will ignore the factor of \$N\$ preceding [54b]. Sometimes a factor of \$(1/N)^{1/2}\$ premultiplies both [54a] and [54b]. It is thus important to check the exact computation performed by any available algorithm.

The computational complexity for the DFT can be ascertained from equation [54]: \$N\$ complex operations are needed for the computation of a single \$X(k)\$, and for \$N\$ values of \$k\$, this requires \$N^2\$ operations. In

this context ‘complex operation’ refers to a complex product and summation). The number of operations for a Radix 2 FFT of N points is approximately $N \log_2(N)$. The seemingly modest improvement is deceiving. As an example, with $N = 2^{13} = 8192$, the saving would be:

$$N^2/N \log_2(N) = 2^{26}/(13 \times 2^{13}) = 630$$

Many analyses necessitate the computations of hundreds of FFTs, with a tremendous saving. Actually it is only the availability of the FFT algorithm which has made modern signal processing (and, obviously, Fourier-based methods) practical.

The FFT in its present form was published in the 1970s, but some of the ideas can already be found in the works of Gauss. The constraint on the block size N limits to some extent use of an exact pre-determined frequency spacing

Example Let us assume data acquisition with a sampling interval of $\Delta t = 4$ ms, and two scenarios.

Scenario 1 The desired frequency resolution (spacing) is $\Delta f = 1$ Hz. Then:

$$N \rightarrow \frac{1/\Delta t}{\Delta f} = 250$$

We thus will choose $N=256$ with a resulting actual resolution of $\Delta f = 0.98$.

Scenario 2 The desired frequency resolution is 0.6 Hz. Then:

$$N \rightarrow \frac{1/\Delta t}{\Delta f} = \frac{250}{0.6} = 417$$

and two choices for N can be taken, with different resulting frequency resolutions:

$$\begin{aligned} N_1 &= 256, & \Delta f_1 &= 0.98, \\ N_2 &= 512, & \Delta f_2 &= 0.49 \end{aligned}$$

The first choice results in a resolution less than required. The second one results in a resolution better than required, but at the expense of an increase in computational effort.

Introduction

Many signals encountered in the field of vibration analysis can be modeled as nonstationary. One nat-

ural tool for the study of such signals is to employ time-frequency methods (see **Transform methods**). An alternative, but complementary, approach is to exploit time-scale methods based on the wavelet transform (WT). A WT seeks to represent a signal, fundamentally, as a function of time and scale, rather than time and frequency. In most applications one can directly relate scale to frequency and hence the WT can be considered as a form of time-frequency representation.

The WT can be regarded in many equivalent ways. It can be viewed as a transform method allowing one to represent a signal in terms of elementary functions. The nature of the decomposition allows one to zoom in on discontinuities in the signal. This allows one to regard the WT as a form of multiresolution analysis, whilst the WT also offers the opportunity to implement filter banks with perfect reconstruction properties. This article will predominantly address wavelets from the transform perspective, since this represents the most appropriate standpoint for most vibration-based applications.

The WT is closely related to the short-time (term) Fourier transform (STFT). Indeed, these two transforms share a common mathematical framework. This chapter begins with a discussion of the STFT and then outlines the principles behind the continuous WT (CWT). The issues associated with sampling these representations within the transform domain are then discussed, leading to a discussion of the discrete WT.

The Short-time Fourier Transform

The STFT is an extension of the Fourier transform to the case where a signal is nonstationary, i.e., its spectral characteristics vary as a function of time. The STFT is computed by windowing the signal at various times and Fourier-transforming the resulting product. The STFT, $S(t, f)$, can be defined in several fashions (all are equivalent to within a constant phase factor). The definition used herein is:

$$\begin{aligned} S(t, f) &= \int x(\tau)w(t - \tau)^* e^{2\pi if(t-\tau)} d\tau \\ &= \int x(t - \tau)w(\tau)^* e^{2\pi if\tau} d\tau \end{aligned} \quad [1]$$

where $w(t)$ is a windowing function, f represents frequency and $*$ denotes complex conjugation (note that the windowing function is commonly real-valued, in which case the conjugation is obsolete). The STFT is a complex valued function. When inspecting the STFT it is often the squared magnitude of the STFT that is presented, which is termed the spectrogram (see **Transform methods**).

The form of the spectrogram/STFT critically depends on the choice of the duration of the windowing function $w(t)$. If a window with a long duration is used then the STFT will fail to resolve short-duration events, whereas if a short-duration window is used, the STFT will fail to adequately resolve narrow-band components. This is a direct consequence of the time-frequency uncertainty principle that states that there is a lower limit to the product of a signal's duration

and its bandwidth. This implies that, for a given duration, one cannot construct a signal whose bandwidth is arbitrarily small. A consequence of this is that one cannot select $w(t)$ such that the STFT possesses good time and frequency resolution simultaneously. This forces the user to trade off time resolution against frequency resolution.

The following discusses an example that illustrates the practical implications of this tradeoff. The signal to be analysed is described by:

$$\begin{aligned} x(n) &= \sin(2\pi n/11) + 5\delta(n) \\ n &\in [-512, 512] \end{aligned}$$

where $\delta(n)$ is the Kronecker delta function, $\delta(n) = 1$ when $n = 0$ and $\delta(n) = 0$ for $n \neq 0$. **Figure 1A** shows this signal in the time domain. A good time–frequency representation of this signal contains a single horizontal and a single vertical line. The horizontal line, representing the narrow-band component, should be centered at a normalized frequency of 0.09, whilst the vertical line, representing the impulse, should be located at $n = 0$. **Figure 1B** shows a spectrogram computed with a window of root mean square duration 6.6 samples. This relatively short window generates a distribution in which the impulsive component is well resolved; however, the tonal signal is spread in frequency. **Figure 1C** shows a spectrogram computed using a window of duration 14.8 samples. This window causes both lines to smear somewhat. Finally, **Figure 1D** shows the results of applying a spectrogram using a window of duration 33 samples. This longer window causes considerable spreading of the impulse, but the tonal contribution becomes more concentrated about the correct frequency.

This example illustrates how the results using a STFT/spectrogram vary with the choice of windowing function. It also highlights that it may be difficult to select a window duration that is suited to all components in a signal.

In the following we consider how the STFT of a signal is affected by two basic operations on a signal. To aid this discussion, the notation for the STFT is extended slightly such that $S_x(t, f)$ is used to denote explicitly the STFT of $x(t)$.

Time Shifts

Consider $y(t)$ formed by delaying $x(t)$, specifically, $y(t) = x(t - \tau_0)$, then the STFTs of these two signals are related via:

$$S_y(t, f) = S_x(t - \tau_0, f)$$

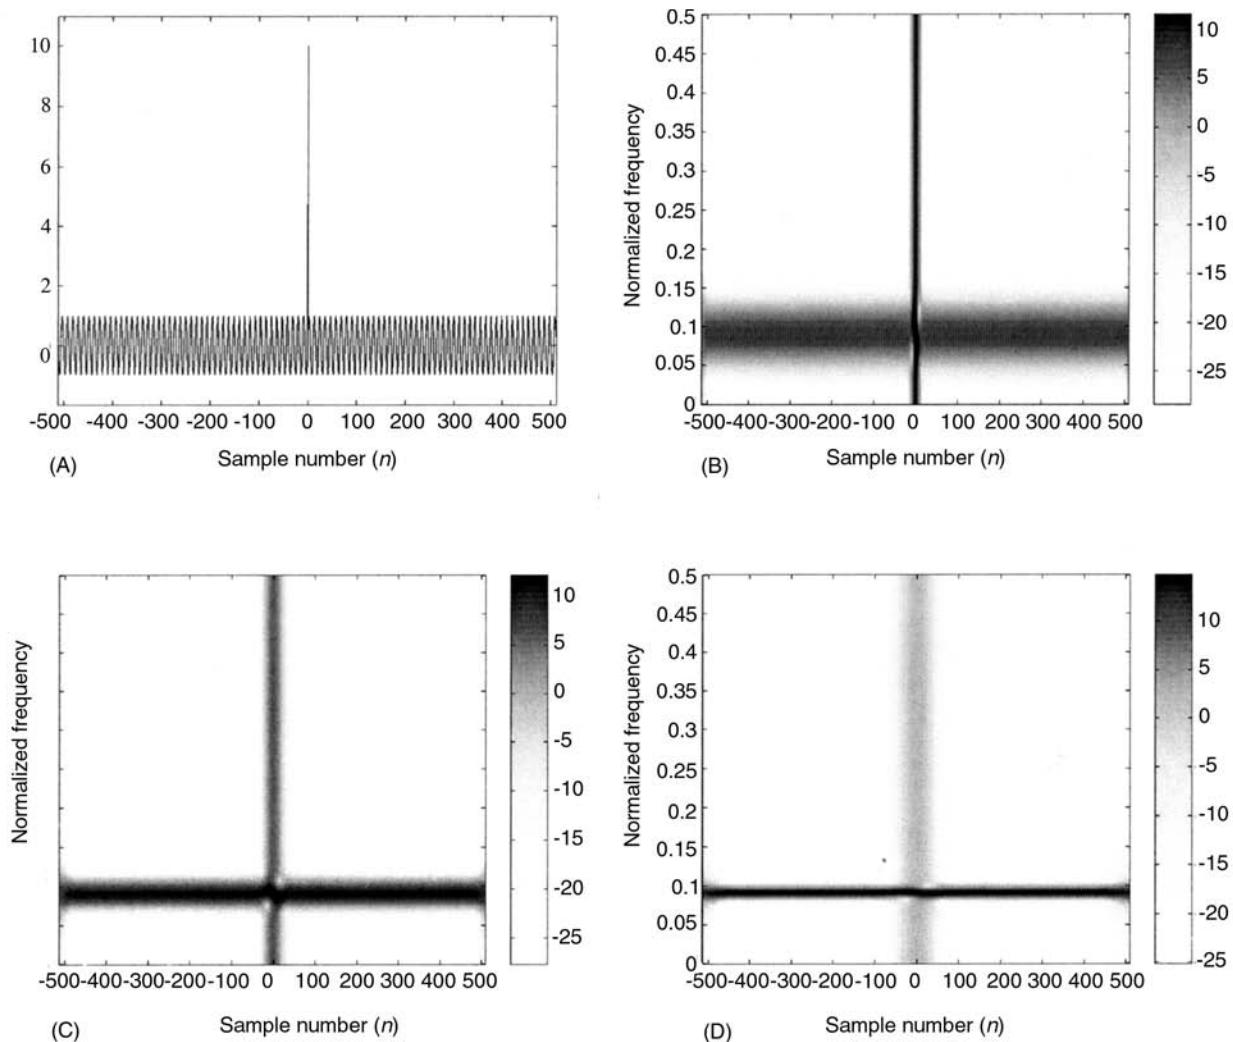

Figure 1 Examples of spectrograms. (A) Test signal; (B) spectrogram, $\sigma = 6.6$; (C) spectrogram, $\sigma = 14.8$; (D) spectrogram, $\sigma = 33.0$.

That is to say, delaying the signal merely translates the STFT along the time axis.

Frequency Shifts

Consider $y(t)$ formed by shifting $x(t)$ in frequency, by modulating it with a complex exponential, so that $y(t) = x(t)e^{2\pi if_0 t}$, then the STFTs of these two signals are related via:

$$\begin{aligned} S_y(t, f) &= e^{2\pi if_0 t} S_x(t, f - f_0) \Rightarrow |S_y(t, f)| \\ &= |S_x(t, f - f_0)| \end{aligned}$$

Thus, the act of frequency shifting a signal translates the STFT along the frequency axis, with the inclusion of a linear-phase term. However, the magnitude of the STFT (and hence the spectrogram) translates exactly along the frequency axis.

The above two properties of the STFT indicate how it copes in an intuitively appealing manner with the operations of time and frequency shifts.

Let us continue to consider the form of the STFT. Eqn [1] can be regarded as a set of inner products with time-shifted versions of the function $\Psi_s(t, f)$, so that:

$$S(t, f) = \int x(\tau) \Psi_s^*(t - \tau, f) d\tau \quad [2]$$

where the function $\Psi_s(t, f)$ is a complex exponential multiplied by the function $w(t)$, i.e.:

$$\Psi_s(t, f) = w(t) e^{-2\pi ift} \quad [3]$$

The analyzing operation [2] loses considerable potency if no inverse operation exists, that is, if one

cannot recover the original data from the transform domain representation. A general inversion relation for the STFT is:

$$x(t) = \frac{1}{C_{w,\tilde{w}}} \iint S(t,f) \Gamma_s(t-\tau,f) df d\tau \quad [4]$$

where, $\Gamma_s(t,f)$ and $C_{w,\tilde{w}}$ are defined as:

$$\Gamma_s(t,f) = \tilde{w}(t)e^{-2\pi ift} \quad [5]$$

$$C_{w,\tilde{w}} = \int w^*(t)\tilde{w}(-t) dt \quad [6]$$

where $\tilde{w}(t)$ is a second windowing function. In view of eqn [4], the STFT can be regarded as a decomposition of the signal $x(t)$ in terms of the functions $\Gamma_s(t-\tau f)$. Indeed, one can regard the standard Fourier transform as a special case of the STFT in which $w(t) = 1$ and $\tilde{w}(t) = \delta(t)$ (where $\delta(t)$ is the Dirac delta function). In which case $C_{w,\tilde{w}} = 1$, the basis functions, $\Gamma_s(t,f)$, become the complex exponentials and $S(t,f)$ is independent of time t .

The only formal condition for the inversion formula [4] to exist is that $C_{w,\tilde{w}}$ be nonzero. There is, somewhat surprisingly, no requirement that the two functions $w(t)$ and $\tilde{w}(t)$ be the same, but this restriction is often imposed and we shall concentrate on this case here, so that $\Psi_s(t,f) = \Gamma_s(t,f)$.

Whilst the choice of the function $w(t)$ is mathematically only restricted to functions that satisfy (6), with $w(t) = \tilde{w}(t)$, it is convenient to select these functions as windowing functions, so they are centered at the origin of the time–frequency plane and are well localized in both domains. Assuming $w(t)$ is selected in accordance with the above, then the spectrogram at t_0 and f_0 , i.e., $|S(t_0, f_0)|^2$, reflects the energy of the signal close to frequency f_0 and time t_0 .

The spectrogram can also be interpreted as a filtering operation, by realizing that eqn [4] represents a convolution between the signal $x(t)$ and $\Psi_s(t,f)$. Hence $|S(t_0, f_0)|^2$ can be interpreted as the instantaneous energy of the output of a filter whose impulse response is given by [3] with $f = f_0$. One can evaluate the spectrogram by employing a bank of filters, each filter having an impulse response that is a frequency-shifted version of $w(t)$. Each filter in such a bank has the same bandwidth, but different quality factors (Q-factors). Figure 2 shows the impulse responses for various center frequencies, assuming that the windowing function has the form of a Gaussian function:

$$w(t) = e^{-t^2/2\sigma^2}$$

The user-defined parameter σ controls the signal's duration. Figure 2 emphasizes that neither the duration nor the bandwidth of the basis functions depend on the center frequency.

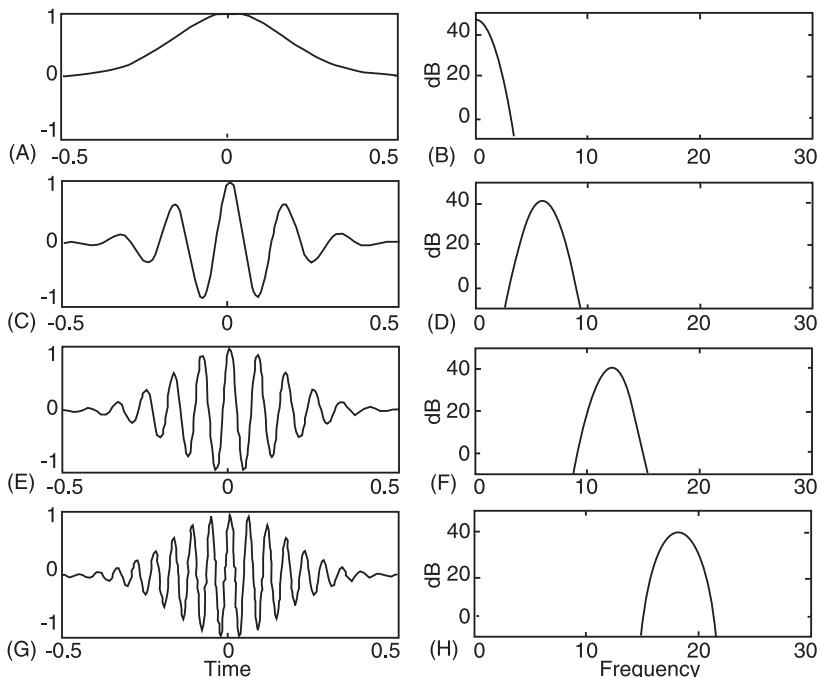

Figure 2 Basis functions for the short-time Fourier transforms.

The Continuous Wavelet Transform

The STFT is based on the operations of time and frequency shifts; the basis functions for the decomposition are time- and frequency-shifted versions of $w(t)$; see eqns [4] and [5]. The CWT is an alternative, but related, decomposition based upon the operations of time shifts and scalings. The CWT is defined as:

$$w(t, a) = \frac{1}{\sqrt{a}} \int g^*\left(\frac{t-\tau}{a}\right) x(\tau) d\tau \quad [7]$$

The parameter a represents scale, here assumed to be positive, and is closely allied to frequency. The CWT is, in general, a complex valued function and it is often the squared magnitude of the CWT that is considered; the squared magnitude of the CWT is dubbed the scalogram.

Like the STFT, the CWT satisfies two basic invariance properties. These are discussed below, and we temporally adopt a subscript in the notation for the WT to indicate the signal being analyzed.

Time Shifts

If $y(t)$ is formed by delaying $x(t)$, specifically, $y(t) = x(t - \tau_0)$, then the CWT of $y(t)$ satisfies:

$$W_y(t, a) = W_x(t - \tau_0, a)$$

Hence the effect of delaying the input signal is to shift the time axis of the CWT.

Scale Changes

If $y(t)$ is a scaled version of $x(t)$ such that, $y(t) = x(t/a_0)$, then the CWT of $y(t)$ is given by:

$$W_y(t, a) = a_0 W_x(t/a_0, a_0 a) \quad a_0 > 0$$

Thus, the effect of scaling the signal is to rescale the time axis of the CWT and to shift its center scale. The rescaling in time is necessary to account for the fact that the duration of $y(t)$ will be different to that of $x(t)$. Rescaling the time signal also introduces a multiplicative constant into the CWT which is of little practical importance.

The basic form of the CWT can, like the STFT, be expressed as a series of inner products. Eqn [7] can be expressed in the same form as eqn [2], namely:

$$W(t, a) = \int x(\tau) \Psi_w^*(t - \tau, a) d\tau \quad a > 0 \quad [8]$$

where:

$$\Psi_w(t, a) = \frac{1}{\sqrt{a}} g\left(\frac{t}{a}\right) \quad [9]$$

The functions $\Psi_w(t, a)$ are scaled versions of the function $g(t)$; the leading factor of $a^{-1/2}$ is included to ensure that the energy of $\Psi_w(t, a)$ is invariant to the choice of a . The general inversion formula for the CWT is given by:

$$x(t) = \frac{1}{C_{g,\tilde{g}}} \iint W(\tau, a) \Gamma_w(t - \tau, a) \frac{da dt}{|a|^2} \quad [10]$$

where:

$$\Gamma_w(t, a) = \frac{1}{\sqrt{a}} \tilde{g}\left(\frac{t}{a}\right) \quad [11]$$

$$C_{g,\tilde{g}} = \int G(f) \tilde{G}(f)^* \frac{df}{|f|} \quad [12]$$

where $G(f)$ and $\tilde{G}(f)$ are the Fourier transforms of $g(t)$ and $\tilde{g}(t)$ respectively. The inversion (10) is valid as long as $C_{g,\tilde{g}}$ is nonzero. As with the STFT, it is common to select $\tilde{g}(t) = g(t)$, a convention that will be adhered to here. In which case, one can regard the CWT as a decomposition of a signal with respect to the functions $\Psi_w(t, a) = \Gamma_w(t, a)$.

It is informative to consider how the elementary functions, $\Psi_w(t, a)$, vary with the scale parameter a . Large values of a correspond to stretched (dilated) versions of the basic function $g(t)$, whilst small values relate to compressed (contracted) versions of $g(t)$. The function $g(t)$ is referred to as the mother wavelet. The term wavelet arises because the condition [12] equates, for most reasonable choices of function, to constraining $g(t)$ to be zero mean, ensuring that it must contain some oscillations, i.e., waves. Figure 3 shows four examples of the basis functions for the CWT, using a modulated Gaussian windowing function and mother wavelet:

$$g(t) = e^{-t^2} e^{2\pi i f_0 t}$$

The above mother wavelet is generally referred to as the Morlet wavelet, where f_0 is a user-defined parameter. From Figure 3 one can see that the duration of the basis functions reduces, and the bandwidth increases, for the high-frequency components (small values of a). This is in contrast to the STFT basis functions (Figure 2) whose shape changes with frequency (the number of oscillations in the elementary functions increases with frequency) but the duration of the STFT basis functions is constant. This different

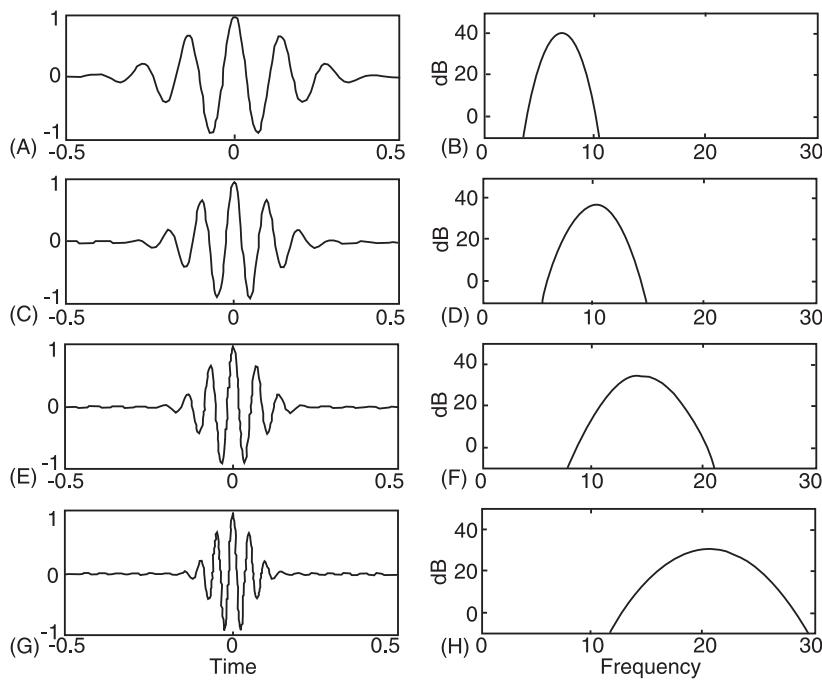

Figure 3 Basis functions for the continuous wavelet transforms.

behavior of the STFT and CWT basis functions gives rise to the different characteristics of the two methods.

As the CWT basis functions reduce in duration, their bandwidth necessarily increases. A consequence of this is that both the temporal and frequency resolution of the CWT vary with a . Specifically at small scales (high frequencies) the basis functions are short in duration and have wide bandwidths, leading to good temporal resolution but poor frequency resolution, whereas at large scales (low frequencies) the basis functions are long in duration and have narrow bandwidths, leading to poor temporal resolution but good frequency resolution.

The link between scale and frequency becomes explicit if one considers mother wavelets of the following form:

$$g(t) = w(t)e^{2\pi i f_o t} \quad [13]$$

where, as before, $w(t)$ is a windowing function, i.e., a nonoscillating function. The elementary functions for the CWT can then be expressed as:

$$\Psi_w(t, a) = w(t/a)e^{2\pi i (f_o/a)t}$$

In this form it is apparent that a particular value of a corresponds to frequency f according to:

$$f = f_o/a$$

Under these conditions the CWT can be truly regarded as a time-frequency representation. As discussed, the CWT has nonuniform resolution over the time-frequency plane, in contrast to the STFT where the resolution is uniform.

Like the STFT, the CWT can be interpreted as the output of a filter bank. This observation can be drawn from [8] that represents a series of convolutions. The filter bank implied by a CWT uses filters that do not have constant bandwidth but instead have constant percentage bandwidths (constant Q). Such a filter bank has a constant number of filters within an octave, for example a third-octave filter bank uses three filters to span each octave.

Figure 4 shows the CWT computed for the test signal shown in **Figure 1A**. The good-frequency resolution of the CWT at low frequencies ensures that the tonal component is well resolved, whilst the impulse, which contains all frequencies, is well localized (in time) within the high-frequency region. As has been demonstrated, the STFT cannot well resolve both components of this signal simultaneously. The best that can be achieved by the STFT is a compromise, such as that seen in **Figure 1C**.

The variable resolution of the CWT is well matched to the signal in the first example, allowing good resolution of both components simultaneously. This variable resolution is a fundamental difference between the CWT and the STFT. However, it should be emphasized that the CWT is subject to the same

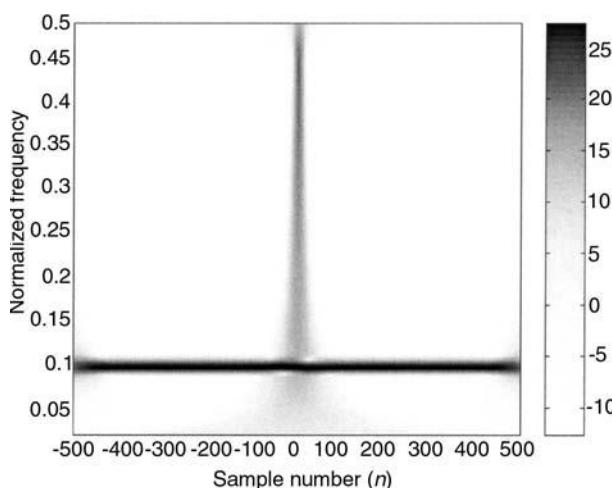

Figure 4 Continuous wavelet transform of test signal depicted in Figure 1A.

fundamental resolution limitations as the STFT, namely the uncertainty principle. One cannot reasonably claim that the CWT has better resolution than the STFT in any meaningful sense; it merely trades time and frequency resolution in a different manner to the STFT.

The CWT, computed for a second test signal, is depicted in Figure 5. The signal analyzed in this case is:

$$x(n) = \sin(2\pi n 4/11) + 5\delta(n)$$

$$n \in [-512, 512]$$

This second signal is the same as the original test signal, except that the narrow-band component has a much higher center frequency. Figure 5 shows the CWT computed using the same parameters used to compute the distribution shown in Figure 4. The tonal component exists in a frequency band where the CWT's frequency resolution is poor. The impulse's major contribution lies in the lower-frequency bands, where the temporal resolution is comparatively poor. Consequently, for this signal the CWT is poorly matched to the signal's character and the resulting distribution is a relatively poor representation of the signal.

The two examples in Figures 4 and 5 emphasize that the CWT is not a panacea, but for signals of suitable types the CWT offers definite advantages over the STFT. It is apparent that if a signal contains long-duration, low-frequency components, in conjunction with short-duration, high-frequency components, then the CWT is an advantageous tool. Many naturally occurring signals containing the high-frequency components decay more rapidly

than the low frequencies, in which case the CWT should be considered.

Sampling of Distributions

The STFT and CWT, as presented so far, are formulated in terms of continuous functions. They represent mappings of a one-dimensional continuous signal into a two-dimensional continuous domain. A practical algorithm for implementation on a digital computer must define a transformation that maps a sampled time series to a series of points in the two-dimensional space. There are two distinct sampling issues to be addressed. The first relates to the fact that the signal to be analyzed is sampled. The second considers the effect of evaluating the distributions on a discrete set of points, i.e., the sampling of the distributions.

The issues associated with the fact that the signal is sampled rather than continuous mirror those issues encountered when considering the interrelationship between the Fourier transforms of sampled and unsampled time-series. Specifically, if one assumes that there is no aliasing introduced by the sampling process, then the distributions can be discretized in a direct manner and the results so obtained agree in the frequency range 0 to $f_s/2$ (f_s being the sampling frequency).

The operation of sampling the distributions in two-dimensional space (time-frequency or time-scale) introduces a raft of new theoretical considerations. The points at which the distributions are evaluated are called the sampling grid (or lattice). The issues associated with this sampling process for the STFT and CWT are subtly different and two different forms of grid are used. In the following sections we shall continue to assume a continuous time signal, $x(t)$,

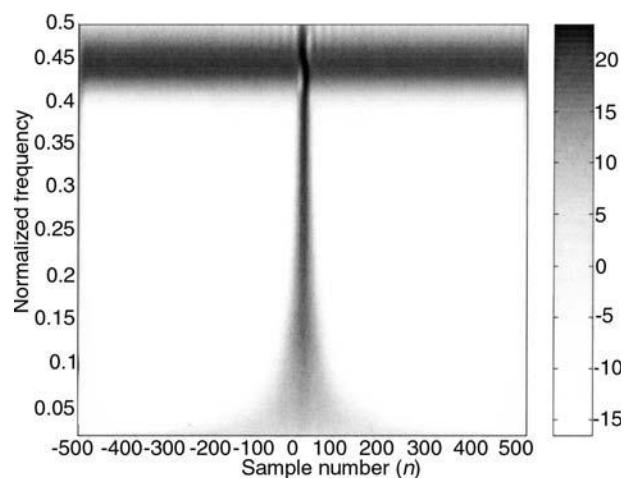

Figure 5 Continuous wavelet transform of second test signal.

and concentrate on the problems associated with sampling the distributions.

Sampling the STFT

When sampling the STFT it is conventional to use a regular sampling grid, i.e., a grid in which the sampling intervals in time and frequency are constant. This reflects the fact that the STFT has constant resolution in the time–frequency plane. Use of such a regular grid leads to the sampled STFT, $S(n, k)$, being defined as:

$$\begin{aligned} S(n, k) &= S(t, f)|_{t=n\Delta t, f=k\Delta f} \\ &= \int x(\tau)w(\tau - n\Delta t)e^{-2\pi i(\tau - n\Delta t)k\Delta f}d\tau \\ &= \int x(\tau)\Psi_{n,k}(\tau)^*d\tau \\ \Psi_{n,k}(\tau) &= w(t - n\Delta t)e^{2\pi i(t - n\Delta t)k\Delta f} \end{aligned}$$

where Δt and Δf are the sampling intervals in time and frequency respectively; the appropriate sampling grid is illustrated in Figure 6A. The functions $\Psi_{n,k}(t)$ form a set of functions referenced by the double index n, k .

It is natural to question whether one can continue to recover the original time series from the sampled STFT, $S(n, k)$. It is unsurprising to learn that, for fine grids, i.e., grids for which Δt and Δf are small, then signal reconstruction is possible. Clearly, if one can reconstruct a signal from a sampled STFT, then the STFT represents the signal and one can be reassured that there has been no loss of information in the transformation.

One can show that for reconstruction to be possible then the grid must be such that:

$$\Delta t\Delta f \leq 1$$

An obvious implication of this is that the coarsest possible grid that can be used to sample an STFT without losing information is one for which $\Delta t\Delta f = 1$: such grids are referred to as Von Neumann grids. These grids are attractive since they capture the full information contained within a signal with no redundancy. One subclass of such representations occurs when the windowing function and grid are selected so that the functions $\Psi_{n,k}(t)$ are orthonormal, so that:

$$\begin{aligned} \int \Psi_{n,p}(t)\Psi_{m,q}(t)^*dt &= 1 \quad m = n \quad \text{and} \quad p = q \\ &= 0 \quad \text{elsewhere} \end{aligned}$$

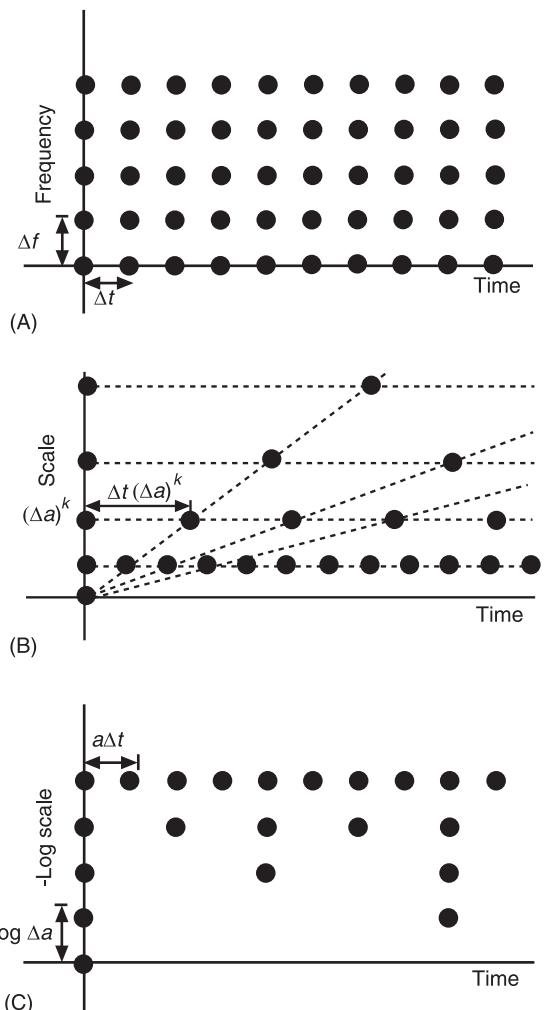

Figure 6 Sampling grids for (A) short-time Fourier transform; (B) continuous wavelet transform; (C) continuous wavelet transform grid plotted with an inverted logarithmic scale axis.

In which case one can readily show that:

$$x(t) = \sum_k \sum_n S(n, k)\Psi_{n,k}(t)$$

This formula readily allows one to interpret the sampled STFT values as the coefficients of an expansion of the signal in terms of the functions $\Psi_{n,k}(t)$. It is necessary to employ a Von Neumann grid to obtain an orthonormal decomposition. The condition of orthonormality can be relaxed using the concept of a frame, which provides the appropriate framework for analyzing such decompositions.

There is a fundamental limitation encountered when using the STFT. If a Von Neumann grid is used to sample a STFT, then the Balian–Low theorem

states that the window $w(t)$ must be poorly localized in either time or frequency. This implies that nonredundant STFT representations are incapable of yielding good simultaneous time–frequency localization. This point can be illustrated through a simple example.

Consider the STFT computed using a rectangular window, $w(t)$, with no overlapping, so that $\Delta t = T$, where T is the window's duration. The Fourier transform of the data within each window is evaluated using a sampling interval $\Delta f = 1/T$. For a digital signal, $x(n)$, this is trivial to implement using a fast Fourier transform. Clearly, this scheme employs a Von Neumann grid since $\Delta t \Delta f = 1$ and the basis functions $\Psi_{n,k}(t)$ can be shown to be orthonormal. The window $w(t)$ does have good time-localizing properties (since it has finite support), but its Fourier transform, which is a sinc function, decays very slowly in frequency and (mathematically at least) fails to give good frequency localization. This is one example that verifies the Balian–Low theorem.

Sampling the CWT

To implement a CWT, one again needs to sample it on a grid. However, in this case it is conventional to select a nonuniform grid structure. The sampling scheme almost universally employed is:

$$a_k = (\Delta a)^k \quad t_{n,k} = n\Delta t a_k = n\Delta t (\Delta a)^k$$

where Δa is the geometric scale increment and Δt is the time increment at scale $a = 1$. This scheme ensures that there are a fixed number of scales in each octave, referred to as voices. The fact that at each scale (frequency) the temporal resolution is different means that it is appropriate to adopt a scale-dependent time increment. The time increments become smaller at higher frequencies (smaller values of a). Such a sampling grid is depicted in Figure 6B. Note that the points on this grid lie on lines that pass through the origin, reflecting the affine nature of the transformation. Figure 6C depicts the same grid, but using an inverted logarithmic axis to represent scale. Such an axis is akin to a logarithmic frequency axis; this allows one to interpret the way in which the sampling occurs in the time–frequency plane.

Using such a grid, the discretized form of the CWT is:

$$\begin{aligned} W(n, k) &= W(t, a)|_{a=a_k, t=t_{n,k}} \\ &= \frac{1}{(\Delta a)^{k/2}} \int g^* \left(n\Delta t - \frac{t}{(\Delta a)^k} \right) x(\tau) d\tau \end{aligned}$$

Like the STFT, the sampled CWT can be inverted, assuming that a sufficiently fine grid is used. However, unlike the STFT, there is no absolute limit on the values of Δa and Δt . This is in part a consequence of the fact that the base scale used to define the mother wavelet, i.e., the scale that corresponds to $a = 1$, is selected arbitrarily. This problem can be overcome by specifying the original scale of the mother wavelet. Even under these conditions there still remains no equivalent of a Von Neumann grid, i.e., a grid size that demarks the boundary between grids upon which reconstruction can and cannot occur.

The most significant theoretical advantage offered by WTs over the STFT is the fact that one can construct nonredundant wavelet transforms that are truly localized in time and frequency. (Recall that the Balian–Low theorem precludes the possibility of such STFT representations.) These nonredundant representations usually employ grids in which $\Delta a = 2$ and $\Delta t = 1$, termed a dyadic grid, with the mother wavelet scaled to suit the user.

Discrete Wavelet Transforms

A discrete wavelet transform (DWT) is, normally, defined as a nonredundant sampled CWT. The DWT aims to represent a discrete time series, $x(n)$, as a set of (wavelet) coefficients. These coefficients are sampled from a CWT, usually in a manner to yield an orthogonal (or biorthogonal) set of basis functions. There is a wealth of DWT formulations, with differing characteristics. In this section attention is restricted to the case of orthogonal wavelets with finite support.

The use of orthogonal bases ensures that the representation is nonredundant. In general, the use of orthogonal representations leads to simple algorithms for both reconstruction and decomposition. Efficient DWT algorithms exist that require computational loads that are often less than that needed to implement a fast Fourier transform.

There are several equivalent viewpoints from which the DWT can be regarded. Here we choose to discuss the DWT through the concept of a filter bank. A pair of finite impulse response (FIR) filters, with L coefficients, are defined. One of these filters is a high-pass filter, whilst the second is low-pass; both filters cut on/off at half the sampling frequency. The DWT can be defined using these filters and applying them recursively. The filters are first applied to the input time series to yield low-pass and high-pass components, $x_1(n)$ and $x_2(n)$ respectively:

$$x_1(n) = \sum_{k=0}^{L-1} c_k x(n-k)$$

$$x_2(n) = \sum_{k=0}^{L-1} d_k x(n-k)$$

where c_k and d_k are the coefficients of the low-pass and high-pass filters. It is normal to construct the high-pass filter based on the low-pass filter, which is commonly achieved using the alternating flip scheme, so that the two sets of filter coefficients are related through:

$$d_k = (-1)^k c_{L-k}$$

The output of both filters is half the bandwidth of the input sequence, such that $x_1(n)$ occupies the lower frequency range and $x_2(n)$ the upper band. The outputs of each of the filters is half the original bandwidth of $x(n)$, so that these two time series contain redundant information. One can subsample the two filter outputs to half the original sampling rate. The subsampling is achieved by discarding alternate samples in each sequence. Such a resampling means that both signals once again occupy the full bandwidth. Because of the imperfect design of the two FIR filters, the action of resampling introduces aliasing to both components.

To counter the artefacts introduced by aliasing, one can design the two filters so that the two aliasing effects cancel. If the filters are designed to ensure that aliasing cancellation occurs, then it is possible to reconstruct the original signal from the two subsampled sequences. The recovery of the original input sequence from the two subsampled sequences is realized by up-sampling the two subsampled signals, filtering them, and then summing the two components. For an orthogonal WT, using FIR filters, the synthesis filters are the same as those used for decomposition, but with the impulse responses reversed in time. The process of decomposing a signal into two subsampled sequences and then reconstructing the original signal is depicted in Figure 7A. Throughout Figure 7 the symbols 2 and 2 are used to denote up and down sampling and $H_1(z)$ and $H_2(z)$ are the transfer functions of the low-pass and high-pass decomposition filters respectively, with $H_3(z)$ and $H_4(z)$ being the transfer functions of the corresponding synthesis filters.

The scheme shown in Figure 7A represents the basic building block of a wavelet filter bank. These elements are applied in a tree structure. Having applied the filtering and subsampling to the original time series to generate low- and high-frequency

components, the operation can then be repeated on either of the new components. Most commonly one decomposes only the low-frequency (large-scale) component. This form of scheme is depicted in Figure 7B.

Every stage of the decomposition of the input sequence results in two sequences, each of which is half the length of the original sequence. Hence each stage of the decomposition preserves the total number of data points. The final result of the decomposition, indicated on the right side of Figure 7B, consists of N wavelet coefficients, which are a representation of the original N point input sequence (N is assumed here to be a power of 2). The N wavelet coefficients comprise $N/2$ coefficients at the smallest scale, $N/4$ coefficients at the next scale, etc. and at the largest scale there are two single values. If one considers the total number of coefficients required, namely $N/2, N/4 \dots 2, 1$ and 1 additional coefficient then it is straightforward to show that this gives an overall total of N coefficients.

Reconstruction of the time series from the wavelet coefficients proceeds using the reverse of the decomposition procedure. This reconstruction is illustrated in Figure 7C. At each stage two signals are up-sampled, filtered, and then summed.

The above derivation of the DWT hides the basis functions that are used in the DWT. These functions are completely specified by the choice of FIR filters. In fact, the basis functions are the solution of a dilation equation, the coefficients of which are the filter coefficients. The solutions of these dilation equations may have undesirable properties, for example, they may be fractal. In a reasonable decomposition one would like these orthogonal basis functions to be well behaved, at least being smooth to some extent. This effectively imposes additional constraints to the filter design procedure.

The basis functions that result from the design operation may be rather unnatural-looking (for example, they cannot, in general, be expressed in the form of eqn [13]), but do have powerful mathematical properties. Figure 8 shows three examples of such basis functions for a common class of DWT. This family of wavelets is known as the Daubechies wavelets. The three wavelets shown correspond to different choices of filter length L . The higher-order filters also correspond to basis functions that are more smooth, so they decay more rapidly in the frequency domain. The Daubechies wavelets are designed to have compact support, so, in the time domain, they are zero outside a finite region. The frequency domain representations for these basis functions show that the basis functions are essentially band-pass in character, but they possess relatively

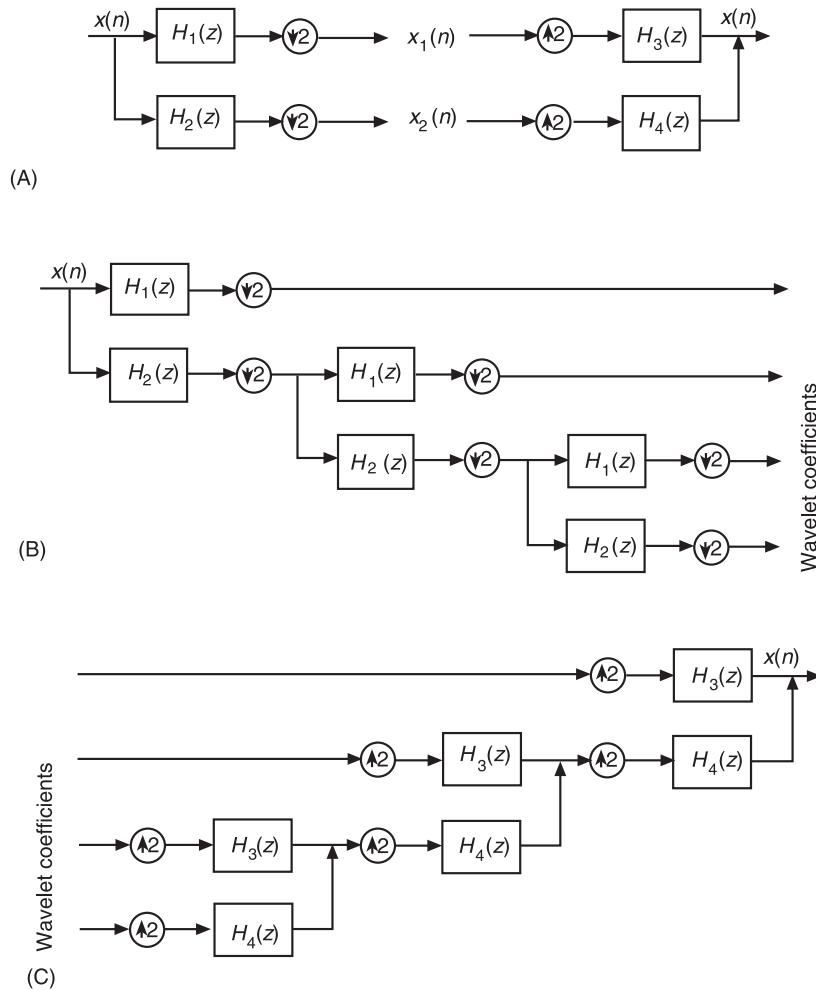

Figure 7 Filter bank implementation of a wavelet transform.

large sidelobes. This reflects the fact that the wavelet functions are designed to satisfy conditions that relate to regularity rather than classical filter design criteria.

Comparison of DWTs and CWTs

The choice of which of the two basic classes of wavelet transform to use is critically application-dependent. The critical difference between the two approaches is that the DWT is nonredundant. It completely represents the time series $x(n)$ using only as many coefficients as were present in the original signal. The CWT, as defined by eqn [7], is a continuous representation. However, it is conventional to use the term CWT to describe wavelet representations computed using a fine grid, so that the WT is greatly oversampled. (We avoid considering cases where the WT is mildly oversampled and neither of the terms DWT or CWT is really appropriate.) In this section the term CWT is understood to refer to such oversampled WTs, in which case the DWT has the

obvious advantage of using a representation that employs the minimum number of coefficients, resulting in large computational savings over the CWT. Further, it is intuitively appropriate to employ such a minimalist representation of a signal when considering data compression applications.

This computational advantage is gained at some cost. The DWT fails to retain some of the most attractive properties of the CWT, namely its invariance to time and scale shifts, as described above. The loss of these two properties is a direct consequence of the sampling of the CWT that is undertaken to form the DWT. Indeed, the appearance of a lack of shift invariance similarly occurs when one samples the STFT. In both cases these invariances are lost as a result of the coarseness of the sampling of the representation relative to the sampling of the original time series. So, the loss of shift invariance is not a function of the underlying transform but is a consequence of one's choice of using a nonredundant representation.

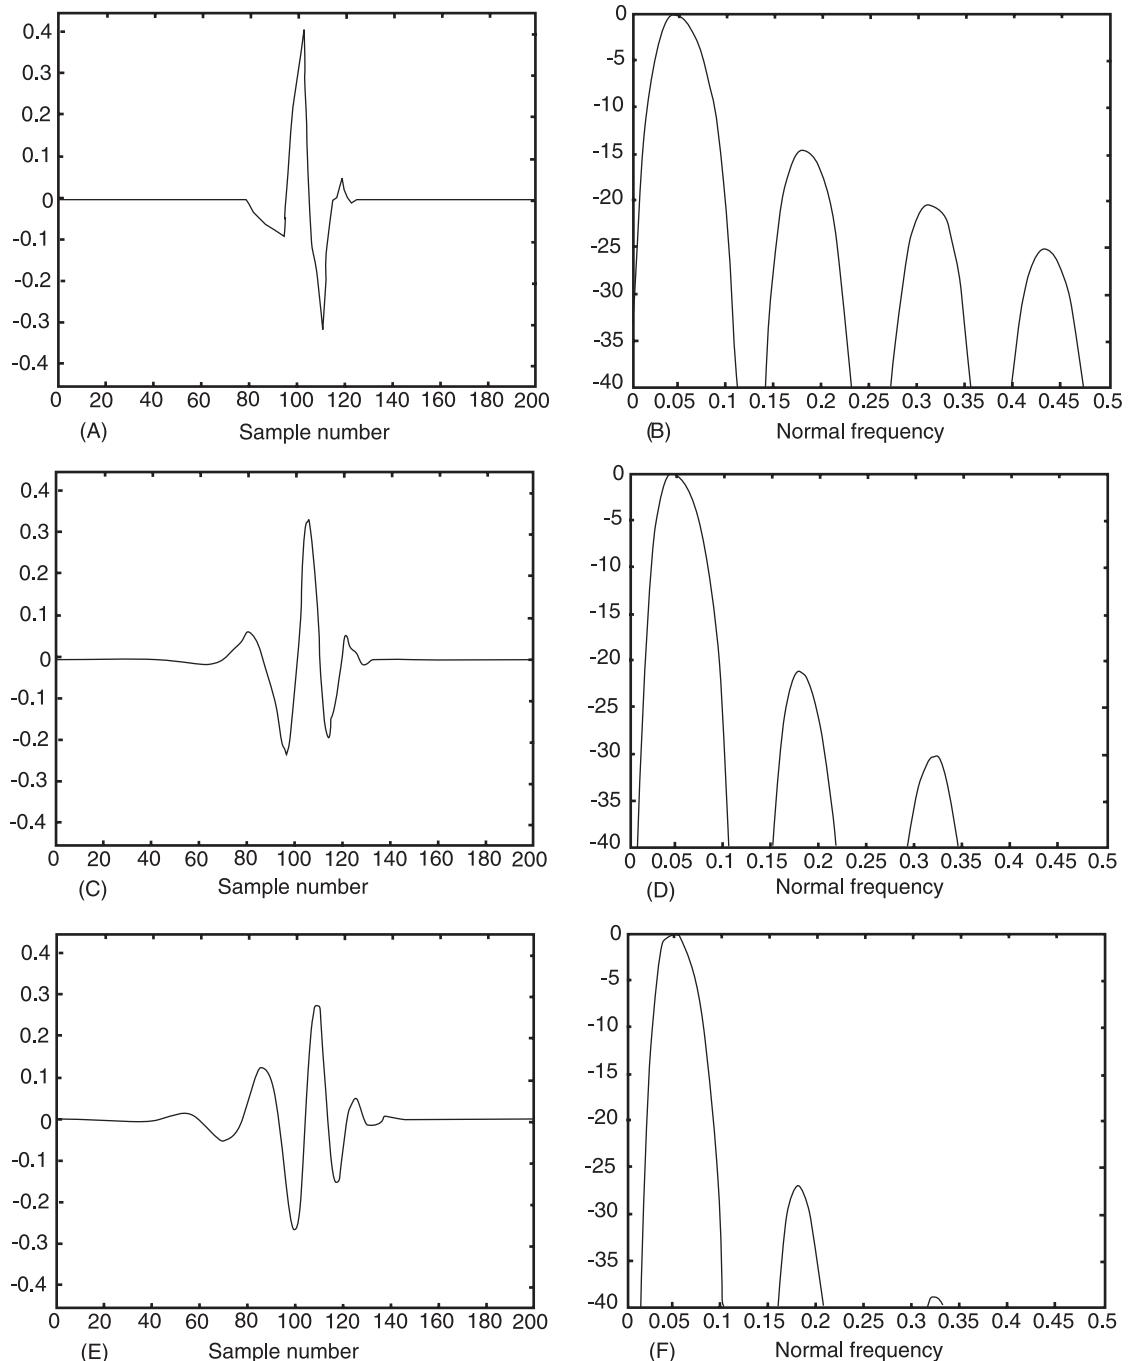

Figure 8 Examples of basis functions used in discrete wavelet transforms. (A), (C), and (E) Daubechies wavelets in the time domain using $L = 4, 8$, and 12 respectively. (B), (D), and (F) Daubechies wavelets in the frequency domain using $L = 4, 8$, and 12 respectively.

Figures 9 and 10 illustrate lack of shift invariance in the DWT for a simple signal, specifically a cosine wave modulated by a Gaussian window. In both these figures the DWTs, shown in the right-hand frames, are displayed using the same convention. Time is depicted on the horizontal axis. The vertical

axis is linear in scale. Large scales (low frequencies) are depicted towards the bottom of the graph and are given small arguments. For each scale the same number of time points are shown (128 in this case), even though there are fewer different coefficients at the larger scales. For example, at scale 1 there

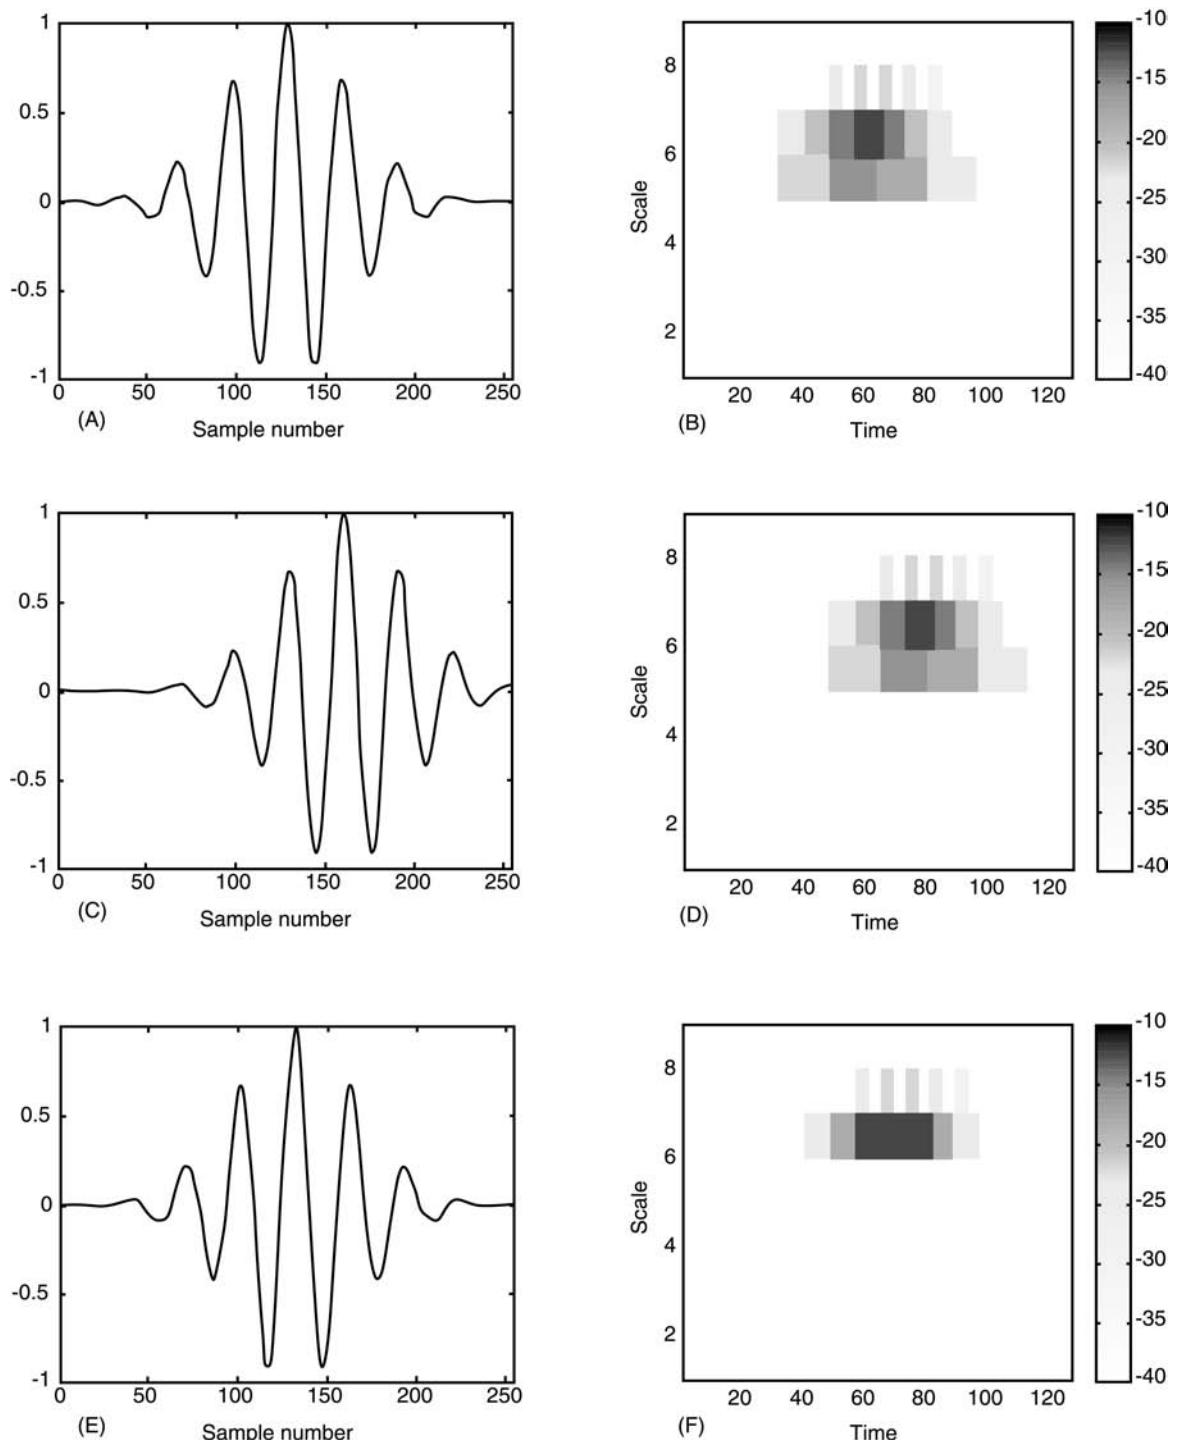

Figure 9 Discrete wavelet transform (DWT) of a Gaussian pulse with various time shifts. (A) Time series of the Gaussian pulse; (B) DWT of signal in (A); (C) Gaussian pulse shifted by 32 samples; (D) DWT of signal in (C); (E) Gaussian pulse shifted by four samples; (F) DWT of signal in (E).

is only one coefficient. To generate the DWT plots this value is repeated 128 times, at scale 2 there are two values, each repeated 64 times. The values plotted are the absolute values of the DWT coefficients on a logarithmic scale. Throughout these exam-

ples a Daubechies wavelet based on a filter of length 4 is used.

Figure 9A shows the time series of the Gaussian pulse. Its DWT, Figure 9B, shows that the majority of the energy in this signal is in scales 5 and 6 and

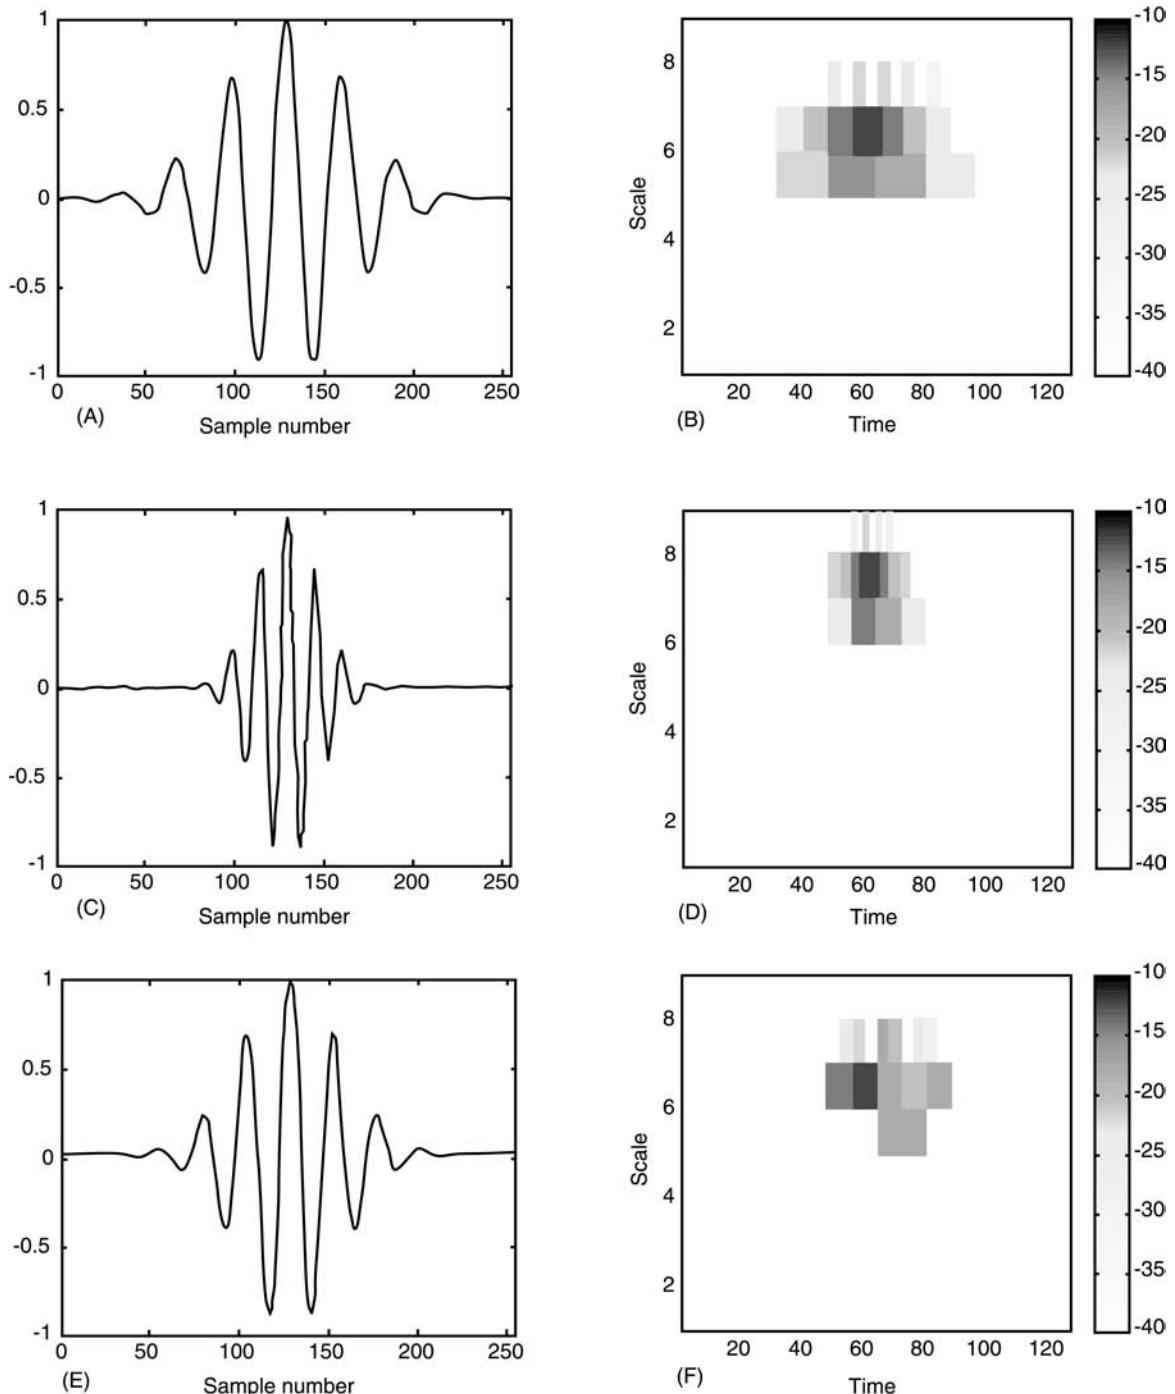

Figure 10 Discrete wavelet transform (DWT) of a Gaussian pulse with various scale shifts. (A) Time series of the Gaussian pulse; (B) DWT of signal in (A); (C) Gaussian pulse compressed by a factor of 2; (D) DWT of signal in (C); (E) Gaussian pulse compressed by a factor of $2^{1/3}$; (F) DWT of signal in (E).

centered close to 64 samples on the time axis. Figure 9C shows this signal shifted by 32 samples in time. The DWT coefficients correspondingly shift, as can be seen in Figure 9D. The two representations shown in Figure 9B and 9D behave according to intuition; specifically a shift time in the signal results

in a shift in time of the DWT coefficients. This result is fortuitous and only comes about through careful selection of the time shift. If one shifts the time signal by four samples, as shown in Figure 9E, the DWT, Figure 9F, changes significantly; almost all of the energy vanishes from scale 5. The two DWTs in

Figure 9B and **9D** give the impression of having arisen from very different signals, rather than two signals that are translated versions of each other. This variability in the DWT coefficients with respect to the origin of a signal makes them difficult to use for the purposes of signal interpretation.

A similar effect arises when one considers signals that are related to each other in scale. This is shown in **Figure 10**. The top two frames are identical to those in **Figure 9**. **Figure 10C** shows the effect of compressing the signal by a factor of 2. The corresponding DWT coefficients shift up one level scale, as shown in **Figure 10D**. The manner in which these plots are constructed tends to make the DWTs look more disparate than is appropriate. The coefficients shown in **Figures 10B** and **10D** are the same but they are only translated up one scale bin. **Figure 10E** shows the effect of compressing by $2^{1/3}$ (a third octave); like the time shifts, this serves to alter the character of the DWT coefficients rather than only to shift them.

The lack of shift invariance in the DWT is due to the fact that it is a CWT computed on a coarse grid. Using a finer grid results in a WT that is more robust to shifts in time and/or scale. To avoid the problem of shift invariance in time, one can implement the DWT but omit the subsampling operations. This results in a representation which is nonredundant, there being as many coefficients for each scale as there is in the original time series. Such schemes are still poorly suited for the purposes of signal interpretation. Their sampling time is as fine as is possible, but their sampling in scale is maximally coarse. It is better to construct a WT in which the oversampling occurs in both time and scale, rather than in only one domain; such a scheme is a CWT.

If the user opts to use a WT that is nonredundant, using a grid that is finer than a dyadic grid, then there seems little advantage to using DWT basis functions. One should select a mother wavelet that in some sense matches the signal being analyzed, or in the absence of such *a priori* knowledge one should use a wavelet that is well localized in the time-scale plane. This leads one commonly to use a Morlet wavelet which satisfies the uncertainty principle: which is the wavelet with the smallest area in the time–frequency plane.

Results

To illustrate the performance of WTs we present an analysis of structural response data. The data set used represents the impulse response of a beam with a semianechoic termination at one end; for details of the experimental procedure see *Transforms: Time-Frequency*. **Figure 11** shows the time series to be analyzed; this consists of two distinct wave packets:

the first corresponding to the arrival of energy without reflection, the second derives from energy reflected from the beam's free end. The second pulse, having travelled further than the first, undergoes a greater degree of dispersion.

Figure 12 shows various representations of this signal. In each case the parameters defining the representations have been selected so that the results produce the most visually appealing representation. The scalogram (the squared magnitude of the CWT) is depicted in **Figure 7A**. The two pulses are clearly discernible and individual characteristics can be seen. For comparison the spectrogram (the squared magnitude of the STFT) is plotted in **Figure 7B**. For this signal the CWT and STFT are relatively similar. The greater temporal resolution at high frequencies offered by the CWT allows one to identify more accurately the onset of each component, whereas the loss of temporal resolution in the CWT at low frequencies makes it harder to distinguish the frequency laws for each component below, say, 1 kHz. **Figure 7C** shows the DWT computed using a 6 coefficient Daubechies wavelet. This figure is plotted using the convention used in **Figures 9** and **10**, except that the vertical axis is transformed to represent frequency rather than scale. A comparison of **Figures 7A** and **7C** shows that DWT produces plots in which the underlying dynamics of a system are not revealed as clearly as the CWT.

Conclusion

The CWT and STFT offer complementary approaches to the decomposition of a signal. The CWT is based on the operations of time shifts and

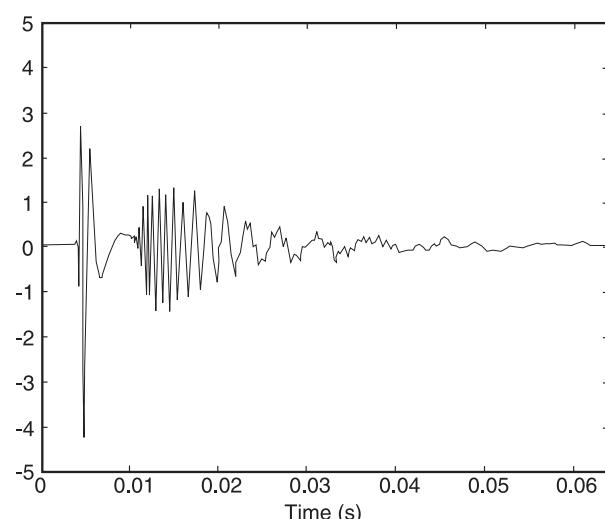

Figure 11 Beam impulse response data.

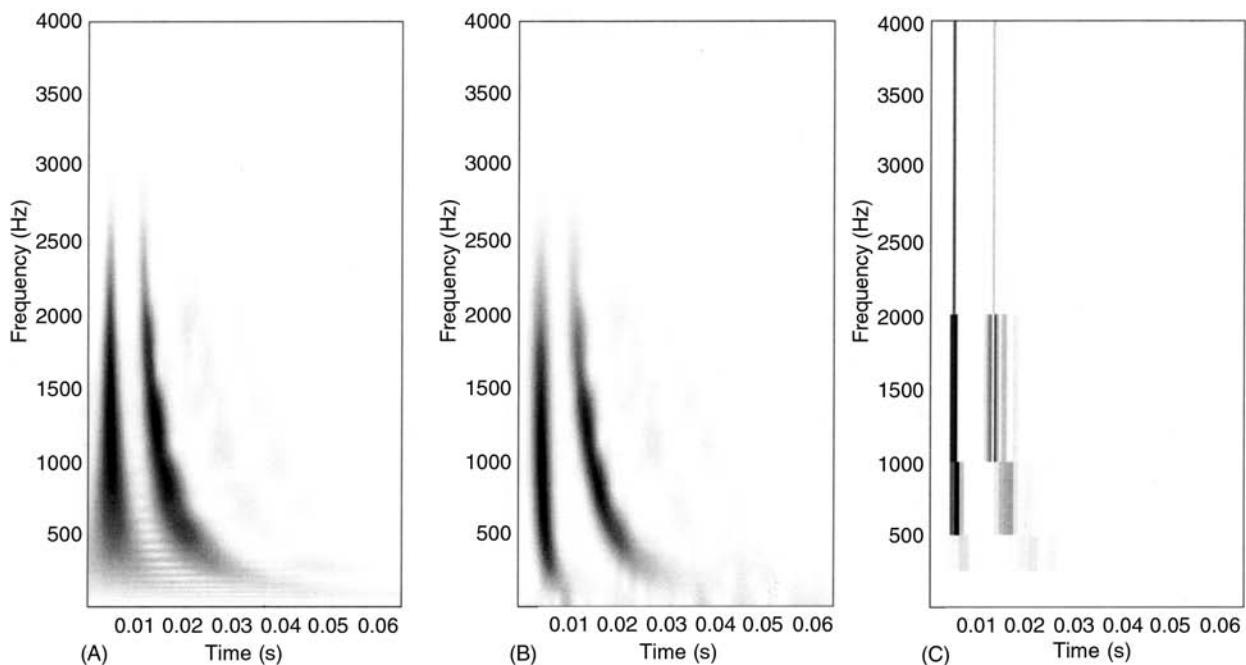

Figure 12 Time scale and time frequency representations for beam impulse response data. (A) Continuous wavelet transform; (B) short-time frequency transformation; (C) discrete wavelet transform.

temporal scalings, whilst the STFT exploits time and frequency shifts. The essential difference between the two approaches is that the time and frequency resolution in the STFT is uniform in the time–frequency plane. This is in contrast to the CWT. The CWT exploits variable resolution, has good temporal resolution in the high-frequency bands and good frequency resolution in the low-frequency bands. This makes them well suited to many classes of naturally occurring signals.

The DWT offers a nonredundant representation, which is not intended for visual inspection. It is a powerful and efficient tool in many applications, e.g., signal compression. However, its nonredundant nature makes it poorly suited to applications where one seeks to represent a signal in a manner that clearly exposes its underlying nonstationary structure.

Nomenclature

a	scale
f	frequency
f_s	sampling frequency
$G(f)$	Fourier transform of $g(t)$
$\tilde{G}(f)$	Fourier transform of $\tilde{g}(t)$
$S(t, f)$	Short-time Fourier transform
$x(t)$	continuous time signal
$w(t)$	windowing function
$\delta(n)$	Kronecker delta function

Δf sampling intervals in frequency
 Δt sampling intervals in time

Definition of Ultrasonics

Ultrasonics is a name given to various specific topics in which the properties of ultrasound are exploited. Ultrasound is simply sound whose frequency is too high to be heard by the human ear, that is to say the frequency is above c 20 kHz. At the top end of the scale, ultrasound is used at frequencies up to several GHz. Ultrasound waves are characterized by elastic oscillations of the material in which they travel, that is, they are essentially traveling vibrations. This entry gives a brief introduction to the physics of ultrasound, and the concepts underlying some of its applications in fields of engineering.

Essential Features of Ultrasound

Sound travels in the form of a wave, involving the elastic straining of the material in which it travels, so the properties of the sound depend on the properties of the material. In the simple case of sound traveling in air, or indeed in any gas or fluid, the air is compressed and dilated as the wave passes through; the properties of the wave then depend on the compression stiffness and the density of the air. Elastic waves also travel in solid materials, in which case they are still commonly known by the names sound or ultrasound. Two different possible forms may propagate in solids. There are compression (or longitudinal) waves, which are essentially the same as those in gases or fluids, but there are also shear (or transverse) waves, in which the volume of the material does not change; instead the motion is at right angles to the direction of propagation and consists of shear deformation of the material (see **Wave propagation, Waves in an unbounded medium**). In brief, the velocities of the waves in elastic materials are given by, in a fluid or gas:

$$C_L = \text{compression wave speed} = \left(\frac{K}{\rho} \right)^{1/2} \quad [1]$$

in a solid:

$$C_L = \text{compression wave speed} = \left[\frac{E(1-v)}{\rho(1+v)(1-2v)} \right]^{1/2} \quad [2]$$

$$C_S = \text{shear wave speed} = \left[\frac{E}{2\rho(1+v)} \right]^{1/2} \quad [3]$$

where K is the bulk stiffness modulus of the fluid or gas, ρ is the density, E is Young's modulus, and v is Poisson's ratio. The velocities of sound wave propagation in a material are thus properties of the material, and in these relationships it can be seen that there is no variation of the velocities with frequency. Values of the acoustic properties for some materials are given in Table 1.

The propagation of a sound wave is described by a harmonic function, usually expressed as a complex exponential. For example, the particle displacement, u , the particle velocity, v , and the pressure, σ , of a compression wave traveling in the X direction can be described by:

$$u_X = A e^{i(kx - \omega t)} \quad [4]$$

$$v_X = i\omega u_X \quad [5]$$

$$\sigma_{XX} = i\omega C \rho u_X = C \rho v_X \quad [6]$$

A is the displacement amplitude of the wave, C is the wave velocity and k is the wavenumber, defined as:

$$k = \frac{\omega}{C} = \frac{2\pi}{\lambda}$$

and:

$$\lambda = \text{wavelength} = \frac{C}{\text{Freq(Hz)}} = \frac{2\pi C}{\omega} \quad [7]$$

The complex exponent in eqn [4] describes the characteristic space-time harmonic nature of the wave: the wave varies sinusoidally in both distance and time. Eqn [6] shows that, for a given amplitude of the particle displacement, the pressure in the wave increases linearly with the frequency, ω . Therefore when comparing low-frequency and high-frequency waves, one may think of the former as being displacement-dominated and the latter as being pressure-dominated. The relationships between the displacement, velocity, and pressure also include the material constants ρ and C ; their product, ρC , often appears in wave theory and is known as the acoustic impedance, conventionally represented by the symbol Z . Solid materials have two acoustic impedances, one for compression waves and one for shear waves, although references often give only one value, that for the compression waves.

The wavelengths of ultrasonic waves cover an enormous range. At the low-frequency end of the scale, 20 kHz, the wavelength in air is 17 mm, and in steel

the wavelength of longitudinal waves is 300 mm. At 1 GHz, the wavelength in steel is just 6 μm .

Sound waves carry energy along their direction of propagation, and in the case of elastic waves the energy is transported at the same velocity as the wave. The energy transmission is often expressed by the intensity of the wave. The intensity is the quantity of energy which is propagated per second per unit cross-sectional area, where the cross-section is taken normal to the direction of propagation. The intensity is:

$$I = \overline{\sigma_{XX}}\overline{v}_X = \frac{\rho Cv_X^2}{2} = \frac{\sigma_{XX}^2}{2\rho C} \quad [8]$$

in which the overscore denotes the root mean square (RMS) value of the quantity. Thus, the propagation of the energy is determined by the acoustic impedance and the square of the particle velocity or stress.

Ultrasound waves are affected on arrival at any discontinuity of the material, including any change of the material properties of the medium. For example, they partially reflect and partially transmit at an

interface between two materials. The relative strengths of the reflected and transmitted components depend on the acoustic impedances of the two materials. If there are voids in a material, or there are small inclusions of another material, then the ultrasound is again partially reflected and partially transmitted and is also in general scattered in other directions. These properties are exploited in ultrasonic nondestructive testing (NDT) for the detection of voids and cracks (see **Wave propagation**, **Interaction of waves with boundaries**).

The assumption that the material is perfectly elastic is not strictly correct. All materials exhibit some sound-attenuating properties, including absorption (hysteresis) and scattering from small inhomogeneities. However, this assumption is practically realistic for many engineering materials; the attenuation effects are usually sufficiently small that they can be ignored in the calculation of the propagation and interaction phenomena. When the attenuation is significant, then it can fundamentally affect the nature of the propagation. For example, the velocity of a material may then be frequency-dependent (this is called dispersion), and the energy may be propagated at a different speed from that of the wave fronts.

Ultrasound in Engineering

Ultrasound is used in very many devices and applications in engineering. The following paragraphs give summary descriptions of some of the topics and concepts which are employed.

Nondestructive Testing

The principle of ultrasonic NDT is to transmit a wave signal into a structure, and then to detect defects by receiving and examining subsequent signals. A common configuration ('pulse-echo') is to position a transducer on one side of the structure, to transmit a signal into the structure, and then to receive reflections using the same transducer. If defects are present, then sound is reflected from the defects. Most ultrasonic testing is done using compression waves, although there are techniques which use shear waves and others which use structure-guided waves. An important example of the use of shear waves is the inspection of welds: in this, a shear wave is projected at an oblique angle into the material in order to detect cracks which are aligned normal to the surface; these would not be seen by a wave which was projected normal to the surface of the material. Ultrasonic NDT is very widely used; it is very sensitive to defects whilst being totally insensitive to the parts of the structure

which are remote from the test location and to the support conditions.

Imaging

Ultrasound reflection or transmission measurements are used for imaging in a number of application areas. In NDT, two-dimensional maps, or C-scans are created by scanning a transducer in a raster sequence over an area of a structure. The intensity of the reflected or transmitted signal at each location is used to set the color on the image, thereby producing a map of any defective areas. Tomographic three-dimensional images, constructed by processing multiple transmitted signals, may also be generated, but this is rarely done in NDT. Ultrasound scanning is of course a routine procedure in medical diagnostic imaging, using advanced signal-processing procedures to enhance the contrast and resolution. Another area of imaging is acoustic microscopy. The acoustic microscope uses a sharply focused transducer, both sending and receiving the signal, operating at high frequencies (from 100 MHz to more than 1 GHz) to scan the surface of an object. The scans can reveal detailed information about the surface and the material just below the surface.

Cleaning

Ultrasonic cleaners use high-power ultrasound to remove grease and dirt from the surfaces of materials. It is not difficult, particularly at the low-frequency end of the ultrasonic range, to generate ultrasonic waves whose oscillating pressure is sufficiently large to create cavitation in a fluid. The growth and collapse of cavities occurs very rapidly, during which time enormous local pressure transients take place. Applied next to a surface, these have the effect of dislodging the dirt and, indeed, if sustained, can damage the material itself.

Measurement of Material Properties

The speed of ultrasonic waves can be used to make accurate measurements of the elastic properties of a material. The compression modulus of a fluid, the elastic modulus, and Poisson's ratio of an isotropic solid, can all be determined using eqns [1]–[3], once the ultrasonic velocity has been measured. Anisotropic materials are characterized by larger numbers of elastic constants, and these can be extracted from measurements of the velocity in different directions. Measurements of attenuation can be used to quantify the characteristics of an absorbing or scattering medium, such as the viscosity of a fluid and the size and distribution statistics of particles in suspension in a fluid.

Electronic Devices

Ultrasound has been used in electronic components for many years. Initial devices provided a delay to a signal simply by propagating ultrasound from a transmitter to a receiver along a short length of a solid rod. This exploited the fact that the ultrasound velocity is very much smaller than that of electrical signals. Surface acoustic wave (SAW) devices were developed in the 1960s to perform more complex operations such as filtering and hardware signal processing and are now very widely used. In these devices, the wave is guided along the surface of a piezoelectric material. The wave is excited by multiple parallel thin 'finger' electrodes which are attached to the surface; the distance between them is matched to the desired wavelength of the wave. A similar pattern of electrodes is used at the receiver location. These devices use waves with frequencies of up to several GHz.

Modifying Chemical Reactions and Processes

High-power ultrasound has many applications in modifying or enhancing chemical reactions and material production processes. It can be used to heat a material in which there are viscous losses; some of the energy is transformed from the ultrasound into heat. The heat source can be localized by using a transducer which focuses a beam at a specific location. Attenuating ultrasonic waves also introduces a steady force, and thus a net motion of a fluid, through the phenomenon of 'streaming'. Similarly, particles suspended in a viscous fluid are set into net motion by ultrasonic waves. Furthermore, the motion of the particles varies according to their size. Cavitation, as mentioned earlier, is quite easy to induce using ultrasound, and involves very large localized pressures. Thus ultrasound may be used to perform functions such as: increasing the speed of chemical reactions, degasing fluids, and dispersing or coagulating materials in suspensions.

Ultrasonic Cutting and Welding

As discussed in the previous paragraph, ultrasound waves carry energy and so can be used to heat a material. If very-high-power waves are generated, and the transduction is designed to focus the sound on a particular location of a material, then it is possible to increase the local temperature very significantly, and even to melt the material. Ultrasonic cutting and welding of materials are achieved using this principle. The transformation of the energy from the wave to heat requires some means of loss in the material, such as hysteretic damping, and so the applications of the technique are particular to those materials which have suitable properties. The main

applications of ultrasonic cutting and welding are with plastics, as these have the helpful properties of high damping and relatively low melting temperature.

Acoustic Emission

When a structure is loaded towards its limit strength, it may emit acoustic signals through the mechanisms of microcracking or rubbing. Acoustic emission is the name given to the techniques which detect these emissions and so can be used to determine the state of distress of the structure. Acoustic emission signals are generally associated with discrete events and so are short-time signals. The frequencies of these signals are quite broad-band; in practice the frequency range between 100 kHz and 1 MHz has been found to be the most applicable. A typical, and popular, application of acoustic emission is to the proof-testing of pressure vessels. A set of transducers is attached to the vessel, then their signals are monitored while the pressure in the vessel is increased. The initiation of any cracking is then indicated by the emitted signals before the pressure is large enough to accumulate any significant damage. The location of the sound sources can be estimated by comparing the arrival times of signals at different receivers.

Generation of Ultrasound

Transducers for the generation of ultrasound most commonly use piezoelectric materials to convert an electrical signal into the mechanical motion. Figure 1 shows a section through a typical ultrasonic NDT transducer, designed to excite longitudinal waves. An electrical signal is supplied as a voltage across the thickness of a piezoelectric disk which then vibrates. The first through-thickness vibration mode of the disk excites waves in the fluid or structure in front of the transducer. Thus, the center frequency of operation of the transducer can be controlled by the selection of the thickness of the disk. Damping material behind the disk absorbs the backward-traveling waves and also damps the resonance of the disk. The damping enables the transducer to produce waves which are short in time and so wide in frequency bandwidth. Transducers usually have a durable material, known as a wear plate, which is attached to the front of the piezoelectric disk for protection. The transducer may also act as a receiver, in which case it simply works in reverse: the incoming waves excite motion in the piezoelectric disk which then generates an electrical signal. The two most popular choices of the material for the piezoelectric disk are the ceramic lead zirconate titanate (PZT) and the polymer polyvinylidene

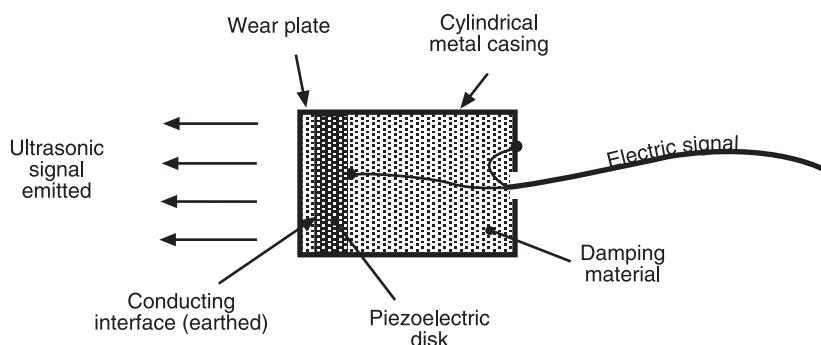

Figure 1 Section through a piezoelectric transducer.

fluoride (PVDF). Piezoelectric transducers may be used throughout the ultrasonic frequency range.

Although piezoelectric transducers are the most common, there are some alternative types in use. Electromechanical transducers which use a moving coil, similar to a loudspeaker, can generate waves with large amplitudes, but their maximum frequency is limited to some tens of kHz. Electromagnetic EMAT transducers generate wave motion directly in a conducting material. An alternating current is passed through a coil which is in close proximity to the body and within a static magnetic field. Either or both of the phenomena of Lorenz forces and magnetostriction then introduce an alternating stress field in the body. Although the electromechanical coupling of these transducers is not strong, they have the advantage that they do not need direct contact with the body and so can be used for example on dirty surfaces. They are used mostly in the frequency range from some hundreds of kHz to a few MHz. Finally, lasers may be used to generate and detect ultrasound. Sound is generated using a relatively powerful source, either by inducing a cyclic thermoelastic strain (by locally heating the material), or by spalling small quantities of the material from the surface, thereby initiating a transient reaction force. Detection of displacements at the surface of a body requires only a low-power laser interferometer. Lasers have very wide bandwidths and have the advantage that the transduction is contactless.

Nomenclature

A	amplitude
C	wave velocity

E	Young's modulus
k	wavenumber
K	stiffness
u	particle displacement
v	particle velocity
Z	acoustic impedance
λ	wavelength
ν	Poisson's ratio
ρ	density
σ	pressure
ω	frequency

doi:10.1006/rwvb.2001.0207

Introduction

Vibration generated sound occurs when vibration waves in a solid elastic medium couple to a compressible fluid in contact with the solid. Normally, the fluid is a gas (e.g., air), although it can be a liquid (e.g., water). This and the subsequent chapter on sound radiation from flexible structures are concerned with the generation of sound waves in gases such as air, by vibrating rigid and flexible solid bodies, respectively; these are caused to vibrate by mechanically (or electromechanically) applied forces or structurally transmitted vibration.

Sound transmission through panels, enclosures and shells occurs when pressure waves are incident on a mechanical body (e.g., a wall panel or pipe wall), resulting in the transmission and radiation of sound by the body (this is not covered here). Sound may also

be generated by the fluid flow over a solid body, e.g., vortex shedding. However, flow-induced sound generation is not caused by mechanically applied forces and is also not discussed here. Vibration generated sound in fluids such as water involves significant fluid loading imposed on the structure by the fluid (see **Vibration generated sound**, **Radiation by flexural elements**). Sound radiated from elementary sources, baffled plates, sound transmission, fluid-structure interaction and structure-acoustic interaction are covered in other articles in this encyclopedia (see **Structure-acoustic interaction, high frequencies**).

Vibration generated sound may be either undesirable (i.e., ‘noise’) or desirable (e.g., a stereo speaker). The desirability or otherwise of a particular sound may be one of perception; except in cases where the sound is destructive, in which case it is always undesirable (e.g., when it causes hearing damage). However, the physics of the generation of sound by a vibrating body is the same for both intrusive (i.e., ‘noise’) sources and useful sound sources. In the engineering context, vibration generated sound is mostly concerned with the reduction of undesirable noise levels and this is reflected in the emphasis here. The two articles on vibration generated sound cover the two main mechanisms of mechanical vibration generated sound radiation.

Sound generated by the motion of inflexible solid bodies in air Sources covered are a baffled piston, finite monopole (i.e., a ‘breathing’ sphere) and a finite dipole (i.e., an oscillating sphere). These all have surface normal vibration velocities that are in-phase at every point. Oscillatory and impulsive sound generation by rigid bodies are both discussed in this article and have fundamentally different mechanisms. Sound generated by elementary point sources (generally used for sound propagation modeling) is discussed in a separate article.

Sound generated by the vibration of flexible solid structures in air Sound radiation by flexible structures is significantly more complex than rigid body sound radiation. Flexible sources have surface normal vibration velocities that are not in-phase at every point on the surface. Classical theory describing sound generation in air caused by the vibration of flexible plate and shell structures, is well established. Analytical and numerical solutions and experimental data are available for many configurations (e.g., flat plates, cylinders). Detailed derivations of the governing equations are available. A limited number of key concepts and equations are presented in the next article on vibration generated sound, along with published experimental data. Analytical procedures for the prediction of noise radiation from baffled plates are discussed in a separate article (see **Noise: Noise radiated by baffled plates**).

Basic Theory

Impedance and Sound Radiation

Mechanical vibration of solid bodies (i.e., structures) requires the application of dynamic forces to the body. With the exception of fluid and flow-induced forces and electromagnetic forces, a mechanical connection exists between the force applicator and the

structure. In some cases the forces are transmitted from a remote source, via structural vibration. Sound radiation requires that the structure applies dynamic forces to the surrounding fluid medium. The surrounding fluid may also apply a fluid loading to the structure. If the fluid medium is a gas, the fluid loading effect is negligible (i.e., the dynamic forces applied to the structure by the gas are negligible). Overall, energy is transferred from the force applicator to the structure and from the structure to the surrounding fluid.

This transmission of energy and radiation of vibration generated sound involves impedances within the system. An impedance is defined as the (complex) ratio of an applied dynamic force (or pressure) to a resulting dynamic velocity (or volume velocity). All three terms are complex.

Consider a dynamic mechanical force, $f_m(x, t)$, that causes a solid body (i.e., structure) to vibrate with a vibration velocity, $v_m(x, t)$. The vibrating body radiates sound into the surrounding fluid, with particle velocity, $u_m(x, t)$, and sound pressure, $p(x, t)$.

Mechanical impedance If the vibrating body is in a vacuum, z_m is the mechanical impedance of the structure. It is a property of the structure only. In practice, mechanical impedance is normally measured in air, because the *in vacuo* and in-air mechanical impedances are not very different.

Radiation impedance If the vibrating body is surrounded by a fluid, the fluid applies an acoustic pressure force in response to the surface vibration. The acoustic radiation impedance is defined to be dimensionally consistent with mechanical impedance (i.e., because it is a mechanical impedance):

$$z_r = \frac{f_p}{v_m} = (R_r + iX_r) \quad [1]$$

Table 1 Mechanical and acoustic impedances

Impedance	Force/Pressure	Velocity	Equation	Units
Mechanical	Mechanical force	Surface velocity	$z_m = f_m/v_m$	$N\text{s m}^{-1}$ (mks mechanical ohms)
Radiation impedance	Sound pressure force at surface (over area A)	Surface velocity	$z_r = PA/v_m$	$N\text{s m}^{-1}$
Specific acoustic impedance	Sound pressure	Particle velocity	$z_{sa} = p/u$	$N\text{s m}^{-3}$ (mks rayls)
Acoustic impedance	Sound pressure	Volume velocity	$z_a = p/(uA)$	$N\text{s m}^{-5}$ (mks acoustical ohms)
Characteristic resistance			$\rho_0 c$	$N\text{s m}^{-3}$ (mks rayls)

where f_p is the acoustic pressure force, R_r is the radiation resistance and X_r is the radiation reactance. Since the fluid particles in contact with the solid must have the same velocity as the solid surface (i.e., $\mathbf{v}_m = \mathbf{u}_{r=0}$):

$$z_r = \frac{pA}{\mathbf{v}_m} = \frac{pA}{\mathbf{u}_{r=0}} = \frac{\mathbf{f}_p}{\mathbf{u}_{r=0}} \quad [2]$$

and:

$$\mathbf{u}_{r=0} = \frac{\mathbf{f}_m}{(z_m + z_r)} \quad [3]$$

Specific acoustic impedance Specific acoustic impedance is the ratio of the acoustic pressure fluctuations in the fluid to the associated acoustic particle velocity in the fluid:

$$z_{sa} = \frac{p}{\mathbf{u}} = (R_{sa} + iX_{sa}) = \frac{z_r}{A} \quad [4]$$

In the region close to a vibrating structure (i.e., the acoustic near field), the specific acoustic impedance is complex, with specific acoustic resistance (R_{sa}) and specific acoustic reactance (X_{sa}) components. At sufficient distance from the structure (i.e., in the acoustic far field), the acoustic resistance dominates and the acoustic reactance becomes negligible ($X_{sa} \approx 0$). At large distances, all sound sources approximate a spherical source. At very large distances, wavefront curvature becomes negligible and all waves approach plane wave propagation, with a characteristic acoustic impedance (resistance) of the fluid of $\rho_0 c$.

Acoustic impedance Acoustic impedance at a given surface (area A) is the ratio of the acoustic pressure averaged over that surface to the associated acoustic velocity through the surface.

Sound Radiation from a Baffled Piston

One of the classical problems in acoustics is the sound radiation from a vibrating circular piston mounted in an infinite baffle. It is a good example of vibration generated sound, with which to illustrate several important concepts. The analysis assumes that all parts of the piston surface are vibrating with exactly the same amplitude and phase. The piston is rigid and vibrates only in the direction of its central axis.

Acoustic near field and impedance The mechanical and acoustic impedances of any vibrating sound source are determined at the surface of the solid, which is the interface between the solid and the surrounding fluid. This interface is in the acoustic near field. The combined mechanical and acoustic

radiation impedances give the total impedance. For the baffled circular piston of radius a , mass m , stiffness k_p , damping c_v and wavenumber k ($k = \omega/c$):

$$z_m = c_v + i[m\omega - (k_p/\omega)] \quad [5]$$

$$z_r = \rho_0 c (\pi a^2) [R_p(2ka) + iX_p(2ka)] \quad [6]$$

$$R_p(x) = \left[\frac{x^2}{(2.4)} - \frac{x^4}{(2.4^2 \cdot 6)} + \frac{x^6}{(2.4^2 \cdot 6^2 \cdot 8)} - \dots \right]$$

$$X_p(x) = (4/\pi) \left[\frac{x}{(3)} - \frac{x^3}{(3^2 \cdot 5)} + \frac{x^5}{(3^2 \cdot 5^2 \cdot 7)} - \dots \right]$$

$$z_{total} = (z_m + z_r) = \frac{\mathbf{f}_{piston}}{\mathbf{v}_{piston}} \quad [7]$$

For the baffled piston, the impedances are known. Piston velocity is calculated from the known mechanical force applied to the piston and the known mechanical impedance. Piston velocity and radiation impedance are then used to determine the radiated sound field (e.g., sound power). For many engineering structural sound sources, it is not practical to determine the applied mechanical force or mechanical impedance. However, it is not necessary to know them, in order to determine useful information about the radiated sound field. A single lineal structural vibration velocity term is sufficient to describe the radiation of vibration generated sound from a vibrating solid body. It is the space (—) and time ⟨ ⟩ averaged RMS surface normal velocity ($\langle v_{rms} \rangle$), i.e., the component of surface vibration velocity that is normal to the surface at every point.

If the surface normal vibration velocity and the radiation impedance of the vibrating structure are both known, then the sound radiation can be determined from:

$$\mathbf{f}_p = \mathbf{z}_r \cdot \mathbf{v}_m \quad [8]$$

Radiation impedance for a baffled piston is shown in Figure 1. It is complex and varies with distance from the piston. The resistive (real) part of the radiation impedance is due to the radiated sound pressure. The reactive (imaginary) part of the radiation impedance is a fluid loading term, due to the fluid in close proximity to the piston. Fluid loading is significant when the fluid is a liquid. The primary effect of significant fluid loading is to reduce the vibration velocity of the piston and thus reduce the sound power radiated. Fluid loading is usually negligible

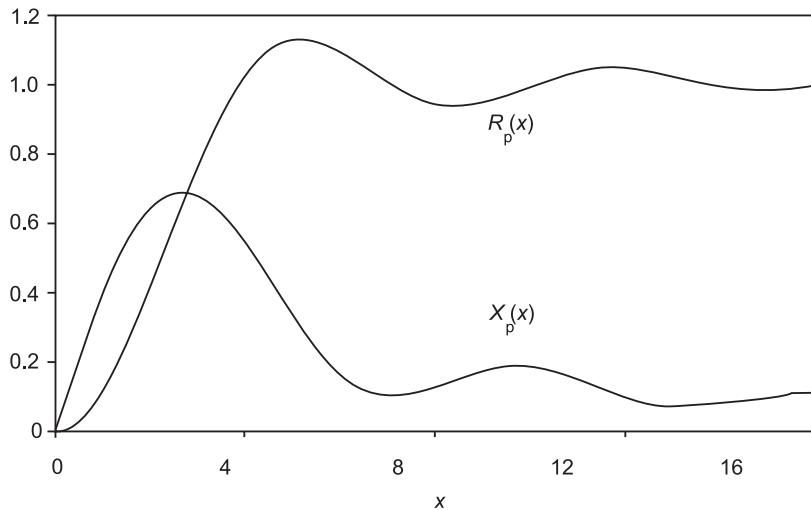

Figure 1 Radiation impedance functions for a circular piston ($x = 2ka$). Used with permission from Norton MP (1999).

for sound radiation in air, except for very thin structures.

Acoustic far field and sound power Sound is radiated into the half-space in ‘front’ of the piston. If the circumference of the piston is much larger than the acoustic wavelength in the surrounding air (i.e., $ka \gg 1$), then the particle velocity of the air in contact with the piston is equal to the surface normal vibration velocity of the piston surface (i.e., $\mathbf{v}_m = \mathbf{u}_{r=0}$). For a rigid piston of surface area S , the radiated sound power (force times velocity) is:

$$\Pi_{\text{piston}} = \rho_0 c S \langle v_{\text{piston}}^2 \rangle \quad [9]$$

Note that the far-field radiation resistance of the piston in air is unity ($X_{r \gg a} = 1$). This result illustrates the general case:

For a body vibrating in air, the radiated sound power is determined by, the averaged surface normal vibration velocity and the (far-field) radiation resistance.

Radiation Ratio

The radiation ratio, σ_r , of an arbitrary structure is defined as the sound power radiated by the structure into half space (i.e., one side of the structure) divided by the sound power radiated by a large piston with the same surface area and vibrating with the same RMS velocity as the structure:

$$\sigma_r = \frac{\Pi}{(\rho_0 c S \langle v^2 \rangle)} \quad [10]$$

where Π is the sound power, S is the radiating surface area of the vibrating body and $\langle v^2 \rangle$ is the space and time averaged mean-square surface normal velocity. In logarithmic form:

$$10 \log_{10} \sigma_r = 10 \log_{10} \Pi - 10 \log_{10} \langle v^2 \rangle - 10 \log_{10} S - 146 \quad [11]$$

Radiation ratio is a frequency dependant property of the structure and surrounding fluid. It may be thought of as the real part of the frequency response function between the radiated sound and the structural vibration velocity. Mathematically, it is the nondimensional far-field component of the radiation resistance. Thus the radiation ratio curve has the same shape as the radiation resistance curve (Figure 1), because:

$$\sigma_r = \frac{R_r}{(\rho_0 c S)} = \frac{\text{Re}(z_r)}{(\rho_0 c S)} \quad [12]$$

If the radiation ratio of a real engineering structure is known (or can be estimated) and the surface normal vibration velocity of that structure can be measured, then the vibration generated sound power radiation can be determined. Typically, an accelerometer and FFT analyzer are used to measure the RMS (time) averaged velocity measurements (spectra) at several locations on a structure. These velocity spectra are then averaged together, producing a single time- and space-averaged velocity spectrum.

For a large rigid piston (i.e., $ka \gg 1$), $\sigma_r = 1$ (note: $\sigma_r < 1$ for $ka < 1$!). Sometimes, the radiation ratio is referred to as the sound radiation efficiency (or index)

where the radiation efficiency of a large, rigid piston is 100 percent. However, since it is possible for flexible structures to have $\sigma_r > 1$, the term radiation ratio is used in this article.

Sound Radiation from Compact Engineering Sources

This section considers the sound radiation by three-dimensional ‘compact’ solid bodies, where the largest body dimension is typically not more than twice the size of the smallest body dimension. Sound radiation from such bodies is typically modeled as sound radiation from a vibrating sphere with a volume equal to the actual body volume. Continuous sound radiation and impact noise are both considered.

‘Point monopoles’ are idealized, spherically radiating acoustic sources with a zero radius. ‘Point dipoles’ are represented as a pair of oppositely phased point monopoles placed a small distance apart. ‘Point quadrupoles’ consist of a pair of equally spaced point dipoles. These idealized point sources are discussed in the article on **Noise: Noise radiated from elementary sources**. They are not the most appropriate source models to use for vibration generated sound source modeling.

In this article, only finite monopoles and dipoles are considered (**Table 2**). A spherical oscillator is a fundamental sound source. A uniformly pulsating sphere is a ‘finite monopole’. A rigid, vibrating sphere is a ‘finite dipole’. A distorting sphere (with particular surface velocity profiles) can represent either a ‘finite longitudinal quadrupole’ or a ‘finite lateral quadrupole’. Combinations of spherical oscillators can be used to model real-world sound sources provided that: (i) the source is compact, so that the size of the source is small compared to the wavelength of the radiated sound, and (ii) the source is sufficiently far away from the receiver, such that the sound waves reaching the receiver are approximately spherical.

Continuous Sound Radiation

Vibration and noise radiation may be deterministic (e.g., harmonic, periodic) or nondeterministic (e.g., nonperiodic, random, etc.). Total vibration of any solid body (i.e., structure) is the summation of two parts:

- At higher frequencies (i.e., at the first natural frequency and above), the body shape distorts due to flexural vibration and the surface vibration velocity at all points may not be in-phase. Flexible-body sound generation is covered in a subsequent chapter.

- Rigid-body motion occurs below the first flexural natural frequency of the structure. The whole body vibrates as a single object and the surface vibration velocity at all points is in phase. Vibration may occur for any of the three lineal (V_1, V_2, V_3) and three rotational ($\theta_1, \theta_2, \theta_3$) degrees-of-freedom.

It was shown earlier that rigid-body lineal vibration of a baffled piston is an efficient sound generator. Air particles in contact with the piston are forced to move in-phase with it. Energy is transmitted to the gas, and planar sound waves are radiated from the piston. In the general case, the surface vibration at any location on a solid object has two components, one normal to the surface and one tangential to the surface. It is the surface normal vibration component that causes sound radiation, by compressing and expanding the air in contact with it. The tangential vibration velocity component cannot cause compression and rarefaction of the air and therefore does not generate sound.

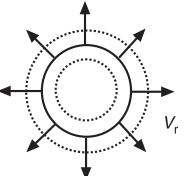

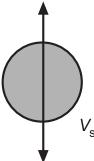

Rotational vibration of a rigid sphere results in zero normal-to-surface vibration velocity, and therefore does not radiate sound. Rotational rigid-body vibration can only radiate sound if the body is sufficiently ‘nonspherical’ (i.e., it has some sharp corners), so that there is significant resulting surface normal velocity at some points on the surface. However, the surface normal vibration velocity is not in-phase at all points. This chapter includes only cases where $\theta_1 = \theta_2 = \theta_3 = 0$ and sound generated by rotational vibration is not considered.

Sound radiation for two particular cases of in-phase solid body vibration of a sphere is considered here. These are the two main cases of practical importance; (i) finite, monopole-type spherical sound sources, and (ii) finite, dipole-type sound sources. Vibration generated sound radiation from many ‘compact’ engineering sound sources can be satisfactorily modeled as either a finite spherical monopole or as a finite spherical dipole. Finite quadrupoles are not commonly used for modeling vibrating sound sources.

Radiation ratios for compact bodies are a function of the nondimensional parameter $ka = 2\pi a/\lambda$ (acoustic wavelength λ), as shown by the formulae for σ_r in **Table 2**. This parameter (ka) maps the number of sound waves corresponding to a characteristic dimension of the body (e.g., spherical circumference = $2\pi a$).

Finite spherical monopole An ideal finite monopole consists of a ‘breathing sphere’, with whole body pulsations that are normal to the body surface. A

Table 2 Compact sound sources

Source	Picture	Radiation impedance	Radiation ratio	Sound power
Finite spherical monopole ('breathing' sphere)		$z_{rM} = \frac{\rho_0 c (4\pi a^2) \{k^2 a^2 + ika\}}{(1 + k^2 a^2)}$	$\sigma_{rM} = \frac{k^2 a^2}{(1 + k^2 a^2)}$	$\Pi_M = \left\{ \frac{k^2 a^2}{1 + k^2 a^2} \right\} \rho_0 c (4\pi a^2) v_{r,\text{rms}}^2$

monopole has uniform directivity and radiates sound in a spherical pattern. Compact, vibrating engineering sources (i.e., $a = \text{volume}^{1/3}$) may be satisfactorily approximated as a finite monopole at the frequencies of interest if:

1. The source is ‘compact’, i.e., small compared to the acoustic wavelength ($a \ll \lambda$).
2. The sound radiation approximates that of a uniform spherical radiator. This applies if the observer is located at large distances from the source ($r \gg \lambda$) and if the source directivity is reasonably uniform.
3. The amplitude and/or direction of the mechanical forces are reasonably constant with time.

Resistive and reactive components of radiation impedance for a finite spherical monopole are shown in **Figure 2**, as a function of distance from the source. Source directivity is uniform (spherical). Radiation ratio is plotted against nondimensional parameter ka in **Figure 3**, and against frequency (for various source sizes) in **Figure 4**.

Finite spherical dipole An ideal finite dipole consists of a rigid sphere, oscillating about the mean position (along a single axis). The sphere has no volume

change and no distortion of shape. A dipole has nonuniform directivity, shown in **Figure 5**. A pair of impacting cylinders radiates sound in a dipole-like manner (**Figure 6**). Vibrating engineering sources may be satisfactorily approximated as a finite dipole at the frequencies of interest if:

1. The source is ‘compact’, i.e., small compared to the acoustic wavelength ($a \ll \lambda$).
2. The source directivity approximates that of a dipole radiator. This is the case if the source directivity is significantly higher along one axis than on the perpendicular axis.
3. The amplitude and/or direction of the mechanical forces vary significantly with time.

Resistive and reactive components of radiation impedance for a finite spherical dipole are shown in **Figure 7**, as a function of distance from the source. Radiation ratio is plotted against (ka) in **Figure 8**, and against frequency and source size in **Figure 9**.

Impact Noise

Consider a fast moving solid object hitting a steel plate structure. Sound is generated by two different mechanisms. Rapid deceleration of the fast moving rigid body results in lost energy that is radiated as

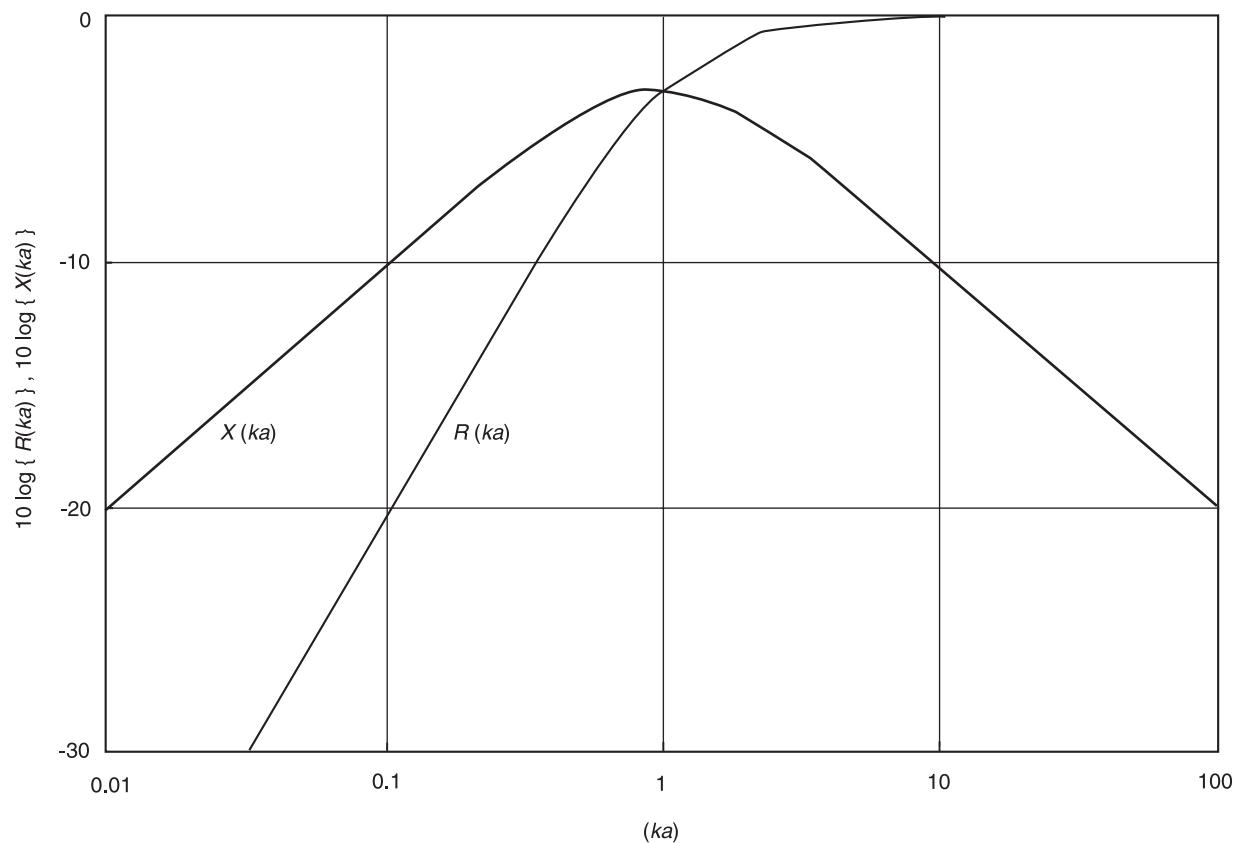

Figure 2 Radiation impedance functions for a finite spherical monopole.

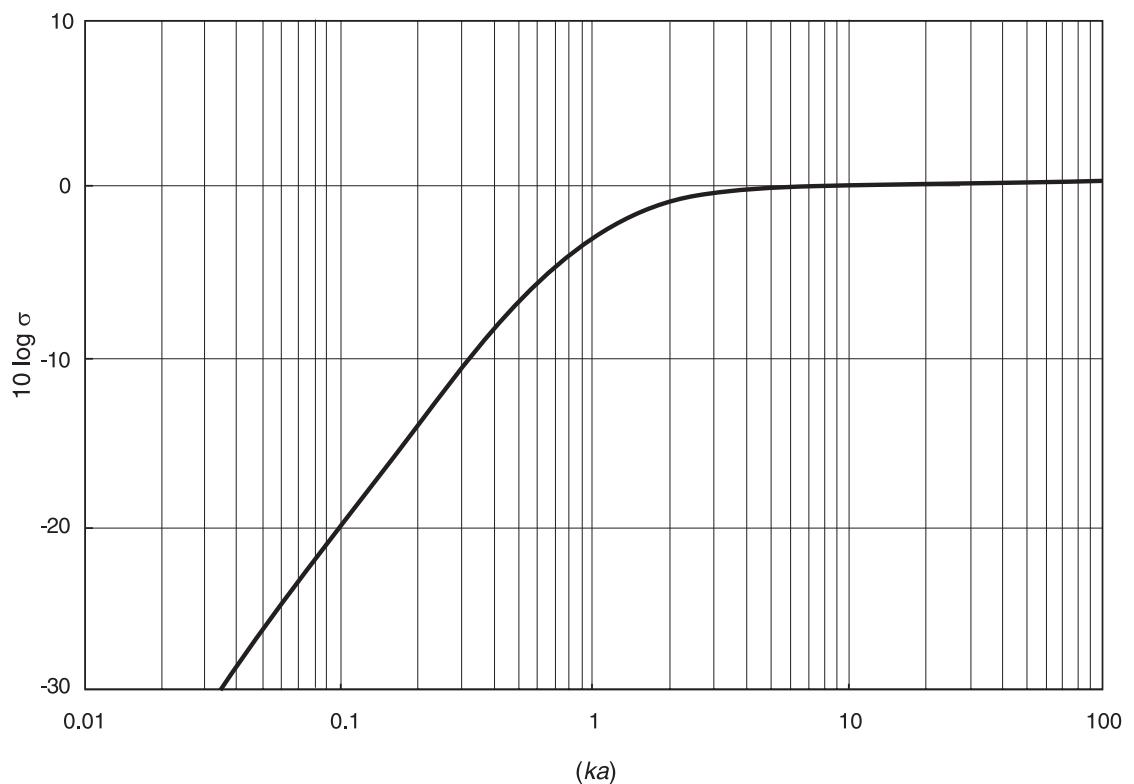

Figure 3 Radiation ratio for a finite spherical monopole.

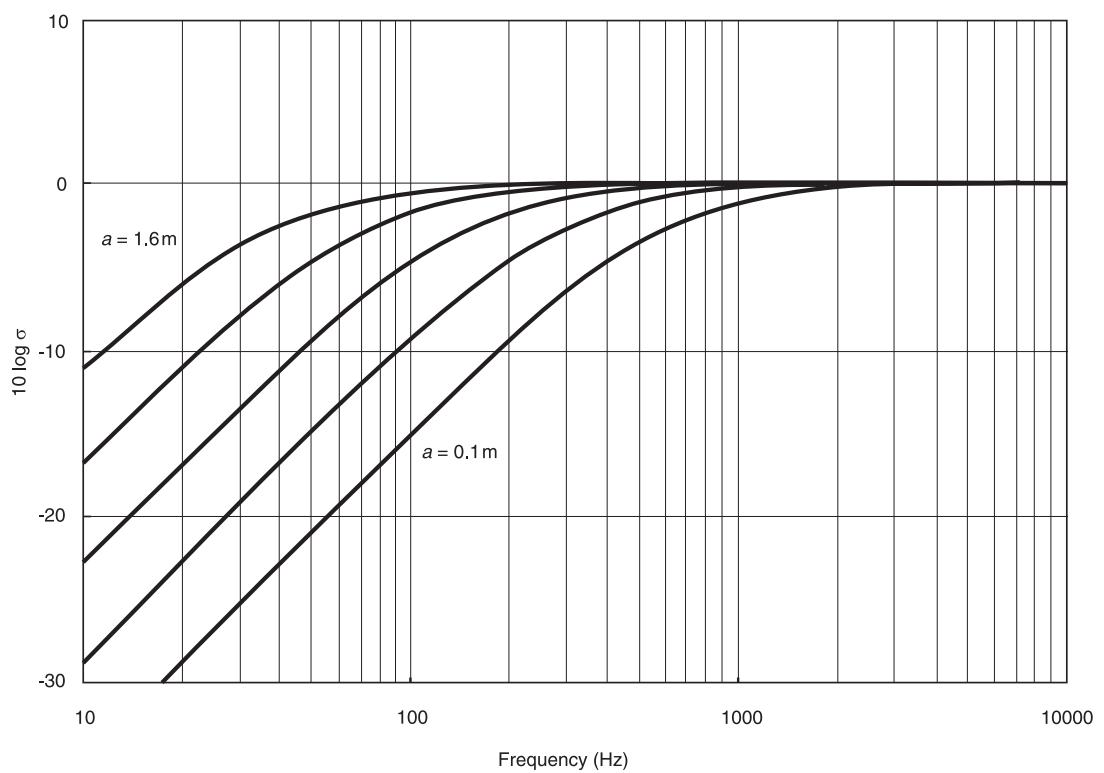

Figure 4 Radiation ratio for finite monopole-like sources (of radius $a = 0.1 \text{ m}$, 0.2 m , 0.4 m , 0.8 m and 1.6 m).

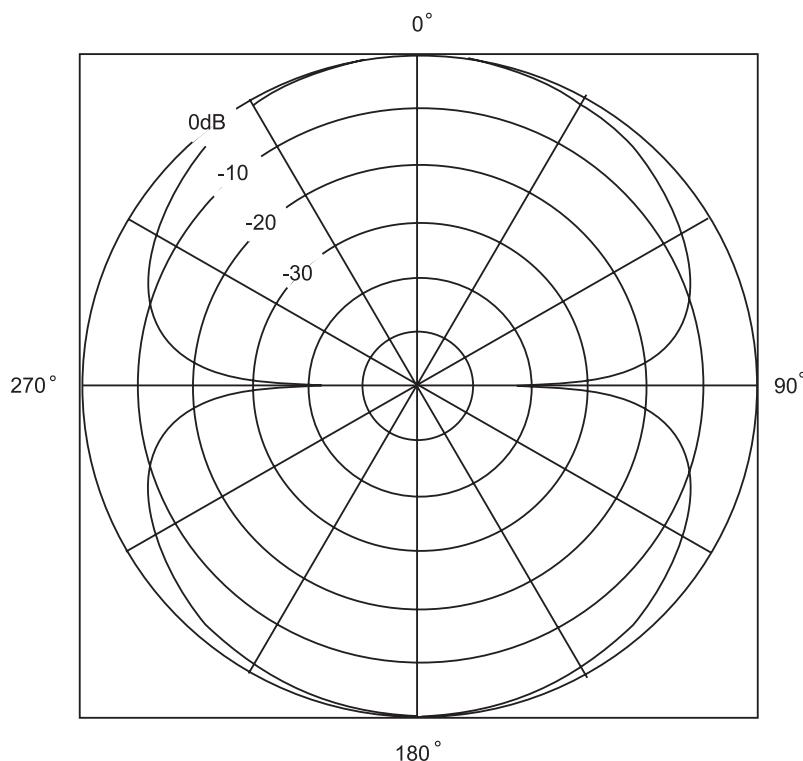

Figure 5 Directivity of a finite spherical dipole. Used with permission from Reynolds DD (1981).

sound. This is called ‘acceleration noise’ (Π_{accn}). Decaying vibration of the flexible steel structure results in additional sound radiation, known as ‘ringing noise’ (Π_{vib}). Both mechanisms are included in this article, as the forces are applied mechanically. Acceleration noise is also covered in this section. Ringing noise is covered in the article on **Vibration generated sound: Radiation by flexural elements**.

Impact noise generated by a rigid body in motion hitting another solid body, is considered to be a special case of vibration generated sound. It may be classified as ‘motion-generated noise’ and is included for consistency with impact noise generated by flexible structures. Flexible structures radiate noise when impulsive or transient mechanical forces are applied to them, as can rigid bodies, although the mechanism of noise generation is quite different.

Consider a solid spherical body of mass m moving with a velocity v_0 , through a nonviscous fluid (e.g., air). Consider also a virtual mass of fluid equal to half of that displaced by the sphere. This virtual mass has kinetic energy. If the sphere was slowly brought to rest, most of the fluid kinetic energy would be returned to the body and very little would be released as sound energy. If the sphere was brought to rest immediately, the fluid kinetic energy would be dissipated immediately, primarily as radiated sound energy. This is referred to as acceleration noise (or deceleration noise).

Some results of measured noise radiation from impacting steel spheres and cylinders are shown in Table 3. There are three noise generation mechanisms; (i) acceleration noise, (ii) ringing noise due to longitudinal waves (vibration), and (iii) ringing noise due to flexural (bending) waves. Acceleration noise is dominant for the two spheres. For the cylinders, flexural ringing noise radiation is dominant.

The acceleration noise efficiency, μ_{accn} , is defined as the impact noise energy radiated by a moving body (mass m , volume V) divided by the impact noise energy that would be radiated if two equal bodies (m , V) were brought to rest immediately upon impact. Based on experimental data, Richards concluded that:

$$\mu_{\text{accn}} = 0.7 \quad \text{for } \delta < 1 \quad [13]$$

and:

$$\mu_{\text{accn}} = \frac{0.7}{\delta^{3.2}} \quad \text{for } \delta > 1 \quad [14]$$

where:

$$\delta = \frac{ct_0}{\sqrt[3]{(V)}} \quad [15]$$

The impact duration is t_0 seconds and the nondimensional contact time, δ , is the number of typical body

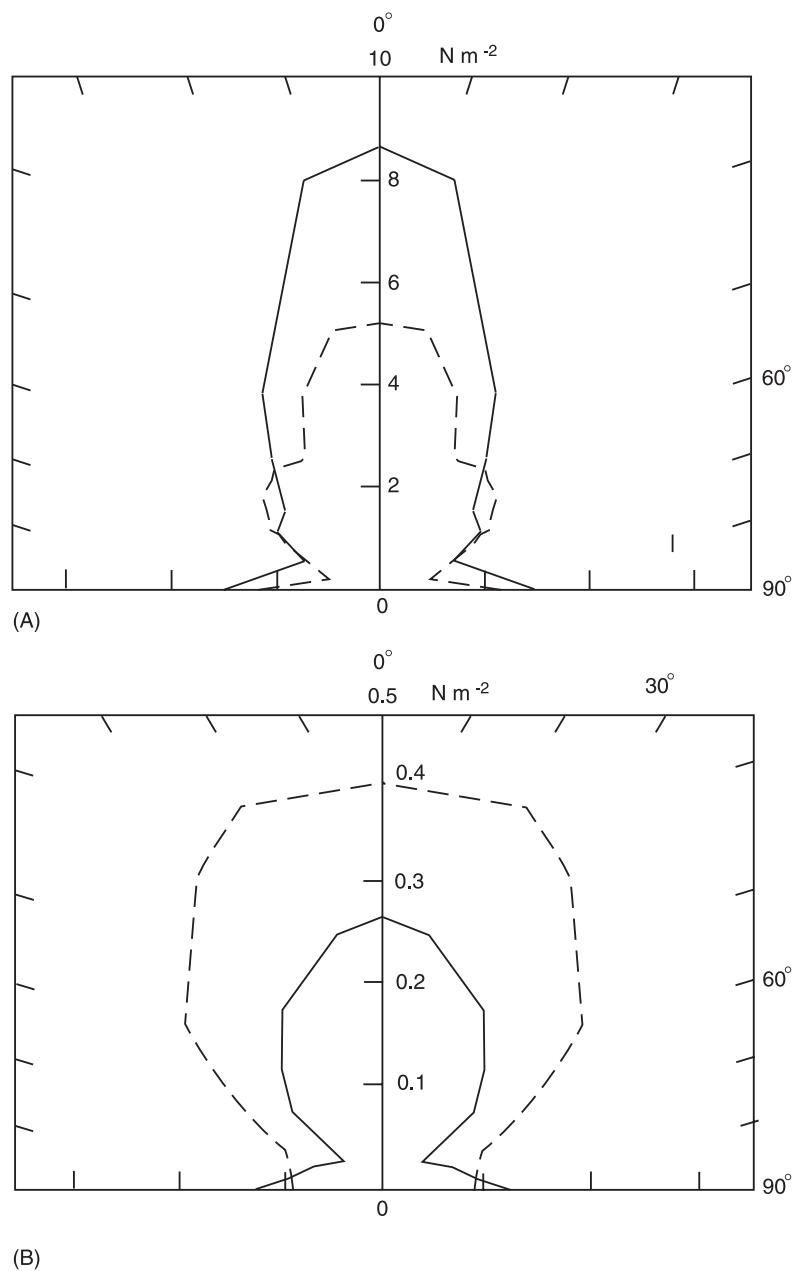

Figure 6 Directivity of two impacting steel cylinders. (A) Hard impact; (B) soft impact. Used with permission from Richards EJ (1982).

dimensions traveled by the sound wave during the deceleration process.

For two impacting solid spheres or for a solid sphere hitting a ground plane and coming to rest, an equivalent impact radiation ratio (Figure 10) can be determined based on the velocity just before impact, v_0 , and the nondimensional impact duration, δ :

$$\sigma_{\text{accn}} = \left[\frac{1}{288\pi} \right]^{1/3} \frac{\mu_{\text{accn}}}{\delta} \approx \frac{\mu_{\text{accn}}}{10\delta} \quad [16]$$

In practical engineering situations, the acceleration noise (sound power) can be estimated by measuring the initial velocity, v_0 , and impact duration, t_0 , and finding σ_{accn} from Figure 10. The peak radiated sound power for the impact is then given by:

$$\Pi_{\text{accn}} = \sigma_{\text{accn}} \rho_0 c S \langle v_0^2 \rangle \quad [17]$$

Summary and Conclusions

This chapter summarizes the fundamentals of vibration generated sound with particular reference to

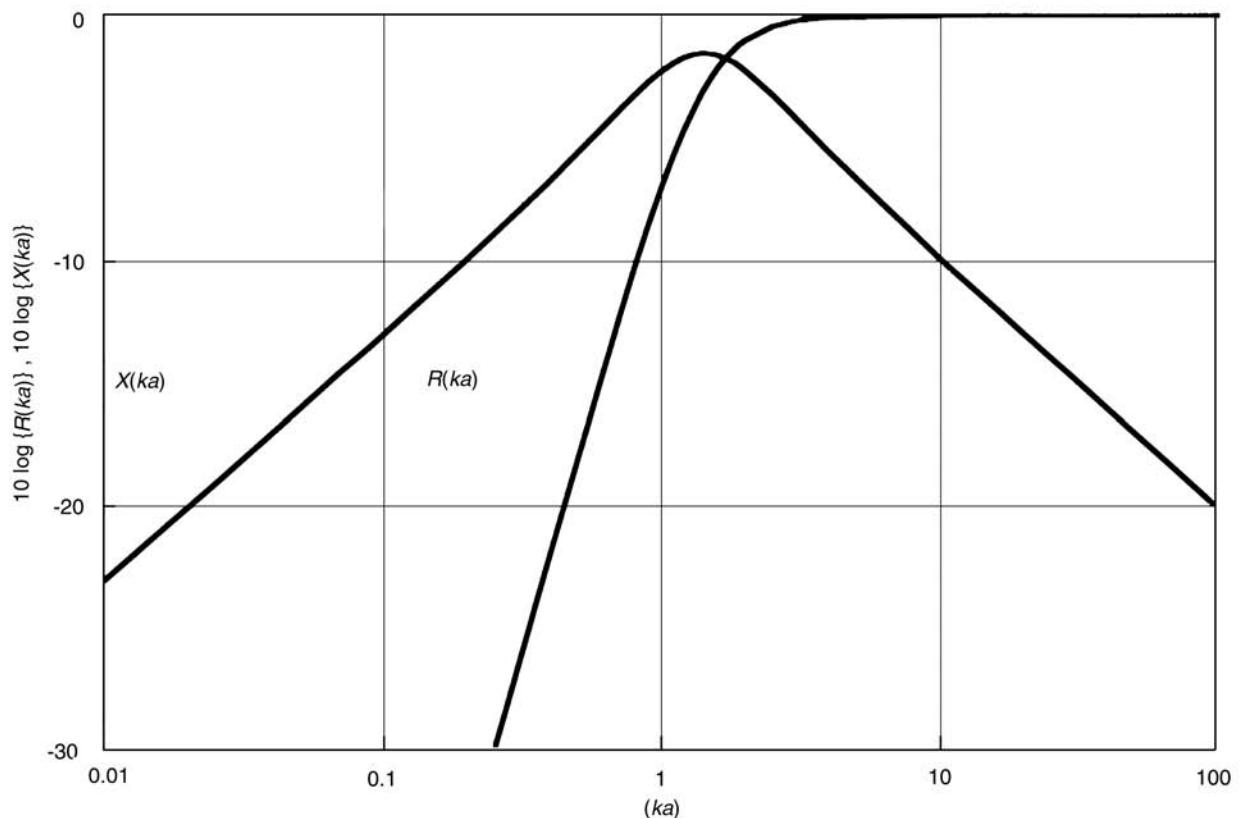

Figure 7 Radiation impedance functions for a finite spherical dipole.

Table 3 Solid body acceleration (Π_{accn}) and ringing (Π_{vib}) noise

Impacting bodies	Ringing mode	Frequency (kHz)	$\Pi_{\text{vib}}/\Pi_{\text{accn}}$ (nearest 0.5 dB)
102 mm diameter steel spheres	Fundamental	26	-9 dB

compact engineering sources. A clear distinction is made with elementary point sources (**Noise: Noise radiated from elementary sources**), the latter being more appropriate for sound propagation modeling. Compact sound source models with finite dimensions (as compared with point sources) are more appropriate for vibration generated sound at locations both in the near and far field but at regions in proximity to the sources such that the finite sizes of the sources are relevant. Examples include electric motors, hand tools, pumps, vacuum cleaners, gearboxes, punch

presses, industrial forges (hammers and anvils), diesel engines, etc.

The chapter discusses the differences between the various types of impedances (mechanical, radiation, specific acoustic, acoustic, characteristic) and develops the concept of radiation ratios. This concept is very important in vibration generated sound as the radiation ratio is the link between vibration and radiated sound. Radiation ratios are presented in this article for compact ‘inflexible’ solid bodies such as finite monopoles and finite dipoles. The issue of

Introduction

This article is concerned with vibration generated sound radiated from flexible structures, and not from rigid bodies (rigid-body sound radiation occurs because the whole body moves and forces the surrounding fluid to move with it). As a general rule, whilst rigid-body sound radiation from compact engineering sources occurs at lower frequencies, vibration generated sound from plates, shells and other flexible structures occurs at higher frequencies.

One of the lower flexural natural frequencies of a structure may be a ‘breathing mode’, where the surface vibration velocity at all points are in-phase. In this special case of flexural vibration, the shape of the body does not change (although the size does). Generally, however, flexural waves distort the shape of the structure’s surface.

The theoretical basis for modal sound radiation from simply supported baffled flexible plates is presented in a separate article in this encyclopedia (see **Vibration generated sound: Fundamentals**). The theoretical basis for forced vibration (of simply supported and clamped rectangular baffled flexible plates) is also briefly discussed there. This article deals with the key concepts of band-averaged resonant and forced vibration generated sound in plates and shells, and a range of published data on radiation ratios of flexible engineering-type structures is presented. As for compact engineering sources (rigid-body sound radiation), the radiation ratio concept is very important for flexible structure vibration generated sound, as it is the link between vibration and the associated radiated sound.

Basic Theory

As for compact solid bodies, radiation ratios are used to quantify the sound power radiated by flexible structures typically used in engineering applications. However, the radiation ratio for a given flexible structure is different for different forms of vibration excitation. For example, mechanical excitation of a plate produces a different radiation ratio than does flow/acoustic excitation (Figure 1). In this section, we consider only mechanical excitation of finite structures. Mechanical and acoustic excitations are both considered in the next section.

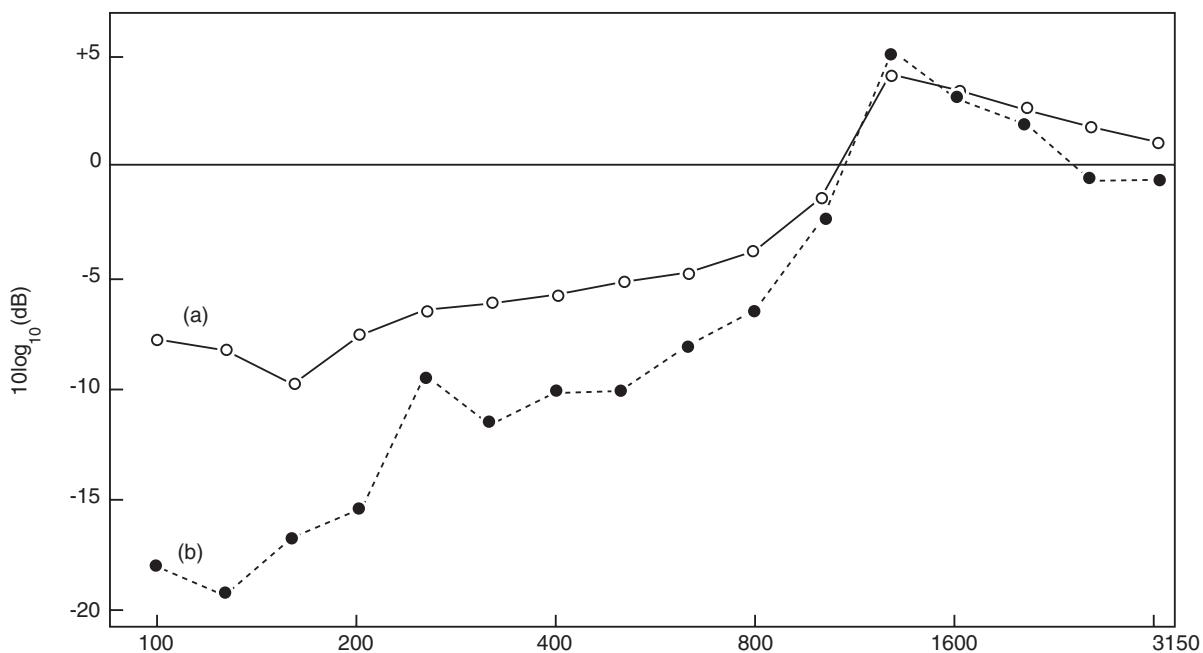

Figure 1 Steel plate radiation ratio for airborne and mechanical excitation ($h = 10 \text{ mm}$, $f_c \approx 1.25 \text{ kHz}$). Reproduced with permission from Macadam JA (1976) The measurement of sound radiation from room surfaces in lightweight buildings. *Applied Acoustics* 9: 103–118.

The classical analysis of sound radiation from flexible vibrating bodies is based on three main foundations.

- The governing equations for the vibration of thin-walled plates and shells*

Resonant vibration may be interpreted as discrete modes and their natural frequencies or as the equivalent propagating waves. Structures respond differently to different forms of forced excitation – only mechanical excitation is considered here. For example, the two-dimensional bending (flexural) wave equation for transverse vibrations of a thin rectangular plate is:

$$\rho_s \frac{\partial^2 u_p}{\partial t^2} + \left(\frac{Eh^3}{12(1-v^2)} \right) \times \left\{ \frac{\partial^4 u_p}{\partial x^4} + \frac{2\partial^4 u_p}{\partial x^2 \partial y^2} + \frac{\partial^4 u_p}{\partial y^4} \right\} = 0 \quad [1]$$

where the mass/unit area = ρ_s , Poisson's ratio = v , Young's modulus = E , the plate thickness = h , and the transverse plate displacement = $u_p(x, y, t)$. Supplementary equations are given in **Table 1**.

- The linear, homogenous acoustic wave equation for sound waves in air:*

$$\nabla^2 p - \left(\frac{1}{c^2} \right) \frac{\partial^2 u}{\partial t^2} = 0 \quad [2]$$

where the acoustic pressure is p , the particle displacement is u and the speed of sound in air is c .

- The Kirchoff–Helmholtz integral equation*

This relates the harmonic surface vibration of an arbitrarily shaped body, to the radiated sound pressure in the surrounding fluid:

$$\mathbf{p}(\vec{r}) = \int_S \{ \mathbf{p}(\vec{r}_0) \frac{\partial \mathbf{G}_\omega(\vec{r}, \omega/\vec{r}_0, \omega)}{\partial \vec{n}} + i\omega \rho_0 \vec{u}_n(\vec{r}_0) G_\omega(\vec{r}, \omega/\vec{r}_0, \omega) \} d\vec{S} \quad [3]$$

where \vec{n} is the unit normal vector, \vec{r} and \vec{r}_0 the position vectors for the receiver and a point on the surface of the vibrating body, respectively, $\mathbf{p}(\vec{r})$ is the surface pressure on the structure, and $i\omega \vec{u}_n(\vec{r}_0)$ is the surface normal vibration acceleration.

Wave propagation Two classical examples of sound radiation by flexible structures are for finite flat plates and finite circular cylinders. Plate and cylinder sound radiation have been extensively studied and analytical, numerical and experimental results are readily

available. Basic theory for these two cases is summarized later in this section. First, some useful concepts are outlined below.

Mechanical vibrations can be considered as the net effect of a number of sinusoidal waves propagating within the structure as a function of time and space. For any simple harmonic wave the circular frequency (ω) describes the phase change per unit increase of time. By analogy, a wavenumber is defined as the phase change per unit increase of distance. The wave propagates with a phase velocity, c_{ph} , so named because an observer travelling in the direction of wave propagation at this speed sees no change of phase (for a single frequency sinusoid). The wavenumber is:

$$k = \frac{\omega}{c_{ph}} = \frac{2\pi f}{c_{ph}} = \frac{2\pi}{\lambda} \quad (\text{m}^{-1}) \quad [4]$$

where f is the frequency in Hertz and λ is the wavelength in meters.

Table 2 summarizes the seven types of waves that propagate in solids. The dispersion relationship (**Figure 2**) indicates whether or not a nonsinusoidal wave will propagate without change in spatial form (it will if $k \propto \omega$). Flexural waves are dispersive, i.e., the bending wave speed (c_{ph}) is a function of frequency. Other wave types have significantly higher phase velocities than bending waves and are nondispersive (i.e., have constant wavespeed).

Sound radiation from a structure into a fluid requires that a structural wave in the solid causes sufficient particle displacements normal to the surface of the structure. Quasilongitudinal and pure bending waves are the only two structural wave types that result in any normal-to-surface vibration. These waves propagate through the solid in a direction parallel with the surface, but generate vibration displacements in the direction normal to the surface. The requirements for effective energy transfer between the structure (source) and the surrounding fluid mean that only bending waves are of practical importance. Only this type of structural wave causes significant transverse displacement of the solid surface and will transfer acoustic energy to the surrounding fluid if impedance matching occurs.

Quasilongitudinal waves have very fast wave velocities (e.g., $c_{ph} \approx 5200 \text{ m s}^{-1}$ for steel) compared to sound waves in air ($c \approx 345 \text{ m s}^{-1}$) and are therefore high impedance waves. Bending wave velocities in solids are typically much lower than the quasilongitudinal wave velocities. In acoustic terms, bending waves are low-impedance waves and efficient sound radiation is possible. The other six wave types are

Table 1 Vibration of a thin rectangular plate

Quasilongitudinal wave velocity (thin plate)

$$c_{L\rho} = \left\{ \frac{E}{\rho(1-\nu^2)} \right\}^{1/2}$$

Bending wave velocity (thin plate)

$$c_B = \omega^{1/2} \left\{ \frac{Eh^3}{12(1-\nu^2)\rho_s} \right\}^{1/4} = \{1.8c_{L\rho}hf\}^{1/2}$$

Bending wavenumber (2D vector) $\mathbf{k}_B = \mathbf{k}_x + \mathbf{k}_y$ where $k_B^2 = k_x^2 + k_y^2$

Critical frequency

$$f_c = \left\{ \frac{c^2}{1.8c_{L\rho}h} \right\} \text{Hz}$$

Normal modes of vibration for a simply supported thin rectangular plate, where L_x and L_y are the x and y plate dimensions.
Natural frequencies

$$f_{m,n} = (1.8c_{L\rho}h) \left\{ \left(\frac{m}{2L_x} \right)^2 + \left(\frac{n}{2L_y} \right)^2 \right\} \text{Hz}$$

with directional wavenumbers

$$k_x = \left(\frac{m\pi}{L_x} \right) \text{ for } m = 1, 2, 3, \dots \text{ and } k_y = \left(\frac{n\pi}{L_y} \right) \text{ for } n = 1, 2, 3, \dots$$

where m and n are the number of half-waves in the x - and y -directions.

Normal modes of vibration for a thin rectangular plate with clamped end conditions

$$f_{m,n_c} = (1.8c_{L\rho}h) \left\{ \left(\frac{(2m+1)\pi}{2L_x} \right)^2 + \left(\frac{(2n+1)\pi}{2L_y} \right)^2 \right\} \text{Hz}$$

with directional wavenumbers

$$k_{x_c} = \left(\frac{(2m+1)\pi}{L_x} \right) \text{ for } m = 1, 2, 3, \dots \text{ and } k_{y_c} = \left(\frac{(2n+1)\pi}{L_y} \right) \text{ for } n = 1, 2, 3, \dots$$

where $(2m+1)$ and $(2n+1)$ are the number of half-waves in the x - and y -directions.

high impedance waves. The form of the wave equation for bending waves is also different to the other wave types, as illustrated below.

Quasilongitudinal vibrations of rods and bars This is a second-order partial differential equation with a nondispersive wavespeed:

$$\frac{\partial^2 u_r}{\partial x^2} = \left(\frac{1}{c_{Lr}^2} \right) \left\{ \frac{\partial^2 u_r}{\partial t^2} \right\} \quad [5]$$

where $c_{Lr}^2 = E/\rho$.

Transverse bending vibrations of beams (Euler equation) This is a fourth-order partial differential equation with a wave velocity that increases with frequency. The physical reason is that bending waves are a combination of shear and longitudinal waves.

$$\frac{\partial^2 u_b}{\partial t^2} + a^2 \left\{ \frac{\partial^2 u_b}{\partial x^2} \right\} = 0 \quad [6]$$

where $a^2 = EI/\rho_L$, ρ_L = mass/unit length, $k_B^4 = (\rho_L/EI)\omega^2$ and $c_B = \omega/k_B = (1.8c_{L\rho}hf)^{1/2}$.

Table 2 Structural wave types

Wave type	Description		
Pure longitudinal waves	Particle displacement only in direction of wave propagation. Occur in large solid volumes	$k_B = \frac{\omega}{c_{ph}} = \frac{2\pi}{\lambda_B}$	in the x direction, for the plate
Quasilongitudinal waves	Particle displacements not purely in direction of wave propagation. Occur in solids with 'thin' cross-section	$k = \frac{\omega}{c} = \frac{2\pi}{\lambda}$	for the acoustic wave [7b]
Torsional waves	Shear wave generated in beams by moment excitation		$\lambda = \lambda_B \sin \theta$ [7c]
Transverse plane waves	Exist in solid bodies due to shear stresses. Same wave velocity as torsional waves		
Pure bending waves	Exist when the bending wavelength is large compared to the cross-sectional area (i.e., large solids).		
Corrected bending waves	Includes the effects of rotary inertia and shear deformation (for smaller structures)		
Rayleigh waves	Surface waves with amplitude decreasing below the surface (e.g., ocean). Occur in large, thick structures		

Adapted from Norton (1999).

Thin Rectangular Flat Plate

Table 1 presents formulas for bending wave motion in a finite thin rectangular plate. Consider an undamped uniform plate in contact with air and mechanically driven to carry a plane, bending wave of constant amplitude and propagation speed, c_{ph} (Figure 3). Wavenumbers are vector quantities, so that:

$$\text{where } \theta \text{ is the acoustic propagation angle.}$$

Resonant two-dimensional vibration of a rectangular flat plate involves vibration modes that are represented by a single point in wavenumber space (Figure 4), with wavenumbers:

$$k_{m,n} = \frac{2\pi}{\lambda_{m,n}} = \left\{ \left(\frac{m\pi}{L_x} \right)^2 + \left(\frac{n\pi}{L_y} \right)^2 \right\}^{1/2} \quad [8]$$

Critical frequency For sound radiation, the most important parameter is the ratio of the structural wavelength compared to the acoustic wavelength at the same frequency. The critical frequency (f_c) relates the ratio of acoustic and structural wavenumbers (and wavelengths) to frequency regions of efficient and inefficient sound radiation. The critical frequency (f_c) occurs when the structural and acoustic wavelengths are equal (i.e., $\lambda_B = \lambda$ and $f_c = f$). One of three conditions can occur at any given frequency:

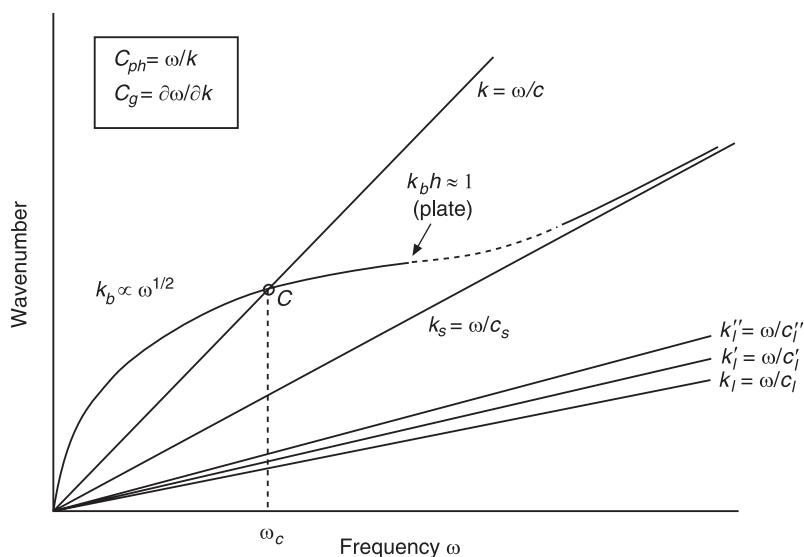

Figure 2 Dispersion curves for structural and acoustic waves. (Reproduced with permission from Fahy, 1985.)

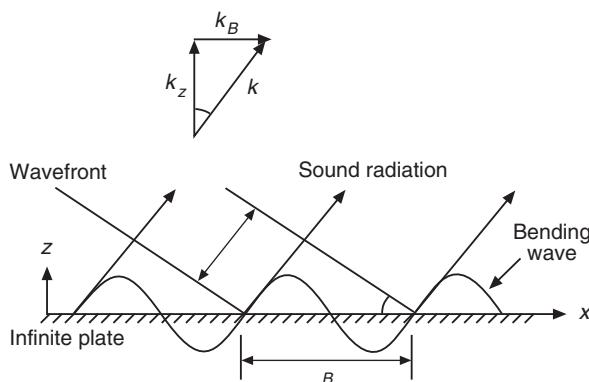

Figure 3 Sound radiation from a flat plate. (Adapted from Norton, 1999.)

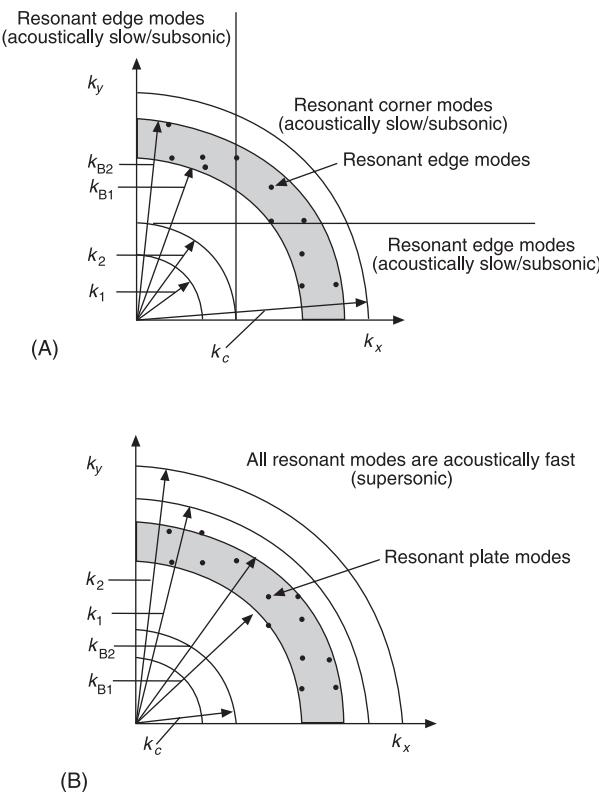

Figure 4 Flat plate wavenumber diagrams. (A) Acoustically slow plate modes ($k_m, n < k_C$), (B) acoustically fast plate modes ($k_m, n > k_C$). (Reproduced with permission from Norton, 1999.)

1. $f < f_c$ or $\lambda_B/\lambda < 1$ (equivalently, $c_{ph} < c$, $\lambda_B < \lambda$, $k < k_B$).

In this case the wave impedance (and k_z) is imaginary. Ideally (i.e., for an infinite structure), no net acoustic energy is radiated. In practice, for finite structures the sound radiation is poor and is generated by the edges and corners. This is

referred to as ‘subsonic’ or ‘acoustically slow’ (AS) sound radiation, since the structural wave-speed is lower than the acoustic wavespeed.

2. $f = f_c$ or $\lambda_B/\lambda = 1$ (equivalently, $c_{ph} = c$, $\lambda_B = \lambda$, $k = k_B$).

This is the condition for maximum efficiency of acoustic radiation because the structural and acoustic wave speeds, wavelengths and frequencies are equal.

3. $f > f_c$ or $\lambda_B/\lambda > 1$ (equivalently, $c_{ph} > c$, $\lambda_B > \lambda$, $k > k_B$).

At a given frequency, when the structural wavenumber is smaller than the corresponding acoustic wavenumber, net acoustic energy is radiated into the surrounding fluid by the plate. This is referred to as supersonic or ‘acoustically fast’ (AF) sound radiation (Figure 5).

Thin Circular Cylinders

A distinction is drawn between large diameter ‘thin shells’ and thicker walled, smaller diameter ‘pipes’. This section is applicable to thin cylinders in which cross-sectional distortion is important to the vibration response and sound radiation. Thick-walled pipes and beams are covered in the next section.

Thin Cylinder Vibration

Important parameters for thin cylinders are included in Table 3. Vibration modes for a cylinder (Figure 6) are characterized by their circumferential (n) and axial (m) orders, and corresponding wavenumbers (Table 4). Alternatively, cylinder vibration may be interpreted in terms of propagating waves. Three

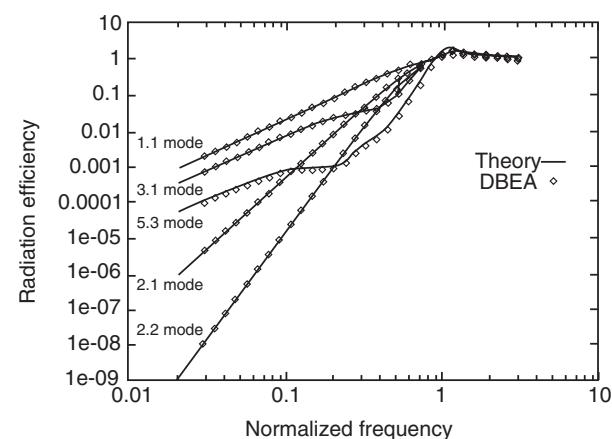

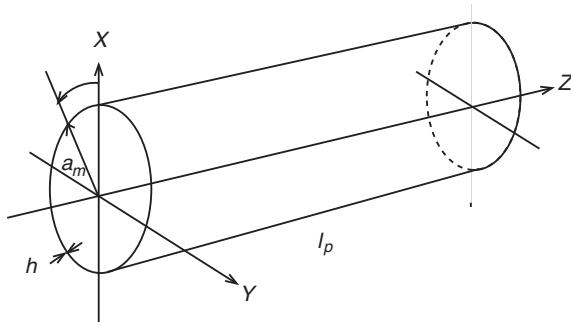

Figure 5 Radiation ratio for the low numbered modes of a square panel. (—) Theory, (o) discrete boundary element analysis. Table 3 Parameters for a simply supported thin cylinder

Parameter	Formula
Quasilongitudinal (plate) wave velocity	C_{LP} (see Table 1)
Poisson's ratio	ν
Cylinder dimensions	Thickness h , mean radius a_m and length L
Ring frequency ($m = 0, n = 0$)	$f_R = (c_{LP}/2\pi a_m)$ Hz
Critical frequency	Same as for a flat plate
Ratio of ring and critical frequencies	$f_c = (c^2/1.8c_{LP}h)$ Hz
Nondimensional frequency	$f_f = f/f_R$
Nondimensional natural frequencies ($n \geq 1$)	$v_{m,n}^2 = \beta^2 K^4 + \left\{ \frac{(1-\nu^2)K_m^2}{K^4} \right\}$
Dimensional natural frequencies ($n \geq 1$) (approximate)	$f_{m,n} = \left(\frac{c_{LP}}{2\pi a_m} \right)^2 \left\{ \beta^2 K^4 + \frac{(1-\nu^2)K_m^2}{K^4} \right\} \text{Hz}^2$
Nondimensional thickness	$\beta = \left(\frac{1}{\sqrt{12}} \right) \left(\frac{h}{a_m} \right)$
K_m (m = number of axial half-waves)	$K_m = k_m a_m = (m\pi/L)a_m$
K_n (n = number of full circumferential waves)	$K_n = k_n a_m = n$
K	$K^2 = K_m^2 + K_n^2$
Nondimensional axial wavenumber parameter	$k_a = k_m a_m \sqrt{\beta}$
Nondimensional circumferential wavenumber parameter	$k_c = k_n a_m \sqrt{\beta}$

**Figure 6** Thin cylinder geometry (after Szechenyi, 1971).

classes of waves may exist for a given circumferential order n , each with different ratios of axial, tangential and radial displacements. Shell curvature gives rise to tangential and axial membrane stresses when radial displacement occurs, coupling the three displacements. When considering acoustic radiation from cylinders, it is only necessary to consider the flexural wave class, for which radial displacement dominates. Cylinder flexural waves form axially propagating helical wave pairs, with the axial wavenumber k_z and circumferential wavenumbers, $\pm k_s$.

Waves of circumferential order n have a 'cutoff' frequency at $k_z = 0$ (i.e., $\lambda_z = \infty$) and cannot propagate freely below this frequency. The most important

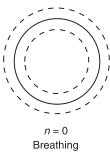

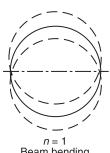

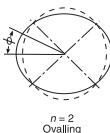

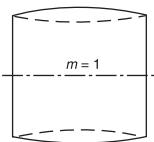

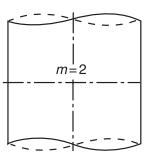

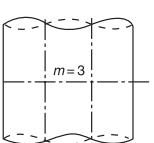

cutoff frequency is that of the $n = 0$ 'breathing' mode, referred to as the ring frequency, f_R . At this frequency, radial hooplike resonance occurs. The ring frequency separates regions in which shell curvature is more and less important. Above the ring frequency, the vibration and sound radiation properties become increasingly like that of a flat plate. Below the ring frequency, the effect of curvature and membrane strain means that phase speeds of flexural waves of low n can be supersonic at frequencies below the flat plate critical frequency (f_c). Formulas for the non-dimensional cutoff frequencies are given in **Table 3**.

Modal natural frequencies and wavenumbers are constrained by the dispersion relationship for a cylindrical shell. One such approximate relationship for $n > 1$ is given by:

$$v_{m,n}^2 = \beta^2 K^4 + \left\{ \frac{(1-\nu^2)K_m^2}{K^4} \right\} \quad [9]$$

where supplementary formulas are given in **Table 3**. For a small number of the lower mode orders, errors in the prediction of natural frequencies exist (up to 50%). However, the equation is sufficiently accurate for most applications. **Figure 7** is the non-dimensional wavenumber diagram for circular cylinders. The

Table 4 Vibration modes for a simply supported thin cylinder

Wave	Order	Description	Wavenumber
Circumferential modes	$n = 0, 1, 2, \dots$	Number of full circumferential wavelengths	
$n = 0$	$n = 0$	Peristaltic (breathing) mode	$k_{s0} = 0$ $\lambda_{s0} = \infty$
			
$n = 1$	$n = 1$	Beam bending	$k_s = 1/a_m$ $\lambda_s = 2\pi a_m$
			
$n = 2$	$n = 2$	Ovalling	$k_s = 2/a_m$ $\lambda_s = \pi a_m$
			
	$n = 3, 4, \dots$	Higher order modes	$k_s = n/a_m$ $\lambda_s = (2\pi a)/n$
Axial modes		Number of axial half-wavelengths	
$m = 0$	$m = 0, 1, 2, \dots$	Waves cannot propagate axially	$k_{z0} = 0$ $\lambda_{z0} = \infty$
			
$m = 1$	$m = 1$	Waves can propagate axially	$k_{z1} = \pi/L$ $\lambda_{z1} = 2L$
			
$m = 2$	$m = 2$	Waves can propagate axially	$k_{z2} = 2\pi/L$ $\lambda_{z2} = L$
			
Propagating helical waves	$m = 3, 4, \dots$	Waves can propagate axially	$k_z = m\pi/L$ $\lambda_z = 2L/m$
	$m = 1, 2, \dots$	$k_{m,n}^2 = \left(\frac{m\pi}{L}\right)^2 + \left(\frac{n}{a_m}\right)^2$	
	$n = 0, 1, 2, \dots$		

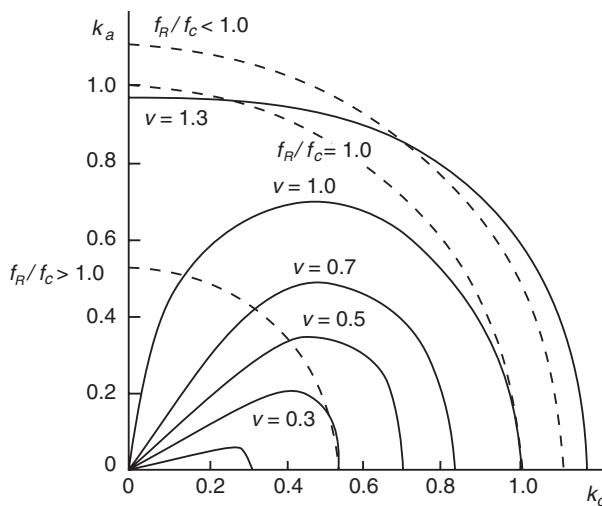

Figure 7 Nondimensional wavenumber diagram for simply supported circular cylinder with superimposed acoustic loci (for external sound radiation). (—) Constant frequency structural wavenumber loci, (---) critical frequency acoustic wavenumber curves (for various f_R/f_c ratios). (Adapted from Szechenyi, 1971.)

membrane effect on wave speed is seen in the bending of constant frequency loci toward the origin, particularly below the ring frequency ($v_f = f/f_R = 1$). An equivalent flat plate has circular loci.

Thin Cylinder Sound Radiation

Cylinders vibrate in response to some exciting force and this vibration will contain all the frequency components present in the excitation. The level of induced vibration and the consequent acoustic radiation depend on the type of excitation and the relative importance of resonant and nonresonant forced response. Preferential excitation of certain classes of modes may occur, where the exciting forces have a particular spatial structure or coupling constraint (such as for internal flow/acoustic excitation). The following discussion is relevant to multimode resonant vibration of cylinders in response to broadband mechanical excitation forces.

External sound radiation by a cylinder has no acoustic-structural coupling constraints other than the requirement that the acoustic wavenumber ($k = \omega/c$) must be greater than the structural wavenumber, for effective radiation. There are three relevant structural wave numbers (k_s , k_z and $k_{m,n}$). Cylinder modes are classified into two groups:

1. ‘AF’ (supersonic) modes ($k^2 \geq k_{m,n}^2$) are efficient sound radiators, with:

$$\sigma_{ra} = \left\{ 1 - \left(\frac{k_{m,n}}{k} \right)^2 \right\}^{1/2} \quad [10]$$

For increasing dissimilarity between $k_{m,n}^2$ and k^2 , this rapidly converges to unity and thus it may be assumed that $\sigma_{ra} = 1$ for AF modes.

2. ‘AS’ (subsonic) modes ($k^2 < k_{m,n}^2$) are inefficient sound radiators, with two subclasses
 1. $k_z < k$, $k_s > k$ (not relevant to the $n = 0$ mode), with $\sigma_{ra} \approx 0$
 2. $k_z > k$, $k_s < k$ which are ‘edge’ modes (Figure 8) with $\sigma_{ra} \ll 1$.

An appreciation of AF and AS modes may be obtained from Figure 7. Acoustically fast modes lie inside the circular arc of the acoustic loci. This diagram illustrates the importance of the ratio of ring to critical frequency (f_R/f_c) on acoustic radiation:

1. $f_R < f_c$
The ‘unwinding’ of the structural constant frequency loci at $v \approx 1$ causes shell waves to become subsonic between f_R and f_c and become supersonic above the critical frequency. The radiation behavior for $f > f_R$ is characteristic of a flat plate. This generally applies to large diameter thin cylinders (Figure 9).
2. $f_R > f_c$
Above the critical frequency, all modes are supersonic. This generally applies to industrial pipes.

Radiation Ratios of Engineering Noise Sources

Flat Plates

Band average radiation ratios Radiation ratios for individual plate and cylinder modes were presented in the previous section. In practice, average ‘band’ or ‘modal’ radiation ratios are more useful and are calculated for specified frequency ranges (e.g., for 1/3 octave bands). A number of modes will have natural frequencies in the frequency range and will contribute to the sound radiation. The analysis is based on the assumption of equipartition of vibration energy for all resonant modes within each frequency band.

This assumption is reasonably valid for mechanical excitation. However, for mechanical excitation there will be an additional contribution from the region of the plate close to the point of excitation. Resonant vibration of a flexible plate results in resonant sound radiation from the plate. This resonant sound radiation is controlled by the radiation ratio. Forced vibration of a small region near the excitation point results in additional forced sound power radiation, not controlled by the radiation ratio.

Acoustic coupling and excitation results in the selective vibration and sound radiation mainly from

efficiently radiating vibration modes. The vibration response of a flexible structure (e.g., plate, pipe) to flow/acoustic excitation will result in radiation ratios significantly different to those obtained for mechanical excitation. This is a crucial issue and was illustrated in Figure 1 for a steel plate. The main difference between the radiation ratios for mechanically and acoustically excited plates occurs below the critical frequency. This difference occurs because of the different contributions from subsonic modes ($\sigma_r < 1$) and supersonic modes ($\sigma_r \approx 1$). Above the critical frequency, all modes are supersonic. Below the critical frequency, sound radiation from ‘edge’ and ‘corner’ modes predominates, particularly the edge modes. Thus, plate radiation ratios are also influenced by the plate boundary conditions (e.g., free, simply supported, clamped, baffled or unbaffled).

Radiation ratio formulas for mechanically excited square and rectangular flat plates (for sensible plate dimensions) are included in Table 5. These are based on formulas for a simply supported plate with an additional term for clamped edges. Alternative formulas are also available. Material parameters for

common engineering materials are included in Table 6. Plate critical frequencies are plotted against plate thickness in Figure 10 for several materials.

Radiation ratio charts (Figures 11–13) prepared by Richards *et al.* (1979) (based on the formulas of Smith and Lyon (1965)), can also be used for square or rectangular plates of various thickness and surface area. Alternative design charts are those of Ver and Holmer (1971) (Figure 14: see **Noise: Noise radiated by baffled plates**) and the nondimensional chart of Bies and Hansen (1996) (Figure 15). Figure 16 shows a comparison between the formulas in Table 5 and the Ver and Holmer approach and some experimental results. Various experimental data are presented in Figures 17–23.

Cylindrical Shells and Cylindrical Bars

Cylinders may be broadly classified as ‘thick’- and ‘thin’-walled, depending on the ratio of the wall thickness to the cylinder radius. High-pressure industrial pipes have thick walls whereas thin cylinders are more representative of structures such as air-conditioning ducts or an aircraft fuselage. This is reflected in the ratio of the critical and ring frequencies, since:

$$\frac{f_c}{f_R} = \text{constant} \times \left(\frac{\text{cylinder mean radius}}{\text{cylinder wall thickness}} \right) \quad [11]$$

Thick cylinders have lower critical frequencies than thin cylinders and for the same radius, have lower ratios of f_c/f_R than thin-walled cylinders.

A cylindrical shell may be thought of as a rectangular plate, that has been rolled into a circular cylinder and the edges joined together. The wall thickness of a ‘shell’ is much smaller than the radius (i.e.,

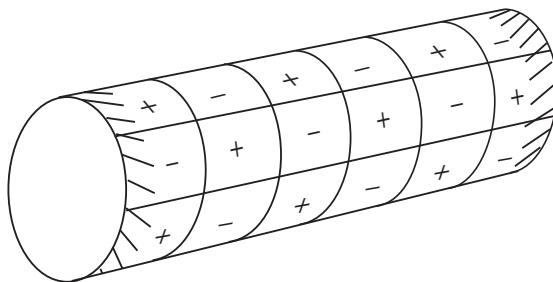

Figure 8 Cylinder ‘edge mode’ radiation (after Fahy, 1985).

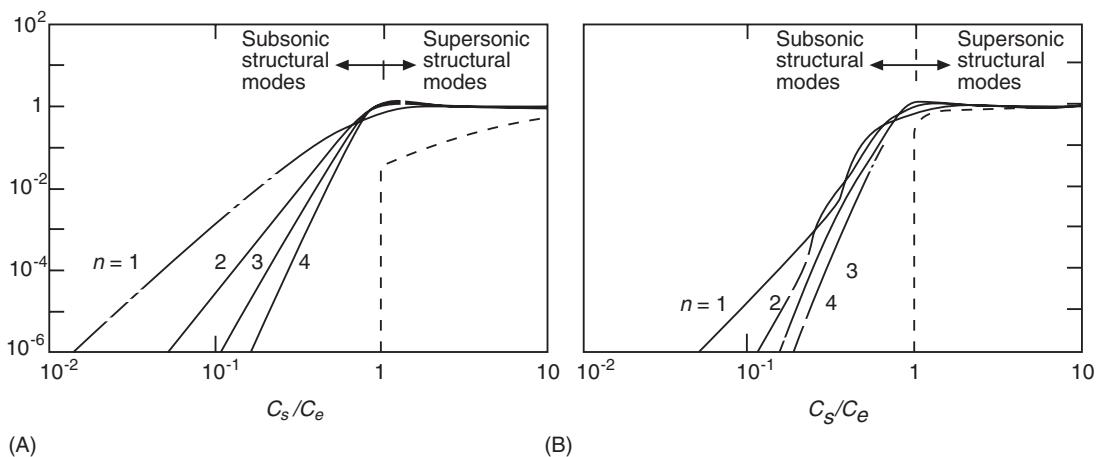

Figure 9 Radiation ratios for selected low-numbered modes of a thin cylinder. (A) $m = 1$, (B) $m = 10$ (Reproduced with permission from Norton, 1999.)

$b \ll a_m$). In the limit, a cylinder with very thick walls and relatively small radius radiates sound in the same manner as a solid circular bar. Cylinder radiation ratios vary depending on several parameters; including the type of excitation (e.g., mechanical or flow/acoustic) and cylinder dimensions (i.e., wall thickness, pipe radius, and length). In principle, there are three types of (external) radiation ratios for cylindrical shells. Formulas for the three 'shell' cases and for solid bar radiation are included in Table 7.

In general, the sound radiation from a mechanically vibrating cylinder may include components due to all four mechanisms, complicating the analysis. In this case, the radiation ratio to be used should correspond to the dominant type of excitation and response at the frequencies of interest.

Type 1: Uniformly radiating (pulsating) cylindrical shell The nondimensional radiation ratio for a long, uniformly radiating (pulsating) cylinder radiating into air is presented in Figure 24A. Figure 24B provides dimensional curves for a range of cylinder diameters.

This type of sound radiation is typical of long runs of industrial pipe with a forced internal pressure pulsation, such as from a reciprocating compressor.

There is no flexure (bending) along the length of the pipe. In practice, if the measured sound radiation from a long, industrial pipe run is reasonably constant (both around the circumference of the pipe and along its length), then Figure 24 provides a reasonable upper estimate of the radiation ratio.

There is an analogy between the vibration and sound radiation characteristics of a finite monopole (i.e., the pulsating sphere in Table 2) and a uniformly pulsating pipe (Table 7). Both radiate sound uniformly, the sphere around its circumference, the cylinder around its circumference and along its length.

Type 2: Oscillating thick-walled pipe or solid circular bar Sound radiation from long vibrating cylinders with small radii and very thick walls approaches that of a vibrating solid bar or rod. Nondimensional and dimensional graphs of the radiation ratio for a long, oscillating solid bar radiating into air, are presented in Figure 25A and in Figure 25B. Some experimental data are included in Figure 25C.

This type of sound radiation is typical of runs of small diameter, heavy industrial pipe or solid bars that vibrate as a rigid body. The radiation from an oscillating solid bar or small radius cylinder with

thick walls is analogous to a finite dipole, with a pronounced directivity in the plane of its cross-section (Table 7 of this article and Table 2 of **Noise: Noise radiated from elementary sources**).

Type 3: Forced peristaltic motion of a cylindrical shell Nonisotropic cylinders have nonuniform wall thickness (or some other nonuniformity) around the circumference or along the length of the cylinder. Forced vibration of the cylinder wall (e.g. due to internal pressure pulsations) results in a nonuniform vibration velocity pattern and sound radiation. The mechanism of sound radiation is similar to a uniformly radiating cylindrical shell (i.e., Type 1), but is complicated by the anisotropy of the cylinder wall. This is a specialized topic and interested readers are referred to the literature.

A reasonable engineering estimation for forced peristaltic sound radiation is to use the radiation

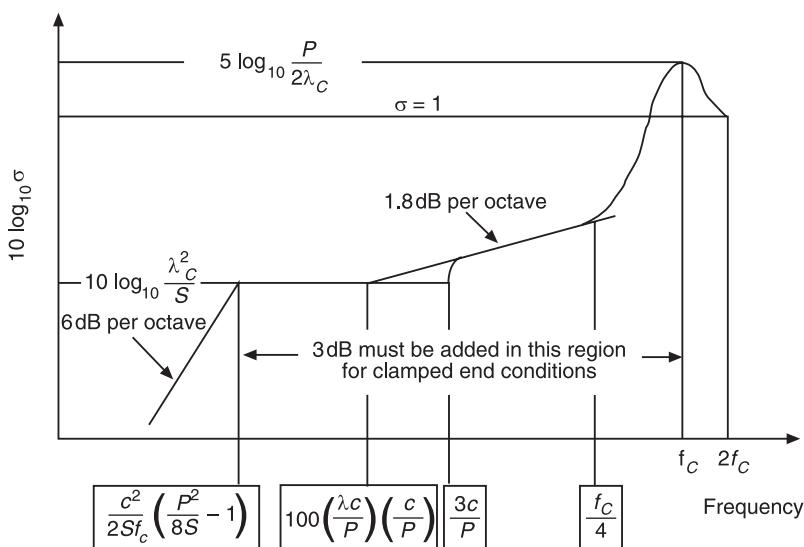

Figure 14 Radiation ratio design curve of Ver and Holmer (1971) for broadband mechanical excitation of flat plates. Perimeter P , (single sided) surface area S and critical wavelength λ_c . (Reproduced with permission from Norton, 1999.)

ratio for a uniformly pulsating cylindrical shell (i.e., Type 1).

Type 4: Resonant flexural vibration of a cylindrical shell Thin-walled cylinders, including low pressure piping, air-conditioning ducts and similar structures are likely to radiate sound due to resonant structural vibration. This is particularly the case where excitation of the cylinder wall occurs over a wide frequency range. Third-octave band radiation ratios of thin cylinders for mechanical excitation have been estimated (Figure 26A) based on the following assumptions:

1. Equipartition of vibration energy for all resonant modes within each band
2. Supersonic modes have $\sigma_{r\alpha} = 1$ and subsonic modes have $\sigma_{r\beta} = 0$
3. No nonresonant contribution to vibration response and sound radiation
4. All structural modes will radiate sound externally.

These four assumptions are reasonably valid for mechanical excitation. They are all invalid for acoustic/flow excitation because of the nature of acoustic-structural coupling.

Alternative radiation ratio charts for point excited tubes radiating into air and water, for a range of pipe radius to wall thickness (a_m/h) values have been calculated (Figure 26B).

Various experimental cylinder radiation ratio data for mechanical excitation are presented in Figures 27–30.

Type 5: Coupled flexural vibration of a cylindrical shell Various experimental cylinder radiation ratio data for flow/acoustic excitation are presented in Figures 31–33.

Beams and structures

The radiation ratios for elliptic beams, I-beams and a frame made from square box section tubes; including various approximate models and experimental radiation ratio measurements have been investigated. A selection of results is presented in Figures 34–37.

Summary

This article summarizes the fundamentals of vibration generated sound with particular reference to flexible structures. The basic theory presented includes the governing equations for thin-walled plate and shell vibration, the linear, homogeneous acoustic wave equation, and the Kirchoff–Helmholtz integral equation. The various types of wave propagation are summarized and compared for ‘acoustic efficiency’. It is demonstrated that low impedance waves dominate vibration generated sound from flexible structures. Published radiation ratio data is summarized for a wide range of practical configurations appropriate for engineering applications.

Flexible structures covered include thin rectangular flat plates, thin cylinder vibration, thin cylinder sound radiation, band averaged response of flat plates, uniform pulsating cylinders, oscillating thick-walled pipes or bars, forced peristaltic motion of shells, resonant flexural vibration of shells, coupled flexural vibration of shells, elliptic beams, I-beams, and frames.

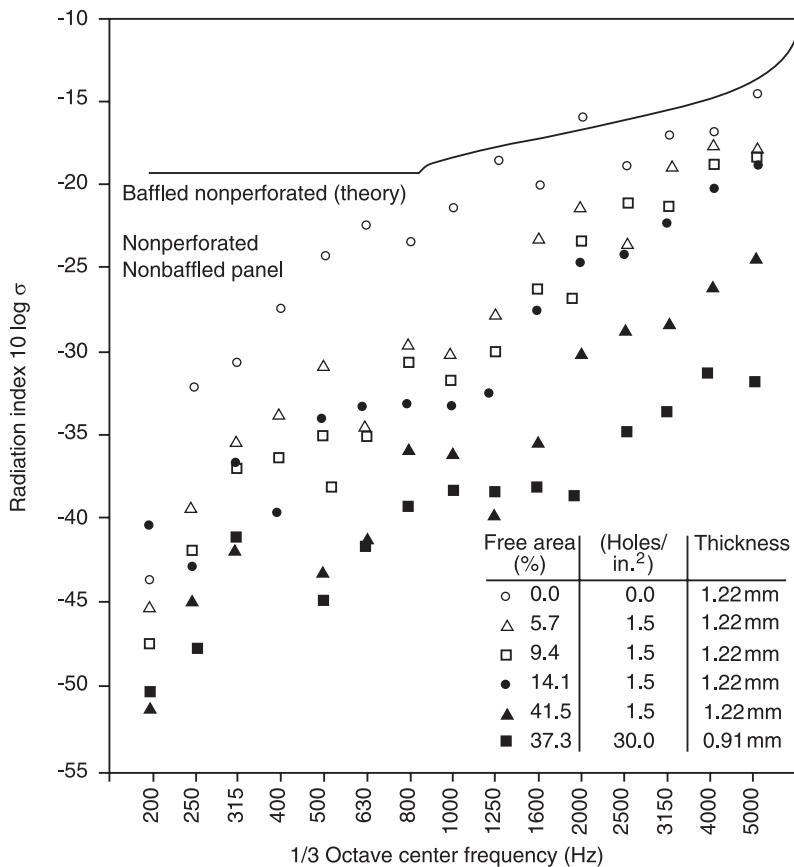

Figure 20 Measured radiation ratios of 1 mm thick perforated panels. Reproduced with permission from Fahy (1985).

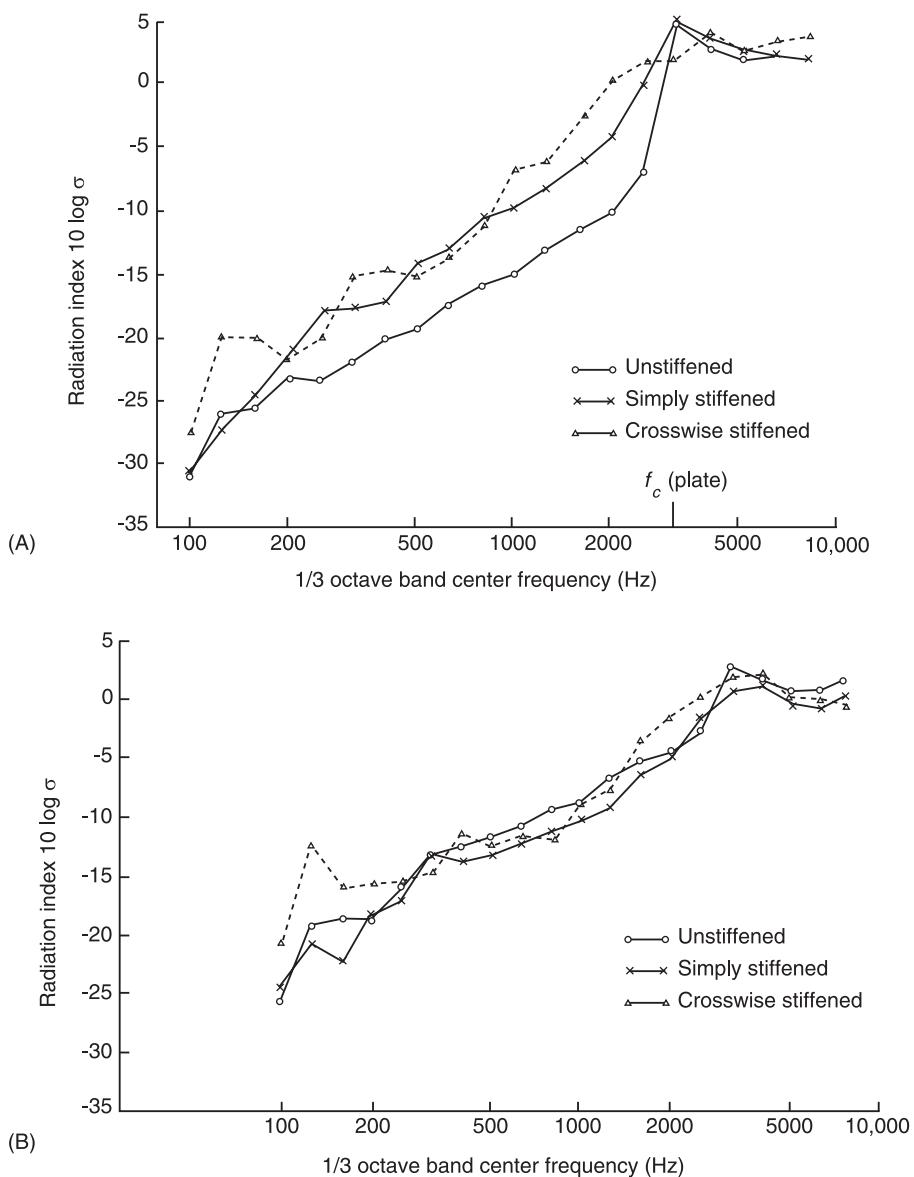

Figure 21 Measured radiation ratios of unstiffened and stiffened plates for (A) point mechanical excitation and (B) diffuse sound field excitation. (Reproduced with permission from Fahy, 1985.)

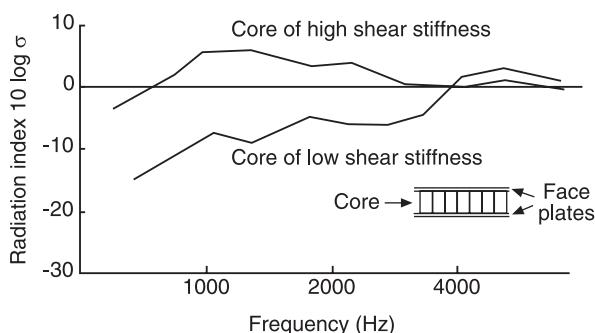

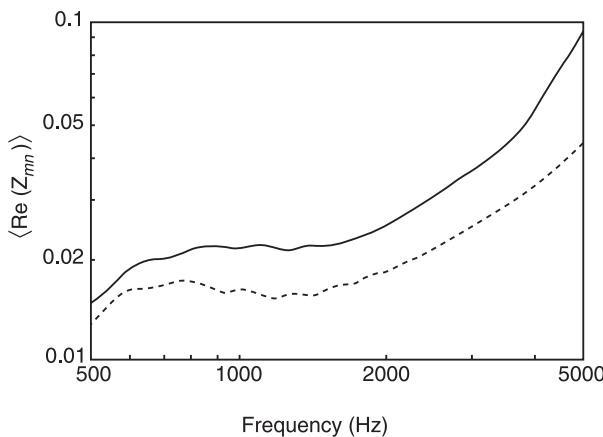

Figure 22 Measured radiation ratios of honeycomb sandwich panels. (Reproduced with permission from Fahy, 1985.)

As for compact engineering sources (rigid-body sound radiation), this article clearly illustrates that the radiation ratio is a very important parameter in vibration generated sound, as it is the link between vibration and the associated radiated sound. Knowledge of the radiation ratio of a structure allows for the prediction of vibration generated sound from measured or predicted vibration levels. The radiation ratio is thus a useful engineering design tool for noise and vibration control optimization studies.

Nomenclature

a_m	mean radius
c	speed of sound in air
E	Young's modulus
f	frequency
h	thickness
L	length
p	acoustic pressure
P	perimeter
S	surface area
u	particle displacement
$\langle v^2 \rangle$	space, time averaged
v	Poisson's ratio
λ	wavelength
θ	acoustic propagation angle
ϕ	incidence angle

VIBRATION INTENSITY

doi:10.1006/rwvb.2001.0169

Introduction

The instantaneous vibration structural intensity (VSI) is defined as the vibration mechanical power passing

through a unit cross-sectional area of a structure. It is defined as the stress traction vector \mathbf{t} at the surface of the cross-section times the projected particle velocity at the same cross-section, i.e.:

$$\mathbf{I}(x, y, z, t) = \mathbf{t} \cdot \mathbf{v} \quad [1]$$

To clarify the concepts involved in this definition, and the physical interpretation of VSI, a one-dimensional elastic structural model is presented first.

Consider an infinite elastic bar of a cross-section $A(x)$ undergoing longitudinal vibration $u(x, t)$, with ρ and E being the constant density and Young's modulus, respectively. The net total mechanical power flow out of the surfaces of an element of length dx at stations x and $x + dx$ with total cross-sectional forces $F(x)$ and $F(x + dx)$ due to deformation of the element is given by:

$$\frac{\partial I(x, t)}{\partial x} = -\frac{\partial}{\partial x} \left[F(x, t) \frac{\partial u}{\partial t}(x, t) \right]$$

Since $F(x) = EA(\partial u / \partial x)$, then the net outflow of mechanical power is:

$$\frac{\partial I(x, t)}{\partial x} = -\frac{\partial}{\partial x} \left[EA \frac{\partial u}{\partial x} \frac{\partial u}{\partial t} \right] \quad [2]$$

The equation of motion for an elastic rod is given as:

$$\frac{\partial}{\partial x} \left(A \frac{\partial u}{\partial x} \right) = \frac{1}{c^2} A \frac{\partial^2 u}{\partial t^2} - \frac{q(x, t)}{E} \quad [3]$$

with $c = \sqrt{E/\rho}$ being both the phase and group velocity for the bar. The potential and kinetic energy densities, U and K , for the cross-section are given by, respectively:

$$U = \frac{1}{2} EA \left(\frac{\partial u}{\partial x} \right)^2$$

$$K = \frac{1}{2} \rho A \left(\frac{\partial u}{\partial t} \right)^2$$

The total energy density e is thus given by:

$$e = U + K$$

Differentiating e partially with time and substituting the equation of motion into the resulting expression one obtains the balance law for VSI.

$$\frac{\partial I}{\partial x} = -\frac{\partial e}{\partial t} + \pi \quad [4]$$

where $\pi(x, t)$ is the externally injected mechanical power into the element by a distributed force $q(x, t)$, i.e.:

$$\pi(x, t) = q(x, t) \frac{\partial u}{\partial t}(x, t)$$

Consider a free propagating longitudinal wave in an infinite undamped rod, propagating in the positive x -direction, where the longitudinal displacement is given by:

$$u(x, t) = u_0 \cos(kx - \omega t)$$

with u_0 being the amplitude. The instantaneous energy density e and VSI are, respectively:

$$e = k^2 EA u_0^2 \sin^2(kx - \omega t)$$

$$I = -EA \frac{\partial u}{\partial t} \frac{\partial u}{\partial x} = ck^2 EA u_0^2 \sin^2(kx - \omega t)$$

thus $I(x, t) = ce(x, t)$.

Generally, this is not true for other vibrational fields. The time- and space-averaged instantaneous \bar{I} and \bar{e} are:

$$\bar{I} = \langle I \rangle_{x,t} = \frac{1}{2} EA u_0^2 k^2 c$$

$$\bar{e} = \langle e \rangle_{x,t} = \frac{1}{2} EA u_0^2 k^2$$

Both \bar{I} and \bar{e} are always positive, and $\bar{I} = c\bar{e}$.

One should note that c is the group velocity for a longitudinal wave propagating in an elastic rod. The instantaneous VSI fluctuates in time. Examining:

$$\frac{I(x, t)}{\bar{I}} = 2 \sin^2(kx - \omega t) = 1 - \cos 2(kx - \omega t)$$

shows that $I(x, t)$ is always positive, with a mean-flow component and a time varying component whose frequency is 2ω , i.e., twice the frequency of the propagating wave. Furthermore, the instantaneous VSI fluctuates between 0 and 2 every half-wavelength. This indicates that the mechanical power flow fluctuates about a mean value \bar{I} .

For a standing wave field, such as that given by two waves propagating in opposite directions, the total displacement field is given by:

$$u(x, t) = \frac{1}{2} u_0 [\cos(kx - \omega t) + \cos(kx + \omega t)]$$

$$= u_0 \cos kx \cos \omega t$$

Here the instantaneous $I(x, t)$ and $e(x, t)$ are given by:

$$I(x, t) = -\frac{1}{4} EAk^2 c u_0^2 \sin(2kx) \sin(2\omega t)$$

$$e(x, t) = \frac{1}{4} EAk^2 u_0^2 [1 - \cos(2\omega t) \cos(2kx)]$$

$$\langle I(x, t) \rangle_t = I_a = \frac{1}{2} \operatorname{Re}[F \dot{u}^*] \quad [8]$$

Note that the $I \neq ce$. The time- and space-averaged value of VSI and e are

$$\bar{I} = 0 \quad \bar{e} = \frac{1}{4} EAk^2 u_0^2$$

This means that for standing wave fields in undamped rods, the net flow of energy is zero.

Complex Vibration Intensity

Frequently, the displacement, velocity and internal stress fields are represented by complex functions. To accommodate such formulation, one can derive the expressions for the VSI in terms of these complex representations. Since $I = -F \dot{u}$, then let:

$$F(x, t) = \operatorname{Re}[\hat{F}(x) e^{-i\omega t}]$$

$$u(x, t) = \operatorname{Re}[\hat{U}(x) e^{-i\omega t}]$$

If one defines a complex VSI as:

$$\begin{aligned} \hat{I}(x) &= \frac{1}{2} (\hat{F} e^{-i\omega t}) (-i\omega \hat{U}(x) e^{-i\omega t})^* \\ &= \frac{i\omega}{2} \hat{F}(x) \hat{U}^*(x) \end{aligned} \quad [5]$$

$$\hat{I} = I_a + iI_r \quad [6]$$

where the starred quantities are the complex conjugates, then one can show that the VSI can be given by:

$$I(x, t) = \operatorname{Re} \left\{ \hat{I}(x) [1 + \exp(-2i\omega t)] \right\} \quad [7]$$

The real part of \hat{I} , I_a , is known as the active intensity and is the VSI defined as $I(x, t)$ and given earlier as the net power flow. The imaginary part of \hat{I} , I_r , is known as the reactive intensity, which represents the inertial power flowing in opposite direction within one cycle and whose time average is zero. Henceforth, using complex representation of the forces and velocities, the VSI is given by:

Waves in Elastic Media

The instantaneous VSI vector $\mathbf{I}(x, y, z, t)$ is defined as the mechanical power passing through a unit cross-sectional area of an elastic solid and is defined by:

$$\mathbf{I}(x, y, z, t) = \boldsymbol{\sigma} \cdot \dot{\mathbf{u}} \quad [9]$$

where $\boldsymbol{\sigma}$ is the stress dyadic at a cross-sectional area and $\dot{\mathbf{u}}$ is the particle velocity at the same cross-section. The dot denotes partial differentiation wrt time t . VSI is a function of location and time.

The mechanical power, (also known as the ‘active intensity’ is defined as the real part of the time-averaged instantaneous intensity, $\mathbf{I}(t)$, i.e.:

$$\mathbf{I}_a = \langle \mathbf{I}(t) \rangle_{\text{time average}} = \frac{1}{2} \operatorname{Re}(\boldsymbol{\sigma} \cdot \dot{\mathbf{u}}^*) \quad [10]$$

Consider elastic waves propagating in an elastic solid. The stress-strain relation is given by;

$$\sigma_{ij} = G \left[\frac{2v}{1-2v} \varepsilon_{kk} \delta_{ij} + 2\varepsilon_{ij} \right] \quad [11]$$

where:

$$\varepsilon_{kk} = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}$$

G is the shear modulus, v is the Poisson’s ratio and the strain tensor is defined by:

$$\varepsilon_{ij} = \frac{1}{2} \left[\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right] \quad i, j = 1, 2, 3$$

resulting in stress-displacement relations given by:

$$\sigma_{ij} = G \left[\frac{2v}{1-2v} \frac{\partial u_k}{\partial x_k} \delta_{ij} + \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right] \quad [12]$$

where u_i , $i = 1, 2, 3$ are the three Cartesian components of the displacement vector, and:

$$\frac{\partial u_k}{\partial x_k} = \frac{\partial u_1}{\partial x_1} + \frac{\partial u_2}{\partial x_2} + \frac{\partial u_3}{\partial x_3}$$

where:

$$\delta_{ij} = \text{Kronecker delta} = 1 \quad \text{if } i = j, \text{ and } = 0 \text{ if } i \neq j$$

The potential energy density U , the kinetic energy density T , and the energy density e are given by:

$$U = \frac{1}{2} \sum_{i=1}^3 \sum_{j=1}^3 \sigma_{ij} \varepsilon_{ij} \quad [13]$$

$$T = \frac{\rho}{2} \sum_{i=1}^3 \frac{\partial u_i}{\partial t} \frac{\partial u_i}{\partial t} \quad [14]$$

$$e = T + U \quad [15]$$

where ρ is the density. The VSI at a cross-section whose normal is \mathbf{n} is defined as:

$$\frac{\partial e}{\partial t} = -\mathbf{I} \cdot \mathbf{n}$$

The total energy in a solid whose volume is V is the volume integral of e , $e_T = \int_V e dV$. The time derivative of the total energy is the integral of the normal component of the VSI on the surface S enclosing V is:

$$\frac{\partial e_T}{\partial t} = - \int_S \mathbf{I} \cdot \mathbf{n} dS = - \int_S \mathbf{I} \cdot dS$$

These result in the VSI vector:

$$\mathbf{I} = I_x \mathbf{i} + I_y \mathbf{j} + I_z \mathbf{k}$$

where each component is expressed by:

$$\begin{aligned} I_x &= -\sigma_{xx} \dot{u}_x - \sigma_{xy} \dot{u}_y - \sigma_{xz} \dot{u}_z \\ I_y &= -\sigma_{yx} \dot{u}_x - \sigma_{yy} \dot{u}_y - \sigma_{yz} \dot{u}_z \\ I_z &= -\sigma_{zx} \dot{u}_x - \sigma_{zy} \dot{u}_y - \sigma_{zz} \dot{u}_z \end{aligned} \quad [16]$$

or more explicitly in terms of the displacement vector in Cartesian coordinates:

$$\begin{aligned} I_i &= -G \left[\frac{2v}{1-2v} \frac{\partial u_k}{\partial x_k} \dot{u}_j \delta_{ij} + \frac{\partial u_i}{\partial x_j} \dot{u}_j + \frac{\partial u_j}{\partial x_i} \dot{u}_i \right] \\ i &= 1, 2, 3 \end{aligned} \quad [17]$$

Similar expressions can also be written for cylindrical and spherical coordinates, respectively.

In cylindrical coordinates, $\dot{\mathbf{u}} = (\dot{u}_r, \dot{u}_\theta, \dot{u}_\phi)$:

$$\begin{aligned} I_r &= -\sigma_{rr} \dot{u}_r - \sigma_{r\phi} \dot{u}_\phi - \sigma_{rz} \dot{u}_z \\ I_\phi &= -\sigma_{\phi r} \dot{u}_r - \sigma_{\phi\phi} \dot{u}_\phi - \sigma_{\phi z} \dot{u}_z \\ I_z &= -\sigma_{zr} \dot{u}_r - \sigma_{z\phi} \dot{u}_\phi - \sigma_{zz} \dot{u}_z \end{aligned} \quad [18]$$

In spherical coordinates, $\dot{\mathbf{u}} = (\dot{u}_r, \dot{u}_\theta, \dot{u}_\phi)$:

$$\begin{aligned} I_r &= -\sigma_{rr} \dot{u}_r - \sigma_{r\theta} \dot{u}_\theta - \sigma_{r\phi} \dot{u}_\phi \\ I_\theta &= -\sigma_{\theta r} \dot{u}_r - \sigma_{\theta\theta} \dot{u}_\theta - \sigma_{\theta\phi} \dot{u}_\phi \\ I_\phi &= -\sigma_{\phi r} \dot{u}_r - \sigma_{\phi\theta} \dot{u}_\theta - \sigma_{\phi\phi} \dot{u}_\phi \end{aligned} \quad [19]$$

The energy propagates at the group velocity defined by:

$$\mathbf{c}_g = \frac{\mathbf{I}}{e}$$

Longitudinal Waves in Elastic Bars

For longitudinal waves in an elastic bar of a variable cross-section $A(x)$, the displacement field is given by $u_1 = u(x)$ and $u_2 = u_3 = 0$ so that stress and strain tensors reduce to:

$$\varepsilon_{xx} = \frac{\partial u}{\partial x} \quad \sigma_{xx} = E \frac{\partial u}{\partial x}$$

These result in an expression for the VSI:

$$I_x = -E \frac{\partial u}{\partial x} \dot{u}$$

and for the total VSI through the cross-section $A(x)$ is:

$$I = \int_A I_x dA = -EA \frac{\partial u}{\partial x} \dot{u} \quad [20]$$

Flexural Waves in Beams (Bernoulli–Euler Theory)

For flexural waves in an elastic beam, the displacement vector is defined by:

$$\begin{aligned} u_1 &= -z \frac{\partial w}{\partial x} & u_3 &= w & u_2 &= 0 \\ -b/2 < z < b/2 \end{aligned}$$

with the transverse displacement being $w = w(x)$. The stresses become:

$$\begin{aligned} \sigma_{xx} &= E \frac{\partial u}{\partial x} = -Ez \frac{\partial^2 w}{\partial x^2} \\ \sigma_{xz} &= \frac{3}{2} \bar{\sigma}_{xz} \left[1 - \frac{4z^2}{b^2} \right] = -\frac{b^2}{8} E \frac{\partial^3 w}{\partial x^3} \left[1 - \frac{4z^2}{b^2} \right] \end{aligned}$$

The only component of the VSI is the x -component, which can be expressed by:

$$I_x(x, y, z) = -\sigma_{xx}\dot{u} - \sigma_{xz}\dot{w}$$

The total VSI is thus given by:

$$\begin{aligned} I &= \iint_{-b/2}^{b/2} I_x(x, y, z) dz dy \\ &= -B \left\{ \frac{\partial^2 w}{\partial x^2} \frac{\partial^2 \dot{w}}{\partial x} \right\} + B \left\{ \frac{\partial^3 w}{\partial x^3} \dot{w} \right\} \end{aligned} \quad [21]$$

where $B = Eb^3b/12$ is the bending rigidity. The first term of eqn [21] is due to the moment and the second term is due to shear.

Flexural Waves in Beams (Timoshenko Theory)

Timoshenko improved the Bernoulli–Euler theory for flexure in beams by introducing shear deformation and rotatory inertia. The displacement vector is given by:

$$u_1 = -z\phi \quad u_3 = w \quad u_2 = 0$$

The potential and kinetic energy densities are thus given, respectively, by:

$$\begin{aligned} U &= \frac{1}{2} GAK \left(\frac{\partial w}{\partial x} - \phi \right)^2 + \frac{1}{2} B \left(\frac{\partial \phi}{\partial x} \right)^2 \\ T &= \frac{1}{2} \rho A \dot{w}^2 + \frac{1}{2} \rho I \dot{\phi}^2 \end{aligned}$$

where the K is the shear correction factor given for two cross-sections:

$$\begin{aligned} K &= 0.833 \text{ rectangular cross-section} \\ &= 1.111 \text{ circular cross-section} \\ &= \pi^2/12 \text{ Mindlin factor} \end{aligned}$$

The total VSI for the cross-section becomes:

$$I = GAK \left(\phi - \frac{\partial w}{\partial x} \right) \dot{w} - B \frac{\partial \phi}{\partial x} \dot{\phi} \quad [22]$$

The first term in eqn [22] is due to shear and the second term is due to moment.

Flexural Waves in Elastic Plates (Classical or Kirchhoff Theory)

The displacement vector for a uniform thickness plate is given by:

$$\begin{aligned} u_1 &= u = z \frac{\partial w}{\partial x} \\ u_2 &= v = z \frac{\partial w}{\partial y} \\ u_3 &= w(x, y) \end{aligned}$$

Substitution of these into the stress–displacement equations results in the total VSI for the cross-section as follows:

$$\begin{aligned} I_x &= B' \left[- \left(\frac{\partial^2 w}{\partial x^2} + v \frac{\partial^2 w}{\partial y^2} \right) \frac{\partial \dot{w}}{\partial x} - (1-v) \frac{\partial^2 w}{\partial x \partial y} \frac{\partial \dot{w}}{\partial y} \right. \\ &\quad \left. + \left(\frac{\partial^3 w}{\partial x^3} + \frac{\partial^3 w}{\partial x \partial y^2} \right) \dot{w} \right] \end{aligned} \quad [23]$$

$$\begin{aligned} I_y &= B' \left[- \left(\frac{\partial^2 w}{\partial y^2} + v \frac{\partial^2 w}{\partial x^2} \right) \frac{\partial \dot{w}}{\partial y} - (1-v) \frac{\partial^2 w}{\partial x \partial y} \frac{\partial \dot{w}}{\partial x} \right. \\ &\quad \left. + \left(\frac{\partial^3 w}{\partial x^2 \partial y} + \frac{\partial^3 w}{\partial y^3} \right) \dot{w} \right] \end{aligned} \quad [24]$$

The first two terms of eqns [23] and [24] are due to bending and twisting moments, and the third term is due to shear.

The VSI written in terms of cylindrical coordinates can be written in terms of the transverse displacement $u(r, \theta)$

$$\begin{aligned} I_r &= \frac{1}{2} B' \left\{ \frac{\partial}{\partial r} (\Delta u) \frac{\partial u}{\partial t} \right. \\ &\quad \left. - \left[\frac{\partial^2 u}{\partial r^2} + v \left(\frac{1}{r} \frac{\partial u}{\partial r} + \frac{1}{r^2} \frac{\partial^2 u}{\partial \theta^2} \right) \right] \frac{\partial^2 u}{\partial t \partial r} \right. \\ &\quad \left. - (1-v) \left(\frac{1}{r} \frac{\partial^2 u}{\partial r \partial \theta} - \frac{1}{r^2} \frac{\partial u}{\partial \theta} \right) \frac{1}{r} \frac{\partial^2 u}{\partial \theta \partial t} \right\} \end{aligned} \quad [25]$$

$$\begin{aligned} I_\theta &= \frac{1}{2} B' \left[\frac{1}{r} \frac{\partial}{\partial \theta} (\Delta u) \frac{\partial u}{\partial t} - \left(\frac{1}{r} \frac{\partial u}{\partial r} + \frac{1}{r^2} \frac{\partial^2 u}{\partial r^2} \right) \frac{\partial^2 u}{\partial t \partial \theta} \right. \\ &\quad \left. - (1-v) \left(\frac{1}{r} \frac{\partial^2 u}{\partial r \partial \theta} - \frac{1}{r^2} \frac{\partial u}{\partial \theta} \right) \frac{1}{r} \frac{\partial^2 u}{\partial r \partial t} \right] \end{aligned} \quad [26]$$

where:

$$\begin{aligned} \Delta &= \text{Laplacian} = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \\ B' &= Eb^3/12(1-v^2) \end{aligned}$$

Extensional and Flexural Waves in Elastic Plates (Mindlin Theory)

The Mindlin plate theory allows for the correction of the classical Kirchoff plate bending theory by the addition of shear deformation and rotatory inertia. Including the extensional components, it assumes that the displacement vector is given by:

$$\begin{aligned} u_1 &= u(x, y, z) = U(x, y) + z\phi_x(x, y) \\ u_2 &= v(x, y, z) = V(x, y) + z\phi_y(x, y) \\ u_3 &= w(x, y) \end{aligned}$$

The stresses are thus given in terms of displacements as:

$$\begin{aligned} \sigma_{xx} &= \frac{E}{1-v^2} \left[\frac{\partial u}{\partial x} + v \frac{\partial v}{\partial y} \right] \\ \sigma_{yy} &= \frac{E}{1-v^2} \left[\frac{\partial v}{\partial y} + v \frac{\partial u}{\partial x} \right] \\ \sigma_{xz} &= G \left[\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right] = G \left[\phi_x + \frac{\partial w}{\partial x} \right] \\ \sigma_{yz} &= G \left[\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \right] = G \left[\phi_y + \frac{\partial w}{\partial y} \right] \end{aligned}$$

The VSI and total VSI are given by:

$$\begin{aligned} \hat{I}_x(x, y, z) &= -\sigma_{xx}\dot{u} - \sigma_{xy}\dot{v} - \sigma_{xz}\dot{w} \\ I_x(x, y) &= \int_{-b/2}^{b/2} \hat{I}_x dz \end{aligned}$$

The x -component of the total VSI vector has extensional and flexural components as $I_x = I_{xe} + I_{xb}$ where the x -component of the extensional and flexural total VSI is given by, respectively:

$$I_{xe} = -\frac{Eb}{1-v^2} \left[\frac{\partial u}{\partial x} + v \frac{\partial V}{\partial y} \right] \dot{U} - G \left[\frac{\partial U}{\partial y} + \frac{\partial V}{\partial x} \right] \dot{U} \quad [27]$$

$$\begin{aligned} I_{xb} &= -\sigma_{xz}h\dot{w} - B' \left\{ \left(\frac{\partial \phi_x}{\partial x} + v \frac{\partial \phi_y}{\partial y} \right) \dot{\phi}_x \right. \\ &\quad \left. + (1-v) \left(\frac{\partial \phi_x}{\partial y} + v \frac{\partial \phi_y}{\partial x} \right) \dot{\phi}_y \right\} \end{aligned} \quad [28]$$

For I_y , exchange $U \leftrightarrow V$, $\phi_x \leftrightarrow \phi_y$ and $x \leftrightarrow y$.

Elastic Waves in Cylindrical Shells

For wave propagation in an elastic cylindrical shell of thickness, b , and radius, a , the displacement vector has the components:

$$\begin{aligned} u(z, s) &= \text{axial,} \\ v(z, s) &= \text{circumferential,} \\ w(z, s) &= \text{radial} \end{aligned}$$

where z is the axial, and $s = a\theta$ is the circumferential coordinate.

The total VSI in the z - and s -directions are given by:

$$\begin{aligned} I_z &= -\frac{Eb}{1-v^2} \left[\frac{\partial u}{\partial z} \dot{u} + v \frac{\partial v}{\partial s} \dot{v} \right] - Gb \left[\frac{\partial u}{\partial s} \dot{v} + \frac{\partial v}{\partial z} \dot{u} \right] \\ &\quad - B' \left[\left(\frac{\partial^2 w}{\partial z^2} + v \frac{\partial^2 w}{\partial s^2} \right) \frac{\partial \dot{w}}{\partial z} - \left(\frac{\partial \Delta w}{\partial z} - \frac{1}{c_1^2} \frac{\partial \ddot{w}}{\partial z} \right) \dot{w} \right] \\ &\quad - \frac{Gh^3}{6} \frac{\partial^2 w}{\partial s \partial z} \frac{\partial \dot{w}}{\partial s} - \frac{Eh}{1-v^2} \frac{v}{a} \left[w \dot{u} + \frac{h^2}{6a} w \frac{\partial \dot{u}}{\partial s} \right] \\ &\quad - \frac{Gh^3}{12a} \left[\frac{\partial u}{\partial s} \frac{\partial \dot{w}}{\partial s} - \frac{\partial^2 u}{\partial z^2} \dot{w} \right] \end{aligned} \quad [29]$$

$$\begin{aligned} I_s &= -\frac{Eb}{1-v^2} \left[\frac{\partial v}{\partial s} \dot{v} + v \frac{\partial u}{\partial z} \dot{u} \right] - Gb \left[\frac{\partial v}{\partial z} \dot{u} + \frac{\partial u}{\partial s} \dot{v} \right] \\ &\quad - B' \left[\left(\frac{\partial^2 w}{\partial s^2} + v \frac{\partial^2 w}{\partial z^2} \right) \frac{\partial \dot{w}}{\partial s} - \left(\frac{\partial \Delta w}{\partial s} - \frac{1}{c_1^2} \frac{\partial \ddot{w}}{\partial s} \right) \dot{w} \right] \\ &\quad - \frac{Gh^3}{6} \frac{\partial^2 w}{\partial s \partial z} \frac{\partial \dot{w}}{\partial z} - \frac{Eh}{1-v^2} \frac{v}{a} \left[w \dot{v} + \frac{h^2}{6a} w \frac{\partial \dot{v}}{\partial s} \right] \\ &\quad - \frac{Gh^3}{12a} \left[\frac{\partial v}{\partial z} \frac{\partial \dot{w}}{\partial z} - \frac{\partial^2 v}{\partial z^2} \dot{w} \right] \end{aligned} \quad [30]$$

Applications

Semi-infinite Elastic Rod

Consider a semi-infinite elastic rod excited by a point force F_0 at $x = \xi$ and fixed at the end $x = 0$. The longitudinal displacement $u(x)$ is given by:

$$\begin{aligned}\hat{u}(x) &= -F_0 \frac{e^{ik\xi}}{kEA} \sin(kx) \quad x < \xi \\ &= -F_0 \frac{e^{ikx}}{kEA} \sin(k\xi) \quad x < \xi\end{aligned}$$

then $I_a = 0, \quad 0 < x < \xi$

$$= \frac{F_0^2}{2AE} \frac{c}{k} \sin k\xi \quad x > \xi$$

This shows that the vibration intensity is zero for $x < \xi$, since the vibration field is a standing wave. For $x > \xi$, the VSI is always positive, i.e., net power flow for all x . It fluctuates between 0 and a maximum $F_0^2 c / 2AE$ due to the constructive and destructive interference of the two propagating waves one from source at $x = \xi$ and one from its image at $x = -\xi$.

Semi-infinite Beam

Consider a semi-infinite beam in flexure, free at end $x = 0$, is acted upon by a point force F_0 at $x = 0$. The complex form of the transverse displacement $u(x)$ is given by:

$$\hat{u} = \frac{iF_0[R \exp(2ikL) \exp(-ikx) + \exp(ikx) + (1 + R \exp(2ikL)) \exp(-kx)]}{EIk^3[(1-i) - (1+i)R \exp(2ikL)]}$$

$$\hat{I} = \frac{\omega F_0^2}{Elk^3}$$

$$\times \left\{ \frac{1 - |R|^2 + i \exp(-kx) \left[(1 + |R|^2)(\sin(kx) - \cos(kx)) - |R| \cos(\theta + k(2L - x)) + \sin(\theta + k(2L - x)) \right]}{1 + |R|^2 + 2|R| \sin(\theta + 2kL)} \right\}$$

$$\hat{u} = -(1-i) \frac{F_0}{2EIk^3} [e^{ikx} + e^{-kx}]$$

One can show that the complex VSI is given by:

$$\hat{I} = \frac{\omega F_0^2}{Elk^3} \left[1 + i\sqrt{2} e^{-kx} \sin \left(kx - \frac{\pi}{4} \right) \right]$$

where

$$k^4 = \frac{EI}{\rho A}$$

then $\bar{I} = I_a = \omega F_0^2 / Elk^3$ is the active intensity and is a constant. The reactive intensity:

$$I_r = \frac{\omega F_0^2}{Elk^3} \sqrt{2} e^{-kx} \sin \left(kx - \frac{\pi}{4} \right)$$

is due to the near-field effect of the force boundary conditions at the end $x = 0$ and inertia terms.

Infinite Beam

Consider an infinite elastic beam in flexure acted upon by a point force at $x = 0$. The transverse displacement $u(x)$ is given by:

$$\hat{u}(x) = -\frac{F_0}{4Elk^3} [i e^{-ikx} + e^{-kx}] \quad x > 0$$

The time averaged VSI is given by:

$$\bar{I} = I_a = \frac{\omega F_0^2}{16Elk^3}$$

Finite Beam with Complex Absorbent Termination

Consider a finite beam of length L with a free end at $x = 0$, is terminated by a complex impedance termination such that the reflection coefficient $R = |R| \exp(i\theta)$. The response to a point force F_0 at $x = 0$ results in the transverse displacement field:

The complex VSI is then given by:

$$I_a = \bar{I} = \frac{\omega F_0^2}{Elk^3} \frac{1 - |R|^2}{1 + |R|^2 + 2|R| \sin(\theta + 2kL)}$$

Thus, the net power flow, i.e. active intensity is:

The reactive intensity, the imaginary part of \hat{I} , is due primarily to inertial terms and the nearfield effects of the boundary conditions. Note that if the termination has a perfect reflection coefficient, i.e., $R = \pm 1$, then the vibration field represents a standing wave and hence $I_a = 0$. Also note that if $R = 0$, there is no reflection representing a totally absorbent end, the beam behaves as if it is a semi-infinite beam.

Infinite Plate

Consider an infinite thin elastic plate acted upon by a point force F_0 at the center. The axisymmetric displacement field $w(r)$ is given by (Hayek):

$$\hat{w}(r) = -\frac{F_0}{8Dk^2} \left[iH_0^{(1)}(kr) - \frac{2}{\pi} K_0(kr) \right]$$

where H and K are the Hankel and modified Bessel functions, respectively. The farfield radial component of the active VSI vector is (Piaud and Nicholas):

$$(\hat{I}_a)_{\text{radial}} = \frac{\omega F_0^2}{32\pi D k^2 r}$$

The other component of the active VSI vector, i.e., the tangential component vanishes due to the symmetry of the point force.

Nomenclature

B, B'	bending stiffness
e	energy density
E	Young's modulus
F_0	point force
G	shear modulus
I_a	active intensity
I_r	reactive intensity
$I(x, y, z, t)$	instantaneous intensity
K	shear correction factor
\mathbf{t}	stress traction vector
T	kinetic energy density
\mathbf{u}	displacement vector
U	potential energy density
V	volume
v	Poisson's ratio
ρ	density
σ	stress dyadic

VIBRATION ISOLATION THEORY

E Riven, Wayne State University, Detroit, MI, USA

doi:10.1006/rwvb.2001.0179

Vibration isolation is one of the vibration control techniques where the source of vibration excitation and the object to be protected are separated by an auxiliary system comprising special devices called vibration isolators or vibration isolating mounts.

The effect of vibration isolation amounts to weakening of dynamic coupling between the source and the object thus reducing transmission of unwanted vibration excitation to the object. The weakening of the dynamic coupling may also cause effects such as: increasing static displacements between the source and the object, increasing low-frequency and transient relative displacements between the source and the object, and increases of size, weight, and cost of the installation. Thus, in many cases a multiparameter optimization is required to provide an acceptable vibration reduction effect while satisfying other constraints.

Vibration isolation is, probably, the most widely-used approach for vibration protection, the other ones being design approaches such as reduction of vibration excitation at the source, changes of masses and/or stiffnesses of the structural components, use of dynamic vibration absorbers, etc.

Vibration isolation devices have to comply with many constraints. Examples include: a need to install highly vibration-sensitive equipment in light and low-stiffness structures; exposure of elastomeric passive vibration control elements or electronic active vibration control elements to high temperatures (e.g., in engine compartments of vehicles); and space restrictions on vibration control devices. With few exceptions, commercially-available passive vibration isolation devices have not changed much during the last 30–50 years. The new developments, such as hydromounts, active mounts, etc., are not as reliable and are much more expensive than the passive mounts, and they are used where their unique performance characteristics justify living with their shortcomings. Their shortcomings are often overlooked and their advantages are often overhyped by clever promotion and they are often used in systems where less expensive, more reliable, and more compact passive isolators could be used, provided that they are properly selected.

Vibration isolation is a very broad area, including isolation of stationary equipment and measuring instruments, both vibration-sensitive and vibration-producing; isolation of vibration-and shock-sensitive electronic boards; isolation of engines and other parts of surface, underwater, and flying vehicles.

The ‘classic’ principles of vibration isolation described in textbooks and handbooks are often not applicable to real-life circumstances because of the dynamic complexity of the isolated objects, supporting structures, excitations, and vibration isolators. Detailed dynamic analysis/modeling of each practical case using available software packages would result in huge expense in both time and money. Even more importantly, the modeling is often impossible because

the input data on structures and excitations are not available with the required accuracy. However, an in-depth understanding of typical groups of vibration isolation problems allows us to formulate general approaches to typical cases of vibration isolation which result in near-optimal performance without the need for complex individual studies. This article addresses the characteristics of basic real-life vibration isolation systems.

Dynamic Properties of Vibration Isolation Systems

A vibration isolation system comprises three subsystems: the object being isolated, the supporting surface (floor, foundation), and the vibration isolators (mounts) placed between them. Depending on circumstances, the object must be protected from the objectionable vibratory motions of the supporting surface, or the supporting surface must be protected from the dynamic loads generated within the object. In some cases both tasks have to be addressed simultaneously. Each of the three subsystems represents a distributed dynamic system with an infinite number of degrees-of-freedom, which have to be considered at high frequencies. However, in many practical cases, the effectiveness of vibration isolation is especially critical in the low frequency range, about 5–100 Hz. Since only the lowest structural modes of the object and of the supporting structure are positioned in this frequency range, the higher modes can be neglected and both the object and the supporting structure can be considered as ideal rigid bodies.

Usually the mass of the flexible element of each isolator is a small fraction of the mass of the object being isolated, so it can be neglected at low frequencies and the isolator can be considered as a massless spring. At higher frequencies, wave resonances in the flexible element have to be considered (see below).

A correct design of the vibration isolation system results in its effective performance (adequate isolation) with maximum stiffness of the isolators, i.e., maximum stability of the system.

Inertia and Geometric Properties of Typical Isolated Objects

Inertia and geometric properties of the isolated object (mass, moments/radii of inertia, position of the center of mass/gravity (CG), directions of principal axes of inertia) significantly influence the dynamic characteristics of the vibration isolation system. Determining these parameters for a real-life object such as a heavy machine or an engine requires a substantial

experimental and/or analytical effort, which can be justified only in special cases. However, typical objects such as machines, engines, etc. demonstrate some generic trends related to their inertia and geometric properties.

Often, the natural coordinate frame is that in which the axis Z is vertical and the axes X , Y are in a horizontal plane. For example, rotational axes of rotors in rotary machines are either vertical (centrifuges, separators, machine tools with vertical spindles, etc.) or horizontal (fans, compressors, turbines, lathes, machining centers with horizontal spindles, etc.). Similarly located are massive reciprocating parts (rams of forging hammers, tables and carriages of machine tools and coordinate measuring machines (CMMs), etc.). In vibration-producing machines dynamic loads are vertical (crank presses, etc.) or horizontal (cold headers, reversing tables and gantries of surface grinders and CMMs, etc.). Vibration-sensitive machines usually have their maximum sensitivity axes in a horizontal plane, while the maximum amplitudes of floor vibration are usually in the vertical direction.

Even if there are no axes of symmetry, the principal axes of inertia are quasiparallel to the structural axes. Usually, the principal axes of inertia deviate from the axes of the natural coordinate frame by not more than 8° – 10° . For a planar system, the centrifugal moment of inertia ('product of inertia') in the coordinate frame X' , Y' inclined at angle α to the principal coordinate frame X , Y is $I_{x'y'} = \frac{1}{2}(I_x - I_y) \sin 2\alpha$. For $\alpha = 10^\circ$, $\sin 2\alpha = 0.34$. Thus, in the worst case when the magnitude of one of the principal moments of inertia I_x , I_y is significantly larger than the other, $I_{x'y'}$ is less than 0.17 of the larger principal moment of inertia. Often, magnitudes of the principal moments of inertia are relatively close to each other, thus magnitudes of the products of inertia are even less significant. In the first approximation, for the machine-like objects whose design axes are close to axes X , Y , Z of the natural coordinate frames, the centrifugal moments (products) of inertia are $I_{xy} \approx I_{xz} \approx I_{yz} \approx 0$.

There are some general trends related to mass distribution in typical machine-like structures, which are similar to a tri-axial ellipsoid. The radii of inertia for a tri-axial ellipsoid are $\rho_i = \sqrt{\left[\frac{1}{20}\left(H_j^2 + H_k^2\right)\right]}$, where H are diameters of the ellipsoid, and i , j , k are cyclically assigned meanings of x , y , z designating the directions of the axes. The radii of inertia of a machine or a machine-like unit can thus be calculated with errors not exceeding 10–15% if H designates the overall sizes of the unit in the respective directions.

Basic Characteristics of Elastic Mounts (Vibration Isolators)

The elastic mount (isolator) is a volumetric elastic (flexible) component having two terminals or surfaces for connecting with the isolated object and with the supporting surface. Unless special restraints are employed, the flexible element develops resistance to motion between the terminals in all translational and angular directions. In the low frequency range, usually of the greatest importance for vibration isolation, the flexible element can be considered as massless. Vibration transmissibility at high frequencies can be significantly affected by wave resonances in the body of the flexible element (see below) and the mass of the flexible element has to be considered.

The flexible elements develop resistance to motion (forces) between the terminals. This resistance is dependent on the magnitude and direction of the relative displacement between the terminals as characterized by the stiffness parameters, and on the magnitude and direction of their relative velocity, as characterized by the damping parameters. In cases when the flexible elements are represented by metal (usually, steel) springs, their damping is negligibly low and is frequently enhanced by specially designed dampers.

In a general case, the application of a force to the flexible element results in its deformation in a different direction from the direction of the force. In an arbitrary coordinate frame, whose origin coincides with the elastic center of the flexible element (see below), the elastic properties of a linear flexible element can be described by 36 stiffness constants k_{ij} where the first subscript indicates the direction of the forcing factor (force or moment), and the second subscript indicates the direction of the displacement (linear or angular) caused by this forcing factor. Three 'proper' translation stiffness constants k_{xx} , k_{yy} , k_{zz} describe deformations of the flexible elements in the directions of the coordinate axes from forces acting along the same axes. Six 'cross' translational stiffness constants k_{xy} , k_{xz} , k_{yx} , k_{yz} , k_{zx} , k_{zy} describe the translational deformations of the flexible element in the directions of the coordinate axes from forces acting along other axes; three 'proper' angular stiffness constants $k_{\alpha\alpha}$, $k_{\beta\beta}$, $k_{\gamma\gamma}$ describe the angular deformations of the flexible element about axes X , Y , Z , respectively, caused by the moments about the same axes. Six 'cross' angular stiffness constants, $k_{\alpha\beta}$, $k_{\alpha\gamma}$, $k_{\beta\alpha}$, $k_{\beta\gamma}$, $k_{\gamma\alpha}$, $k_{\gamma\beta}$, describe the angular deformations about one axis caused by moments about another axis. Another 18 'cross' stiffness coefficients represent translational–angular interactions, e.g., $k_{x\alpha}$, $k_{x\beta}$, $k_{y\alpha}$, $k_{y\beta}$, etc. The

stiffness constants have reciprocity properties; $k_{xy} = k_{yx}$; $k_{xz} = k_{zx}$; ... $k_{\alpha\beta} = k_{\beta\alpha}$; $k_{\gamma\eta} = k_{\eta\gamma}$...; etc. Directions of the deformation and of the forcing factor causing this deformation coincide only when the force or the moment is directed along (or about) one of the principal elastic axes. Any axis of symmetry is a principal elastic axis. The principal elastic axes are orthogonal to each other and intersect in the elastic center of the flexible element which defines the position of the element in the mathematical model of the system. This position is used in the equations of motion for the system. In a coordinate frame having its origin at the elastic center, translational/rotational cross stiffness constants vanish. In the principal coordinate frame of the flexible element all 'cross' stiffness constants vanish, $k_{ij} = 0$.

The overwhelming majority of the real-life vibration isolators have flexible elements with at least one axis of symmetry or one, more frequently two or more, planes of symmetry. Their dimensions are usually much smaller than the dimensions of the isolated object and/or distances between the isolators. Because of this, assuming that the elastic center of the flexible element is located in its geometrical or mass center is an acceptable approximation.

The angular stiffness of the isolation system is an important parameter. When all isolators are located in one (e.g., horizontal) plane, the angular stiffness of the installation about a horizontal axis is determined by the vertical stiffness of the isolators combined with distances between them, and by angular stiffness constants of the isolators. For a beam on two isolators with vertical, angular stiffnesses k_{z_1} , k_{z_2} , k_{α_1} , k_{α_2} , respectively, and distances between the CG and isolators a_1 , a_2 , respectively, the total angular stiffness is $k_{\alpha}^1 = (k_{z_1} + k_{z_2}) + (k_{z_1}a_1^2 + k_{z_2}a_2^2)$. Unless a high angular stiffness is specially designed into the isolator, the first bracket is usually negligible in comparison with the second bracket for the overwhelming majority of practical vibration isolation systems.

Usually, it is assumed that the damping constants of isolators are proportional to their stiffness constants. While it is very convenient analytically, it is not correct. First, this statement can be used only if the isolators have viscous (linear) damping. The overwhelming majority of isolators have elastomeric, wire-mesh, and other elements with nonlinear damping characteristics (e.g., dependent on vibration amplitude which is different for different isolators under the same object and for different directions for the same isolator). Also, their damping constants in various directions can vary in totally different ways from stiffness.

Elastically Supported Solid Object; Dynamic Coupling

In the general case the object is supported by an arbitrary number of arbitrarily located elastic mounts, characterized by all proper and cross-stiffness coefficients and by the corresponding damping coefficients. The system is excited by multiple forcing factors whose set can be resolved into three force components F_x , F_y , F_z , and three moment components M_x , M_y , M_z , as well as by the foundation motion acting on elastic mounts (translational motion components x_f , y_f , z_f and angular motion components α_f , β_f , γ_f). Six equations of motion can be written considering these parameters, which fully describe this six-degrees-of-freedom system. These equations show that all coordinates are dynamically coupled, or that any coordinate component of the external force or moment, as well as any coordinate component of translational or angular motion of the foundation is causing displacements of the object in all coordinate directions. Also, any coordinate component of translational or angular motion of the installed object is causing forces/moment to and displacements of the foundation in all coordinate directions. Such global coupling is not desirable, neither for performance in many important cases, nor for computational synthesis/optimization of the system.

In some cases of vibration isolation, it is required that the highest natural frequency should be below the range of frequencies of the objectionable external excitations, regardless of their directions. If there is a strong coupling between all six natural vibratory modes of the isolation system, it leads to a need to shift all natural frequencies down, thus using very low stiffness isolators and potentially causing instability of the system. This is true for both vibration sensitive objects and for vibration-producing objects. The computational analysis of such globally cross-coupled system becomes very complex and involved, partly due to the fact that the spectral characteristics of all excitations have to be identified and entered into the model.

One of the most effective ways of improving the performance of a vibration isolation system is by eliminating or, at least, reducing the dynamic inter-modal coupling in the system. This simplifies computing the natural frequencies of the system and makes the influences of various design parameters on the natural frequencies and modes more transparent. Also, it makes possible or, at least, simplifies bringing natural frequencies closer together (by some reduction of higher frequencies and some increase of lower frequencies) without a significant reduction of isolator stiffness constants. Finally, it may improve

the performance when the coupling between specific vibratory modes is undesirable.

Means for alleviation/elimination of intramodal coupling can be devised by analyzing the equations of motion. While the general equations are written for the natural coordinate frame, but with arbitrary attitudes of the isolators, with the exception of a special case of inclined mounts below, the isolators, usually having planes of symmetry, are placed in such a way that their principal axes are parallel to the natural coordinate axes. Also, angular stiffnesses of isolators as well as the products of inertia can usually be neglected. For vibration isolating installation of stationary machinery (as well as for many units of mobile machinery) all isolators (mounts) are situated in one horizontal plane, or:

$$a_{z_i} = \text{const} \quad [1]$$

If, in addition:

$$\sum_i k_{z_i} a_{x_i} = 0, \sum_i k_{z_i} a_{y_i} = 0 \quad [2]$$

then vertical (z) vibration of the system is not coupled with motions in other translational or rotational coordinates. If also:

$$\sum_i k_{x_i} a_{y_i} = 0, \sum_i k_{y_i} a_{x_i} = 0 \quad [3]$$

then vibrations along and about axis Z (coordinates z and γ) are uncoupled. These conditions are satisfied if the ratios of $\eta_x = k_x/k_z$, $\eta_y = k_y/k_z$ are constant for all isolators. If also:

$$\sum_i k_{z_i} a_{x_i} a_{y_i} = 0 \quad [4]$$

then the system of equations of motion is separated into two independent equations corresponding to coordinates z and γ , and two pairs of coupled equations in the $x - z$ plane ($x - \beta$), and in the $y - z$ plane ($y - \alpha$). The last condition is satisfied if the object has at least one plane of symmetry. A further reduction of coupling is achieved if the plane of location of the isolators contains the CG or:

$$a_{z_i} = 0 \quad [5]$$

In this case, vibratory motions along all coordinates are independent (uncoupled). The last condition

can be realized if the object is isolated not directly but is attached to a massive ‘inertia block’ allowing the CG position to shift. The inertia block can be then placed on isolators at the new CG level. In some cases, the isolators can be supported by special brackets at the CG level even without the inertia block. The same effect can be achieved by using inclined isolators in the $x - z$ and/or $y - z$ planes (see below). Coordinates x and/or y can also be uncoupled if the angular stiffness values of the isolators in the α and/or β directions, neglected before, are made very high, e.g., by using guideways in these directions; in this case angular vibrations are simply prevented from developing.

The most interesting are vibratory motions within the plane of symmetry, comprising coupled vibratory motions in two linear and one angular coordinates. A study of such a system ($x - z - \beta$) concluded that natural frequencies of a planar vibration isolation system are only weakly dependent on compliance with eqn [2]. They are largely determined by the value of η_x . When the decoupling condition (eqn [2]) is satisfied, the excitation force in the x -direction excites the rocking (horizontal-angular) vibration with resonances at natural frequencies $f_{x\beta}$ and $f_{\beta x}$ but does not excite vibration in the z -direction. When eqn [2] is not satisfied, the third resonance of the rocking vibration appears at the frequency f_z (vertical natural frequency) and intensive vertical (z) vibration of the object develops. With two mounts 1 and 2, amplitude of this vibration at $k_{z1}a_{x1}/k_{z2}a_{x2} = 1.2$ is $0.35/6.7 \approx 0.05$ of the maximum resonance amplitude of the rocking vibration; at $k_{z1}a_{x1}/k_{z2}a_{x2} = 1.7$ it is $0.95/8 \approx 0.12$ of the maximum rocking amplitude; and at $k_{z1}a_{x1}/k_{z2}a_{x2} = 2.5$ it is $1.6/6.5 \approx 0.25$ (it is assumed that $k_{x1}/k_{x2} = k_{z1}/k_{z2} = k_1/k_2$). The results are analogous in cases when the excitation force or motion is vertical. Such coupling, where the excitation in one direction causes a significant response in the perpendicular direction is undesirable in many cases of vibration isolation. Often, precision equipment units are two-to-three times more sensitive to horizontal than to vertical floor vibrations, whereas the vertical vibration amplitudes are 1.5–2 times greater than horizontal. Conservatively, the resonance amplitude of horizontal vibrations of the unit due to vertical excitation should not exceed $1/(2)(3) \approx 0.16$ of the resonant amplitude of vertical vibrations. This implies a maximum permissible asymmetry factor $k_{z1}a_{x1}/k_{z2}a_{x2} \leq 2.0$.

The natural frequencies of the coupled rocking vibrations in relation to the vertical natural frequency f_z (see eqn [10] below) are:

$$\frac{f_{x\beta}}{f_z}, \frac{f_{y\alpha}}{f_z} = \frac{1}{\sqrt{2}} \sqrt{\left(\frac{\sum k_x}{\sum k_z} \left(1 + \frac{a_z^2}{\rho_y^2} \right) + \frac{a_x^2}{\rho_y^2} \right)} \\ \mp \sqrt{\left(\left[\frac{\sum k_x}{\sum k_z} \left(1 + \frac{a_z^2}{\rho_y^2} \right) + \frac{a_x^2}{\rho_y^2} \right]^2 - 4 \frac{\sum k_x a_x^2}{\sum k_z \rho_y^2} \right)} \quad [6]$$

where $\rho_y = \sqrt{(I_y/m)}$ is the radius of inertia of the object about the y -axis, and a_z is the distance from the CG to the plane of the isolator locations.

Considering general trends of mass distribution and magnitudes of $a_{x,y}/a_z$ in typical machines, the following simplified formula provides the lower natural frequencies of rocking vibrations in two vertical coordinate planes within 5–10% for variation of parameters in the ranges $0.25 \leq \eta \leq 4$ and $0 \leq a_{x,y}/a_z \leq 1$:

$$f_{x\beta}, f_{y\alpha} \cong f_z \sqrt{\left(0.9 / \left[\eta_{x,y} + (a_{x,y}/a_z)^2 \right] \right)} \quad [7]$$

This expression does not contain the radii of inertia $\rho_{x,y}$ of the object. It allows us to quickly calculate the required stiffness ratio of the vibration isolators for a given installation if the required natural frequencies are specified. A similar expression can be written for $f_{y\alpha}$.

The natural frequency of the torsional vibration about the vertical axis is:

$$f_r = \frac{1}{2\pi} \sqrt{\left(\frac{k_r}{I_z} \right)} \approx \frac{1}{2\pi} \sqrt{\left(\frac{k_r(a^2 + b^2)}{M \frac{1}{5}(a^2 + b^2)} \right)} \\ = \frac{1}{2\pi} \sqrt{\left(\frac{4k_z}{\eta} \frac{5}{M} \right)} = f_z \sqrt{\left(\frac{5}{\eta} \right)} \quad [8]$$

The most natural way to comply with eqn [2] is to find the object weight W distribution between the mounting points and to use isolators whose stiffness constants k_{z_i} are proportional to the fraction W_i of the total weight acting on the corresponding i th mounting point:

$$k_{z_i} = AR_i, A = \text{const} \quad [9]$$

If each k_{z_i} in eqn [2] is replaced by W_i , it becomes an identity since distances a_x, a_y are measured from the CG. This condition can be satisfied either by constant stiffness isolators; or, by so-called ‘constant natural frequency’ (CNF) isolators, whose axial

(vertical) stiffness in the rated load range is proportional to the axial (weight) load on the isolator.

If constant stiffness isolators are used, the total vertical (z direction) stiffness Σk_{z_i} of all isolators is determined by the desired natural frequency in the z direction:

$$f_z \approx \frac{1}{2\pi} \sqrt{\frac{\sum k_{z_i}}{M}} \quad [10]$$

For selecting individual isolators, the weight distribution between the mounting points should be known and then isolators having stiffness constants proportional to the weight loads at the mounting points should be used. The position of the CG in the horizontal plane can be determined experimentally or by a calculation using detailed design drawings. Usually, the CG position is determined by an ‘expert judgment’ by the user, with at least $\pm 10\text{--}15\%$ error. For objects having heavy moving parts (tables, gantries, etc.) or changeable components, the position of the CG, can shift in addition to the above error. The weight distribution (vertical reactions at the mounting points) with known CG position can be uniquely calculated only for a statically determined case (three-point ‘kinematic mounting’). The weight distribution in statically indeterminate cases requires additional conditions to be known or assumed. For the assumption that the mounting surfaces of both the object and the base/floor/foundation are rigid (or, at least, much more rigid than the isolators) and flat, and the floor surface horizontal, in the first approximation all reactions are identical. Unevenness (deviations from flatness) of the mounting surfaces, not negligible in comparison with the average mount deformation, or reduced stiffness of at least one mounting surface in at least one area lead to uneven deformations of the mounts, and to changing load distribution. Conservatively, variation of weight distribution between the mounting points can be at least $\pm 35\%$. Commercial vibration isolators cannot be selected in accordance with the established/assumed weight distribution since they have a ratio of the stiffness constant between the adjacent mounts in the line of about 1.6 (on average). Hardness of rubber in elastomeric isolators varies within ± 5 Durometer units ($\pm 17\%$ stiffness variation).

With all these uncertainties, the scatter of stiffness-to-weight ratios of the isolators selected in accordance with the calculated/assumed weight distribution is $\pm 1.15 \times 1.35 \times 1.6 \times 1.17 = \pm 2.9$ times, which is equivalent to asymmetry factor $k_{z1}a_z a_{x1}/k_{z2}a_{x2} = 2.9 \gg 2$, see above. It results in excessive intramodal coupling.

CNF vibration isolators have a special nonlinear load-deflection characteristic so that their stiffness values in all directions are proportional to the load in the direction of its main axis (weight load). In the commercially realized CNF vibration isolators, deviation from this proportionality does not usually exceed $\pm 10\text{--}15\%$. It has been shown that the tolerance on the rubber hardness does not influence noticeably the CNF characteristic. Thus, the use of CNF isolators satisfies the decoupling condition (eqn [2]) with the scatter not exceeding $\pm 1.1\text{--}1.15$ times. This provides an adequate decoupling. The nonlinear load-deflection characteristic of CNF vibration isolators may create undesirable nonlinear vibratory effects such as excitation of sub- or superharmonic vibration, but such effects are not significant due to relatively low vibration amplitudes in typical vibration isolation systems, especially when damping in the isolators is not very low.

Vibration Isolation System with Inclined Mounts

The complete decoupling between horizontal and angular (about perpendicular horizontal axis) vibrations can be desirable to create conditions for independent variation of the corresponding natural frequencies in order to make them closer to each other, etc. Such a decoupling in a system having one plane of symmetry can be achieved by placing the vibration isolators in the horizontal plane passing through the CG, but such design is not always easy to realize. Another approach is by using vibration isolators with inclined principal stiffness axes ('inclined mounts'). Figure 1 shows such system in the $x-z$ plane; a similar arrangement can be also realized in the $y-z$ plane. The origin of the coordinate frame coincides with the 'stiffness center' (a force passing through this point causes a purely translational displacement of the installed object, without angular displacements). The moment about the stiffness center causes a pure rotational motion, without any translational displacement. The principal elastic axes of the isolators p, r are inclined relative to the coordinate axes; stiffness coefficients of the isolators in directions p, r are k_p, k_r , respectively.

Decoupling of the coupled rocking (horizontal-angular) vibratory modes can be achieved by selection of the inclination angle of isolators at which the elastic center coincides with the CG. Then the resultant of the elastic reactions, acting on the object from the isolators when the object is displaced in the x -direction, is passing through the CG. Also, the resultant of the elastic reactions at a rotation of the object is a moment about the CG. The decoupling condition is $\varepsilon = 0$ or:

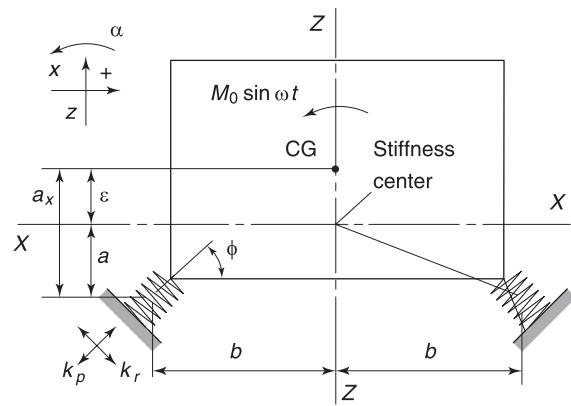

Figure 1 Vibration isolation system with inclined mounts.

$$\frac{k_r}{k_p} = \frac{(a_x/a_z) + \cot\varphi}{(a_x/a_z) - \tan\varphi} \quad [11]$$

When this is satisfied, the natural frequency of the translational vibration is $\omega_{x\beta} = \omega_x$, and the natural frequency of angular vibration is:

$$\begin{aligned} \omega_{\beta x} &= \omega_x \lambda_1 = \omega_\beta \\ &= \frac{a_x}{\rho_y} \sqrt{\left(\frac{4k_z}{m} \frac{1}{\cos^2\varphi + (k_r/k_p) \sin^2\varphi} \right)} \quad [12] \end{aligned}$$

A disadvantage of using inclined vibration isolators is the need for individual selection of the required inclination angle for each object, unless it is done for a mass produced object, e.g., for a car engine. Also, such 'geometric' decoupling does not provide for the complete decoupling if the mass distribution within the object may vary, e.g. due to the presence of moving components or the changing weight of the workpiece for machine tools. If the vibration is excited by stopping/reversal of a moving heavy mass, the complete decoupling would be realized only if the resultant of the dynamic forces passes through the CG. Otherwise, the dynamic exertion can be presented as a combination of a force passing through the CG and a moment, thus causing simultaneous translational and angular vibrations ('coupling by excitation forces').

Dynamics of Single-degree-of-freedom Vibration Isolation System

The object can be vibration-sensitive and in need of protection from steady and/or transient vibrations

transmitted from some vibration-producing objects via the base. In other cases, the object is a source of steady vibrations or shocks whose transmission to the base/foundation as dynamic or vibratory forces should be prevented or reduced. Some objects are vibration-sensitive during their working process while generating objectionable dynamic loads during their auxiliary motions (e.g., a precision surface grinder with a heavy reciprocating table or an internal combustion engine in a car, which produces undesirable dynamic inputs to the occupants but has to be protected from intense vibration transmitted from the road). Thus, transmission of vibratory forces and/or displacements (or accelerations) both from the object to the base and in the opposite direction may be of interest. It depends on correlations between the spectral components of the dynamic inputs to the system and the natural frequencies and natural modes of the vibration isolation system, as well as on the stiffness constants of the isolators, on the effective masses of the object and the base and, last but not least, on the character and magnitudes of damping in the isolators. When the dynamic characteristics of the subsystems have to be considered in more detail, e.g. when wave resonances in the isolators as well as several natural modes of the object/base have to be considered, the subsystems cease to be ‘lumped parameters’ and can be characterized by their impedances.

A single-degree-of-freedom (SDOF), uni-axial vibration isolation system is a convenient model to clarify the basic dynamic effects of vibration isolation installations. This system comprises: object to be isolated (mass m); flexible connectors (vibration isolator); base/foundation, mass m_f . Usually, $m_f \gg m$, or at least $m_f > m$. The vibration isolator can deform only in one direction. Five typical modifications of the dynamic model are shown in Figure 2. In Figure 2A the isolator is represented by a parallel

connection of an elastic element (stiffness k) and a viscous damper whose resistance F_v to the relative motion x between its terminals is proportional to the relative velocity, $F_v = c(\dot{x}_1 - \dot{x}_2)$, where c is the damping coefficient. A pure viscous damper is a convenient idealization for analytical purposes but in most cases not a realistic element. The isolator in Figure 2B combines elastic properties (stiffness k) and energy dissipation properties of a hysteretic type (material damping), whereas the relative energy dissipation ψ (and logarithmic decrement δ) does not depend on the vibration frequency ω . Such hysteretic damping can be represented by a linear (viscous) damper with a variable damping coefficient, $c_h = c(\omega) = \psi/2\pi\omega$. Hysteretic damping is characteristic for elastomers (rubbers), wire mesh, etc.

Figures 2C and D show two embodiments of so-called ‘relaxation’ suspension: a parallel connection of elastic element k and viscous damper c in series with another elastic element $k_1 = Nk$, Figure 2C; a series connection of a damped isolator $k' - c'$ and an undamped isolator $k'' = Nk'$, Figure 2D. In Figure 2E the isolator is split into two elements with stiffness values k_1 and k_2 and an intermediate mass is placed between them (see below).

In applications with large vibration amplitudes (e.g., vehicle suspensions) isolators with Coulomb friction dampers are sometimes used.

The isolation systems shown in Figure 2 can be characterized by absolute and relative transmissibilities. The absolute transmissibility is the degree of reduction of the dynamic force or vibratory motion provided by the isolation system. For dynamic force generated inside the object, transmissibility μ_F is a ratio of the force amplitude F_f transmitted to the foundation to the amplitude F of the excitation force. For vibratory motion of the foundation, transmissibility μ_x is the ratio of the vibration amplitude of the

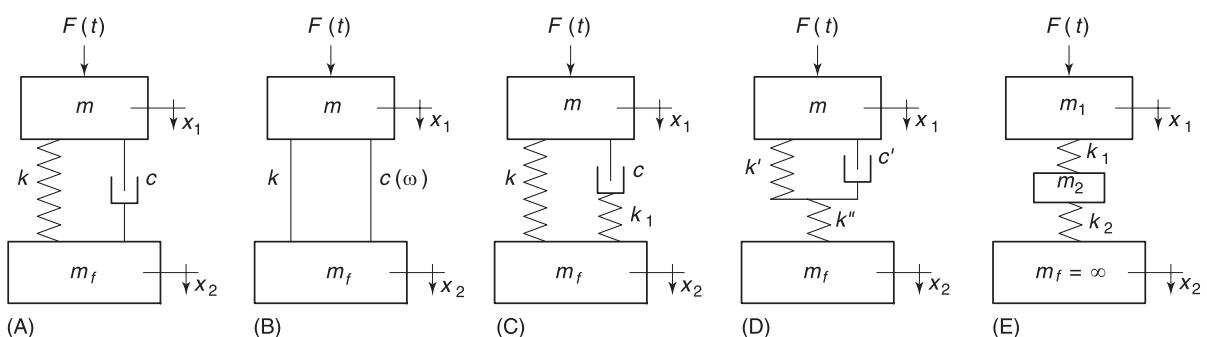

Figure 2 Typical models of general uni-axial vibration isolation system; (A) isolator with linear stiffness k and viscous damper c ; (B) isolator combining stiffness k and hysteretic damping; (C,D) ‘relaxation’ isolators; (E) isolator with intermediate mass.

object x_1 of the foundation x_2 . The relative transmissibility μ_{rel} is the ratio of the amplitude of the vibration between the object and the foundation $x_1 - x_2$ (i.e., amplitude of deformation of the flexible element) to x_2 .

Isolator with Viscous Damping (Figure 2A)

For Figure 2A, the absolute force transmissibility coefficient is:

$$\begin{aligned}\mu_F &= \frac{|F_f|}{|F|} \\ &= \frac{m_f}{m+m_f} \sqrt{\left(\frac{1 + (2\zeta \frac{\omega}{\omega_n})^2}{\left(1 - \frac{\omega^2}{\omega_n^2}\right)^2 + (2\zeta \frac{\omega}{\omega_n})^2} \right)} \quad [13] \\ &= \frac{m_f}{m+m_f} \sqrt{\left(\frac{1 + \left(\frac{\delta \omega}{\pi \omega_n}\right)^2}{\left(1 - \frac{\omega^2}{\omega_n^2}\right)^2 + \left(\frac{\delta \omega}{\pi \omega_n}\right)^2} \right)}\end{aligned}$$

The absolute displacement transmissibility for ‘kinematic excitation’ from the foundation is:

$$\begin{aligned}\mu_x &= \frac{|x_1|}{|x_2|} \\ &= \sqrt{\left(\frac{1 + (2\zeta \frac{\omega}{\omega_n})^2}{\left(1 - \frac{m+m_f \omega^2}{m_f \omega_n^2}\right)^2 + (2\zeta \frac{\omega}{\omega_n})^2} \right)} \quad [14] \\ &= \sqrt{\left(\frac{1 + \left(\frac{\delta \omega}{\pi \omega_n}\right)^2}{\left(1 - \frac{m+m_f \omega^2}{m_f \omega_n^2}\right)^2 + \left(\frac{\delta \omega}{\pi \omega_n}\right)^2} \right)}\end{aligned}$$

Here:

$$\omega_n = \sqrt{\left(\frac{k'(m+m_f)}{mm_f} \right)}$$

is the angular natural frequency, $\zeta = c/c_{cr}$:

$$\delta = \frac{2\pi(c/c_{cr})}{\sqrt{[1 - (c/c_{cr})^2]}} \approx \frac{\pi c}{\omega_n [mm_f/(m+m_f)]} \quad [15]$$

is the log decrement; $\mu_F = \mu_x = \mu$ only for an infinitely large foundation ($m_f = \infty$).

The relative transmissibility is:

$$\begin{aligned}\mu_{rel} &= \frac{|x_1 - x_2|}{|x_2|} \\ &= \frac{\frac{m+m_f \omega^2}{m_f \omega_n^2}}{\sqrt{\left(\left(1 - \frac{m+m_f \omega^2}{m \omega_n^2}\right)^2 \right) + \left(2\zeta \frac{\omega}{\omega_n}\right)^2}} \quad [16] \\ &= \frac{\frac{m+m_f \omega^2}{m_f \omega_n^2}}{\sqrt{\left(\left(1 - \frac{m+m_f \omega^2}{m \omega_n^2}\right)^2 \right) + \left(\frac{\delta \omega}{\pi \omega_n}\right)^2}}\end{aligned}$$

Figure 3 shows $\mu(\omega/\omega_n)$ at $m_f = \infty$ and at various damping levels. The absolute transmissibility $\mu_F, \mu_x < 1$ only at the frequency ratio $\omega/\omega_n > \sqrt{2} \cong 1.4$, or vibration isolation (reduction of vibration transmission) begins only at relatively high frequencies. With increasing damping, transmissibility in the isolation zone deteriorates. However, the relative transmissibility μ_{rel} is always decreasing with increasing damping (Figure 4).

Isolator with Internal (Hysteresis) Damping (Figure 2B)

The log decrement δ in systems with an isolator made from rubber, wire-mesh, etc. does not depend on natural frequency as in eqn [15] but usually has milder and more complicated dependence on frequency than in viscous damping systems and, in many cases, depends on vibration amplitude. For many materials frequently used for vibration isolation, such as rubber blends, in the first approximation the frequency and amplitude dependencies of δ can usually be neglected for a narrow frequency range, up to ~ 50 –100 Hz and small vibration amplitudes. There are many ways of expressing the elastodamping characteristics of such materials. A widely used format of ‘complex stiffness’ is based on the fact that the deformation of such materials has a phase delay β (rad) relative to the stress causing this deformation. Thus the deformation is comprised of two components: elastic (in phase with the stress) and viscous, lagging stress by 90° ($\pi/2$ rad), or directed along the imaginary axis. In such notation, the total complex stiffness of an element is:

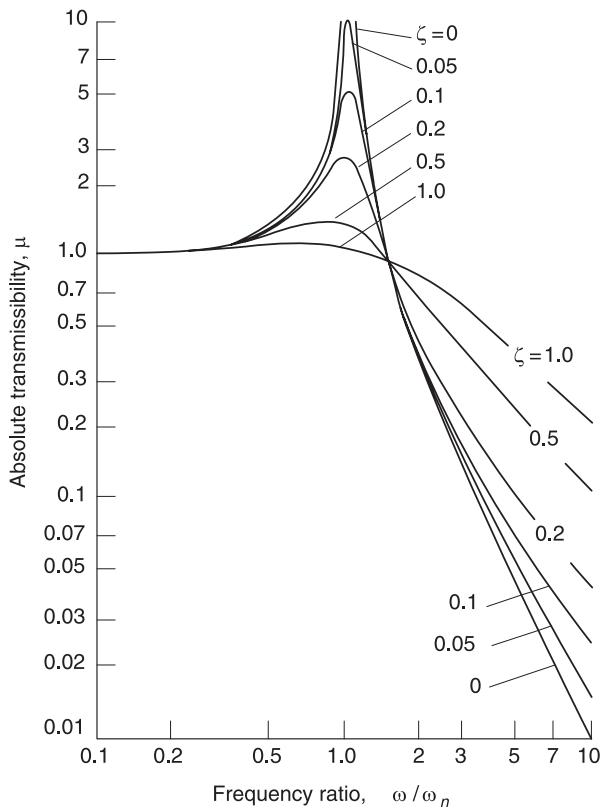

Figure 3 Absolute transmissibility of the system in **Figure 2A** for $m_f = \infty$.

$$\mu_F = \frac{|F_f|}{|F|} = \frac{m_f}{m + m_f} \sqrt{\left(\frac{1 + \tan^2 \beta}{\left(1 - \frac{\omega^2}{\omega_n^2} \right)^2 + \tan^2 \beta} \right)} \quad [18]$$

$$= \frac{m_f}{m + m_f} \sqrt{\left(\frac{1 + \frac{\delta^2}{\pi^2}}{\left(1 - \frac{\omega^2}{\omega_n^2} \right)^2 + \frac{\delta^2}{\pi^2}} \right)}$$

and:

$$\mu_x = \frac{|x_1|}{|x_2|} = \sqrt{\left(\frac{1 + \frac{\delta^2}{\pi^2}}{\left(1 - \frac{m + m_f \omega^2}{m_f \omega_n^2} \right)^2 + \frac{\delta^2}{\pi^2}} \right)} \quad [19]$$

$$\mu_{rel} = \frac{|x_1 - x_2|}{|x_2|} = \frac{\frac{m + m_f \omega^2}{m_f \omega_n^2}}{\sqrt{\left(1 - \frac{m + m_f \omega^2}{m \omega_n^2} \right)^2 + \frac{\delta^2}{\pi^2}}} \quad [20]$$

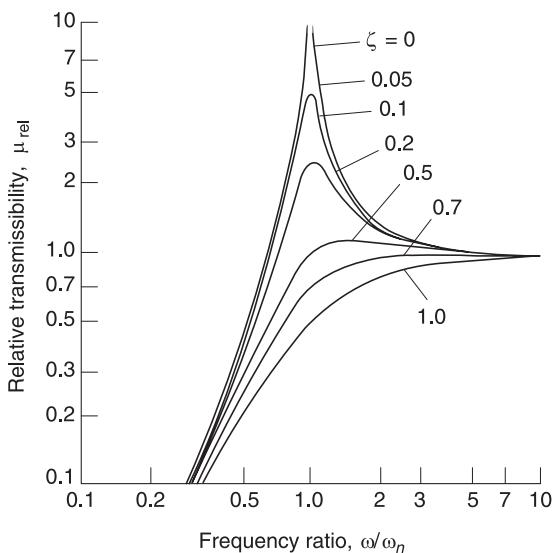

Figure 4 Relative transmissibility of the system in **Figure 2A** for $m_f = \infty$.

$$k = k' + jk'' = k'(1 + j \tan \beta) \quad [17]$$

Neglecting the amplitude and frequency dependences of k' and k'' :

Due to the absence of frequency-dependent terms in the numerators under the square root sign in eqns [18] and [19], their high frequency transmissibility for systems with damping is significantly reduced, thus improving the vibration isolation without deterioration in the resonance behavior. In real systems the improvement is less pronounced due to the mentioned frequency dependencies of k' and k'' , but the improvement is still significant. **Figure 5** shows $\mu_F = \mu_x$ for $m_f = \infty$ and various rubber blends having different values of δ and different stiffness dependencies on the frequency. Plot 1 is for an isolator made from natural rubber without carbon black filler; it has low damping ($\delta = 0.07$) and negligible frequency dependencies below 50 Hz. Plot 2 is for an isolator made from natural rubber with 50 parts by weight of carbon black ($\delta = 0.31$) while plot 2' is for a 'virtual' isolator with viscous damping and the same damping at the resonance (5 Hz). Plot 3 is for highly damped Thiocol RD rubber ($\delta = 1.55$ at resonance frequency 5 Hz and monotonously increasing with frequency, with three-fold increase between 1 and 50 Hz), while the plot 3' is for a 'virtual' viscous damping isolator with the same damping at the resonance (5 Hz). In the isolation zone $\omega/\omega_n > 1.4$, the damping increase has

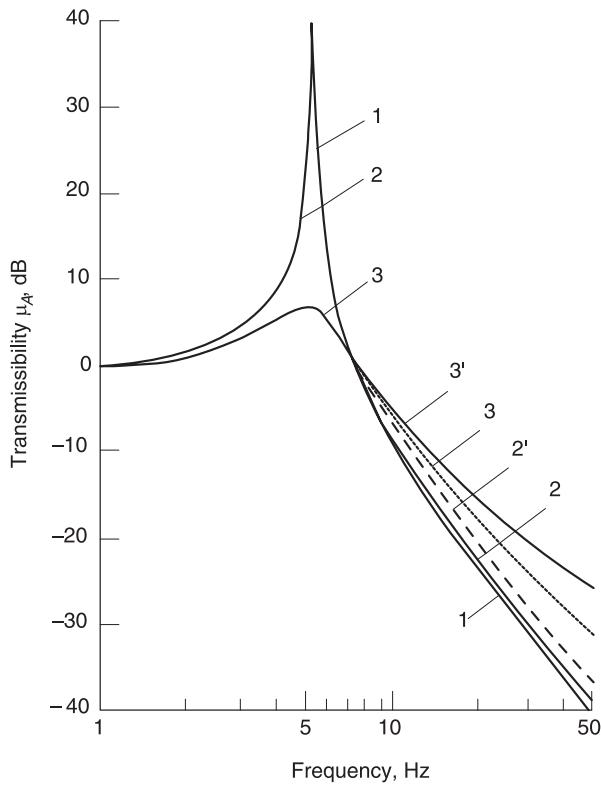

Figure 5 Absolute transmissibility of the system in **Figure 2B** for $m_f = \infty$ and isolator made of various rubber blends considering frequency dependencies of their stiffness and damping. (1) Unfilled natural rubber; (2) natural rubber filled with 50% ppw HAF carbon black; (3) Thiocol RD; (2') isolator with viscous damping having same μ_{res} as (2); (3') same for (3).

much less effect of isolation deterioration than in **Figure 3**.

'Relaxation' Isolation Systems with Viscous Damping (**Figure 2C and D**)

The two systems are equivalent if:

$$k = \left(\frac{N}{N+1} \right) k'; c = \left(\frac{N}{N+1} \right)^2 c' \quad [21]$$

The absolute and relative transmissibilities are:

$$\begin{aligned} \mu_x &= \mu_F \\ &= \sqrt{\left(\frac{1 + 4 \left(\frac{N+1}{N} \right)^2 \zeta^2 \frac{\omega^2}{\omega_n^2}}{\left(1 - \frac{\omega^2}{\omega_n^2} \right)^2 + \frac{4}{N^2} \zeta^2 \frac{\omega^2}{\omega_n^2} \left(N + 1 - \frac{\omega^2}{\omega_n^2} \right)^2} \right)} \end{aligned} \quad [22]$$

$$\mu_{rel} = \sqrt{\left(\frac{\frac{\omega^2}{\omega_n^2} + \frac{4}{N^2} \zeta^2 \frac{\omega^6}{\omega_n^6}}{\left(1 - \frac{\omega^2}{\omega_n^2} \right)^2 + \frac{4}{N^2} \zeta^2 \frac{\omega^2}{\omega_n^2} \left(N + 1 - \frac{\omega^2}{\omega_n^2} \right)^2} \right)} \quad [23]$$

where $\omega_n = \sqrt{(k/m)}$ is the natural frequency of the system in **Figure 2C** where $c = 0$; $c_{cr} = 2\sqrt{(km)}$; $\zeta = c/c_{cr}$. **Figure 6** compares μ_F , μ_x for a rigidly connected viscous damper (**Figure 2A** or **Figure 2C** at $N = \infty$) and an elastically connected viscous damper (**Figure 2C**) for $\zeta = 0.2$. Transmissibility of the latter at high frequencies (isolation zone) decreases much faster with increasing frequency ω than for the former (at 12 dB per octave vs 6 dB per octave), but at the price of an increased resonance amplification factor. For $c = 0$, the mass m is supported only by the main spring k , and μ_F , μ_x are the same as for the system in **Figure 2A**. When $c = \infty$, the transmissibility function is the same as for the case $c = 0$ but with the natural frequency

$$\omega'_n = \omega_\infty = \sqrt{\left(\frac{k + k_1}{m} \right)} = \omega_n \sqrt{(N+1)} \quad [24]$$

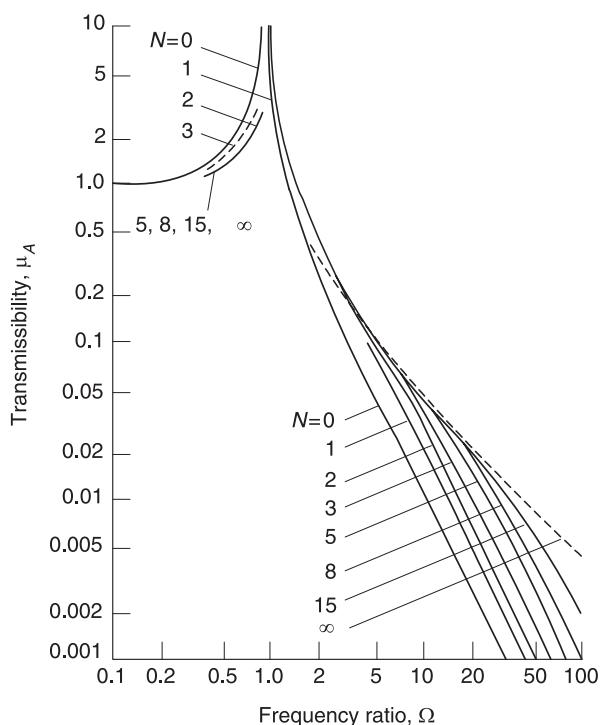

Figure 6 Absolute transmissibilities of uni-axial systems in **Figure 2C** with rigidly ($N = \infty$) and elastically connected viscous damper; $\zeta = 0.2$.

An intermediate value of c , producing the minimum resonance amplification is called the optimum damping. At high excitation frequencies, μ_F, μ_x for any values of c approach μ for $c = \infty$. and the absolute transmissibility at high frequencies is inversely proportional to the excitation frequency.

The transmissibility μ_{res} as a function of ζ and N is plotted in Figure 7. For $\zeta < 0.1$, μ_{res} is weakly dependent on N , but at larger ζ , N determines the maximum μ_{res} . The minimum μ_{res} for a given N corresponds to the optimum damping situation. The resonance frequency ratios are different for absolute (abs) and relative (rel) transmissibility:

$$\left(\frac{\omega_{res}}{\omega'_n}\right)_{abs} = \sqrt{\left(\frac{2(N+1)}{N+2}\right)} \quad [25]$$

$$\left(\frac{\omega_{res}}{\omega'_n}\right)_{rel} = \sqrt{\left(\frac{n+2}{2}\right)} \quad [26]$$

The optimum (minimum) resonance amplification for both absolute and relative motion is:

$$(\mu_{res})_{opt} = 1 + 2/N \quad [27]$$

The damping ratios producing the minimum (optimum) μ values expressed by eqn [27] are:

$$(\zeta_{opt})_{abs} = \frac{N}{4(N+1)} \sqrt{(2(N+2))} \quad [28]$$

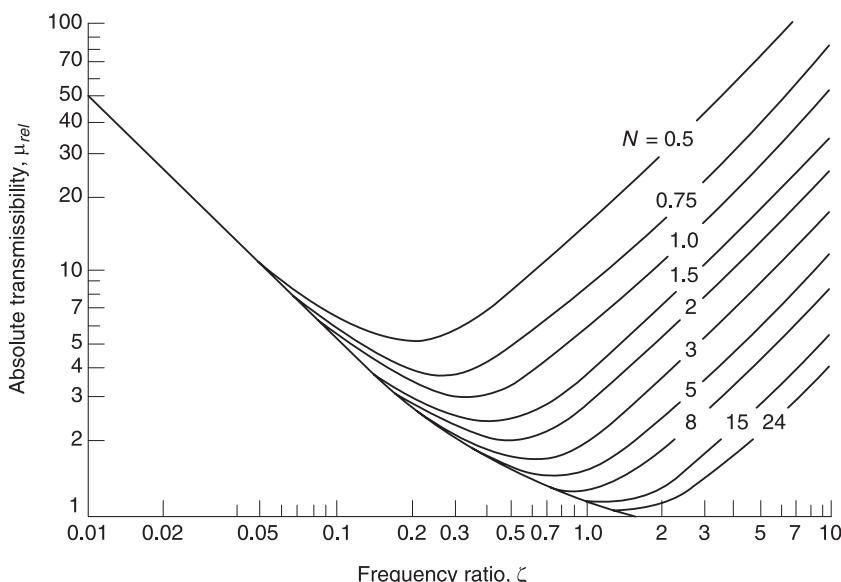

Figure 7 Transmissibility at resonance μ_{res} of the system in **Figure 2C** vs stiffness ratio N and damping ratio ζ .

$$(\zeta_{opt})_{rel} = \frac{N}{\sqrt{(2(N+1)(N+2))}} \quad [29]$$

Transmissibilities $\mu_{F,x}$ and μ_{rel} at optimum ζ are shown in Figures 8 and 9. For low N (soft damper attachment) the μ_{res} is large, but high frequency isolation is good (low $\mu_{F,x}$). On the other hand, large N (stiff damper attachment) reduces μ_{res} , but leads to deterioration of isolation efficiency. For μ_{rel} the influence of N variation is significant only at resonance.

Vibration Isolator with Intermediate Mass (Figure 2E)

Such isolators provide an improved transmissibility function in the high frequency range due to influence of the inertia force interacting with vibratory motions of elastic elements k_1, k_2 . The natural frequencies are:

$$\omega_{1,2} = \omega_{p1} \sqrt{\left(A \pm \sqrt{\left(A^2 - \frac{\omega_{p2}^2}{\omega_{p1}^2}\right)}\right)} \quad [30]$$

where:

$$A = \frac{1}{2} \left(\frac{\omega_{p2}^2}{\omega_{p1}^2} + 1 + \frac{k_2}{k_1} \right)$$

and:

$$\omega_{p1} = \sqrt{\left(\frac{k_1 + k_2}{m_2}\right)}$$

$$\omega_{p2} = \sqrt{\left(\frac{k_1 k_2}{k_1 + k_2} \frac{1}{m_1}\right)}$$

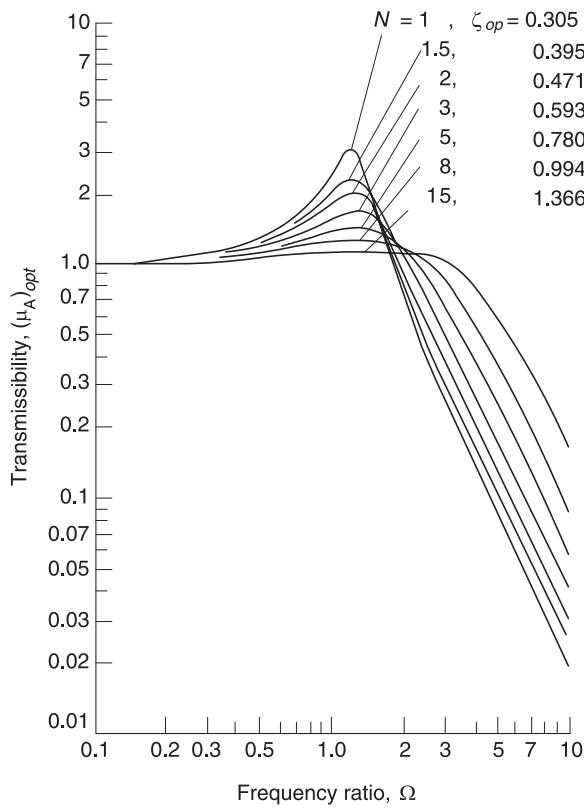

Figure 8 Absolute transmissibility of the system in Figure 2C at optimum damping ratios.

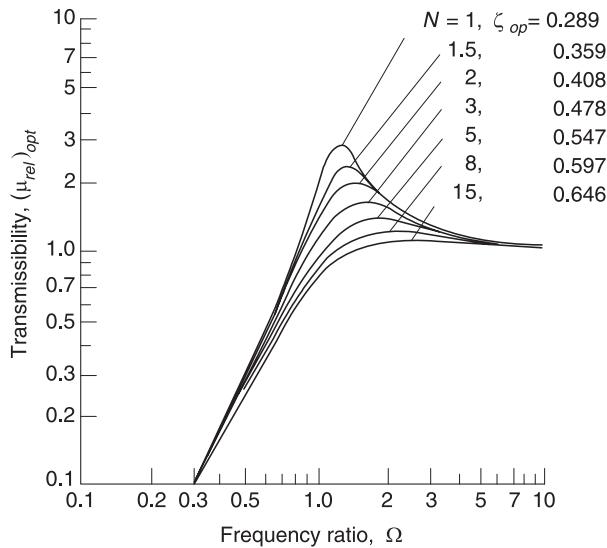

Figure 9 Relative transmissibility of the system in Figure 2C at optimum damping ratios.

are partial natural frequencies representing the subsystems in which m_2 is removed and m_1 is fixed, respectively. The natural frequency ω_1 (for ‘minus’ sign) is lower than both ω_{p1} and ω_{p2} , while ω_2 (for the ‘plus’ sign) is greater than both ω_{p1} and ω_{p2} . Both

force and absolute displacement transmissibility (not considering damping) is given by:

$$\mu = \frac{1}{\frac{\omega_{p1}^2}{\omega_{p2}^2} \left(\frac{\omega}{\omega_{p1}} \right)^4 - \left[1 + \left(1 + \frac{k_2}{k_1} \right) \frac{\omega_{p1}^2}{\omega_{p2}^2} \right] \left(\frac{\omega}{\omega_{p1}} \right)^2 + 1} \quad [31]$$

For the excitation frequency $\omega \gg \omega_{p1}, \omega_{p2}$, $\mu \rightarrow ((\omega_{p1}\omega_{p2})/\omega^2)^2$, or at high ω , μ decreases as the fourth power of the excitation frequency (Figure 10), while for isolators without an intermediate mass, it decreases only as the second power of ω . The price is high transmissibility at two natural frequencies ω_1 and ω_2 , rather than at one resonance frequency for a simple isolator system. The ratio ω_2/ω_1 is a minimum:

$$\frac{\omega_2}{\omega_1} = \frac{1 + \sqrt{(1 + \beta)}}{\sqrt{\beta}} \quad [32]$$

when the stiffness ratio $\alpha = k_2/k_1 = 1 + \beta$, where $\beta = m_2/m_1$. At high frequencies and $\beta \leq 0.5$:

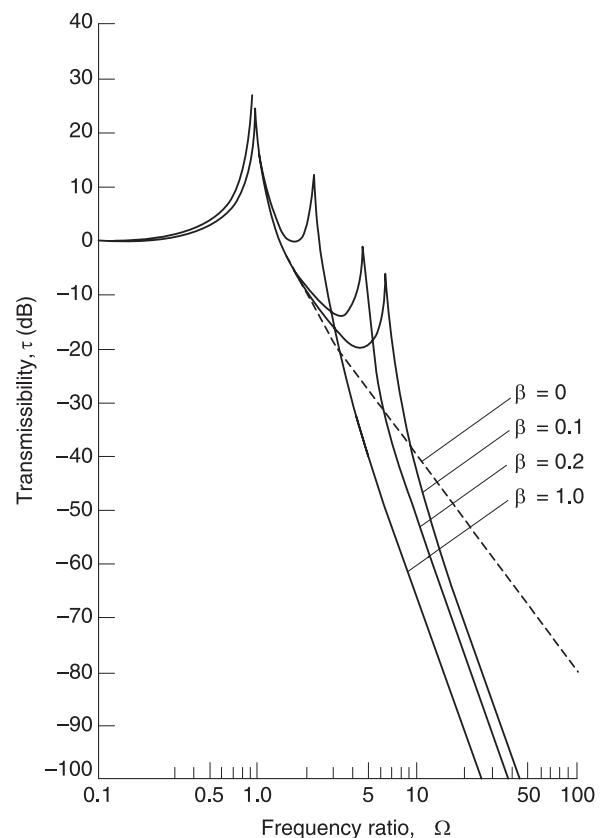

Figure 10 Transmissibility of uni-axial isolation system with intermediate mass m_2 as a function of $\beta = m_2/m_1$

$$\mu_F = \frac{(1 + (\delta^2/\pi^2))(2 + \beta)^2}{\beta(1 + \beta)\Omega^4} \approx \frac{4(1 + (\delta^2/\pi^2))}{\beta\Omega^4} \quad [33]$$

or the transmissibility is inversely proportional to the size of the intermediate mass m_2 .

The advantage of introducing the intermediate mass for high frequency transmissibility begins at quite high values of ω for masses that are not too small. For $\beta = 0.1$, the transmissibility advantage starts at a frequency that is about ten times higher than the natural frequency of the base system (without the intermediate mass). A small intermediate mass may be integrated into a vibration isolator design (Figure 11).

If n intermediate masses connected by spring elements are used, instead of one, then high frequency

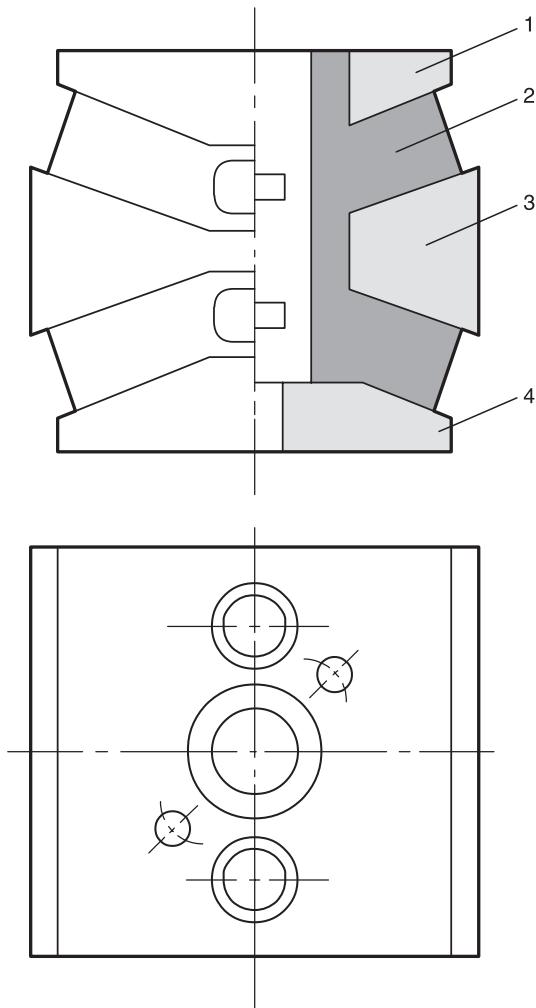

Figure 11 Intermediate mass integrated into vibration isolator; (1), (4) upper, lower base; (2) rubber flexible element; (3) intermediate mass.

transmissibility decline at the rate of $1/\Omega^{2(n+1)}$ is realized, but with $n + 1$ resonances. The starting frequency of the fast decline in transmissibility is also shifting towards higher frequencies with each added mass.

SDOF System with Motion Transformation

Relaxation systems and intermediate mass isolators (see below) improve the performance of the basic SDOF system at high frequencies by having steeper declines of transmissibility at frequencies $\omega \gg \omega_n = 2\pi f_n$. Reducing high-frequency transmissibility by reducing the natural frequency is unrealistic for isolation along the z -axis since a low natural frequency f_z is associated with low stiffness and large deflections of isolators under the weight of the supported objects. Large deflections make the system unstable, especially when the object is light and the absolute stiffness of the isolators is low. Instability associated with low natural frequencies/low stiffness of isolators in the horizontal x -, y -directions is a much lesser problem than for the vertical direction. To reduce the natural frequency in a passive system, the mass of the object should be artificially enlarged by installing it on an ‘inertia block’ so that the stiffness of the isolator can be proportionally increased and stability improved.

By using relatively high stiffness springs and light objects, low vertical (or horizontal) natural frequencies can be realized by motion transformation systems (Figure 12). Object 1 (mass m), is attached to isolator (spring) 2 (stiffness k), damper 3 (c), and a motion transformer composed of flywheel/nut 4 which has same axial displacements as object 1 and is supported for rotation in relation to object 1 by thrust bearings 5. Flywheel 4 is engaged with screw 6 attached to the vibrating foundation 7. The presence of the motion transformer results in the generation of additional dynamic forces caused by the inertia of the flywheel/nut 4.

When object 1 is moving in the axial direction, flywheel 4 is forced to rotate. Axial force from the object to the flywheel should overcome inertia torque from the flywheel, $T = I\ddot{\phi}$, where ϕ is the rotational angle of the flywheel and $\ddot{\phi}$ is its angular acceleration. The resulting axial force is:

$$P = T/r \tan(\alpha \pm \gamma) = \frac{I\ddot{\phi}}{r \tan(\alpha \pm \gamma)} \quad [34]$$

and the natural frequency of this system is:

$$f_n = \frac{1}{2\pi} \sqrt{\left(\frac{k}{m + (I/(r^2 \tan^2 \alpha))} \right)} \quad [35]$$

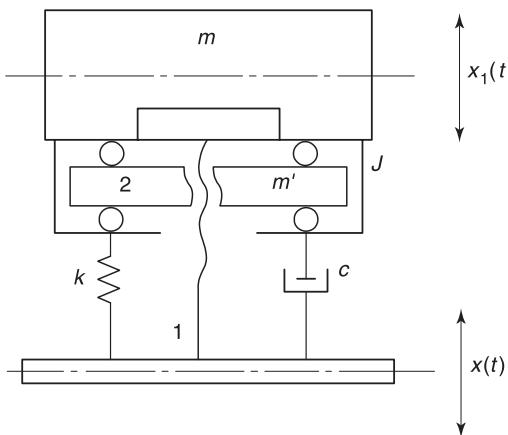

Figure 12 Vibration isolation system with motion transformation.

where I is the moment of inertia of the flywheel, α is the helix angle of the thread, r is the median radius of the thread, γ is the friction angle (friction coefficient in the thread is $f = \tan \gamma$) and its sign depends on direction of sliding in the thread ('minus' – towards equilibrium position, 'plus' – from the equilibrium position). The value of f_n can be very low while k is quite large. Transmissibility of the system is:

$$\mu = \frac{|x|}{|x_1|} = \sqrt{\left(\frac{(1 - \eta\Omega^2)^2 + 4n^2\Omega^2}{[1 - (1 + \eta^2)\Omega]^2 + 4n^2\Omega^2} \right)} \quad [36]$$

or:

$$|\mu| = \frac{|1 - \eta\Omega^2|}{|1 - (1 + \eta)\Omega^2|} \quad [37]$$

at $c = n = 0$. Here $\omega_0^2 = 2\pi f_0^2 = k/m$ (ω_0 is the natural frequency of the system without a motion transformer); $\Omega = \omega/\omega_0$; $c/m = 2n$; $\eta = m'/m$.

Figure 13 shows plots of $\mu(\Omega)$ for $\eta = 0.33$. When $c = n = 0$ (line 1), the system has sharp resonance at $\Omega_1^2 = 1/(1_\eta)$, and transmissibility becomes zero at $\Omega_2^2 = 1/\eta$. Thus, the natural frequency is lower than for the system without the motion transformation (line 3) and also there is a 'dynamic absorption' of vibration at the frequency ratio Ω_2 . The latter effect is rather unusual for a SDOF system. With increasing frequency ratio from Ω_2 to $\Omega = \infty$, transmissibility is approaching the asymptote

$$\mu = \eta(1 + \eta) \quad [38]$$

For $c > 0$, the resonance peak is reduced and the full vibration absorption does not develop (line 2).

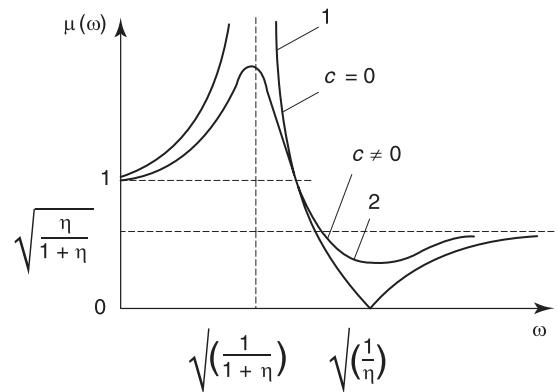

Figure 13 Transmissibility of system in **Figure 12** for $m' = m/3$ and various damping. 1, $c = 0$; 2, $c > 0$; 3, disengaged motion transformer ($m' = 0$).

Relatively small values of η allow a noticeable reduction of the natural frequency and a significant reduction of transmissibility μ across the frequency range, starting from low frequencies.

Vibration Isolation System under Random Excitation

For random vibratory excitation, at each moment the magnitudes of its parameters, such as displacement, velocity, and acceleration are unpredictable. Such excitations are generated, for example, when a vehicle is moving along the road, due to the action of the road asperities on its wheels, due to variations of gas dynamic processes in jet or rocket engines, due to exertions from various processing equipment units on the shop floor, etc. The time history of a single occurrence (realization) of a random (stochastic) vibratory process is unpredictable. However, if the process is repeated under the same conditions, it is possible to forecast a probability that the value of a certain parameter of the process would be within a certain range. Vibration isolation systems usually connect mechanical structures. The mechanical structures of both the supporting surface (foundation) and the object can be described as multidegree-of-freedom dynamic systems acting as filters, thus enhancing some and suppressing other components of the random excitation. As a result, the random vibratory processes usually have some pronounced spectral components whose amplitudes and phases may vary as random variables. Such a process can be described as narrowband random vibration mixed with less intensive broadband random vibration. The vibration isolation system also serves as a powerful filter.

Envelopes of spectral power density (SPD), $S(\omega)$, are specified for testing critical equipment units subjected to random vibration. For example, computers

and sensitive instruments for military applications should be tested for $S(\omega) = 0.1 \text{ g}^2/\text{Hz}$ in the frequency range 10–2000 Hz with the root mean square value $\sqrt{\langle \ddot{x}^2 \rangle} = 14 \text{ g RMS}$. For vibration isolation of precision equipment it is convenient, instead of specifying the envelope of $S(\omega)$, to specify an envelope of maximum floor displacement amplitudes in the potential installation sites for the equipment, or specify envelopes of the floor vibratory velocities for various classes of buildings designed to house precision equipment.

The effectiveness of vibration isolation from random vibration inputs is judged by the mean-square acceleration density on the object being protected while excited by the random vibratory input within the required envelope of $S(\omega)$. The capabilities of the vibration isolation system are limited since the use of soft (more effective) isolators results in greater deflections of the isolators and thus, excursions of the object being protected. The allowable excursions are often limited by packaging conditions.

The SPD of the output signal for the absolute acceleration of the object is:

$$S(\omega)_{out} = S(\omega)_{in} |H(\omega)|^2 \quad [39]$$

where $H(\omega)$ is the transfer function of the system. The mean square of the output signal can be expressed via the mean square value of the input signal as:

$$\bar{y}^2 = \int_0^\infty S(\omega)_{out} d\omega = \int_0^\infty S(\omega)_{in} |H(\omega)|^2 d\omega \quad [40]$$

The SPD for the relative displacement between the object and the base for the acceleration excitation from the base is:

$$S(\omega)_{rel} = \frac{1}{\omega^4} |\mu_{rel}(j\omega)|^2 S(\omega)_{in} \quad [41]$$

Information on the range of displacements of isolators caused by the narrowband relative vibrations, is important for designing/packaging of vibration isolation systems. For low-damping systems ($\zeta \ll 1$) the mean-square of relative displacements is:

$$\bar{x}_{rel}^2 = S(\omega)_{in} \int_0^\infty |\mu_{rel}|^2 d\omega = \frac{\pi}{4\zeta} \frac{S(\omega)_{in}}{\omega_n^3} \quad [42]$$

Vibration Isolation System under Impulse Excitation

In many cases, impulse excitations are more dangerous than steady vibrations. Frequently, it is more difficult to evaluate the response of a system to pulse excitations because interaction of both forced motions and free vibration of the system excited by the impulse should be considered. While for each specific case the response can be computed, it is desirable to have some general criteria for designing isolation systems for impulse excitations, as well as quick ‘first approximation’ techniques. This can be accomplished by using the so-called ‘shock spectrum’ or ‘response spectrum’ approach.

The response spectrum is a graphical presentation of a selected quantity in the response process with reference to a quantity in the excitation process plotted as a function of a ratio between the natural period of the responding system and a significant time measure in the excitation pulse. **Figure 14A** gives the response time history of a SDOF system without damping to a typical versed-sine pulse, while **Figure 14B** gives the ‘response spectrum’ for this excitation and for the ‘decaying sine wave’ pulse for the SDOF system. All plots in **Figure 14** are for relative values $\xi(t)/\xi_p$ and $A = v(t)/\xi_p$, where ξ_p is the maximum pulse height, $\xi(t)$ is the pulse height as function of t , $v(t)$ is the height of the response process as function of t , and A is the pulse response spectrum; T is the natural period of the dynamic system acted upon by the pulse, and τ is the pulse duration. Both parameters should represent the same parameters of the dynamic system (e.g., ξ can be the displacement pulse coming from the foundation m_f in **Figure 2A**, then v is the forced displacement of mass m , or ξ is the impulse of force acting on mass m , then v is the force transmitted to the foundation mass m_f). Plots in **Figure 14** are computed for $m_f = \infty$; if m_f is finite, then the response is:

$$A_f = \frac{m_f}{m + m_f} A \quad [43]$$

In the first approximation the first (and the most intense) part of the time history of the response can be approximated as a verse-sine pulse for many shapes of the excitation pulse, especially if $\tau_p \ll T_n$. The duration τ_r of this response pulse can be determined from **Figure 15**. This approximation is useful for evaluating propagation of pulses across the isolation system since usually only the peak value of the response and shape and duration of its first pulse are of interest. More accurate analysis can be performed

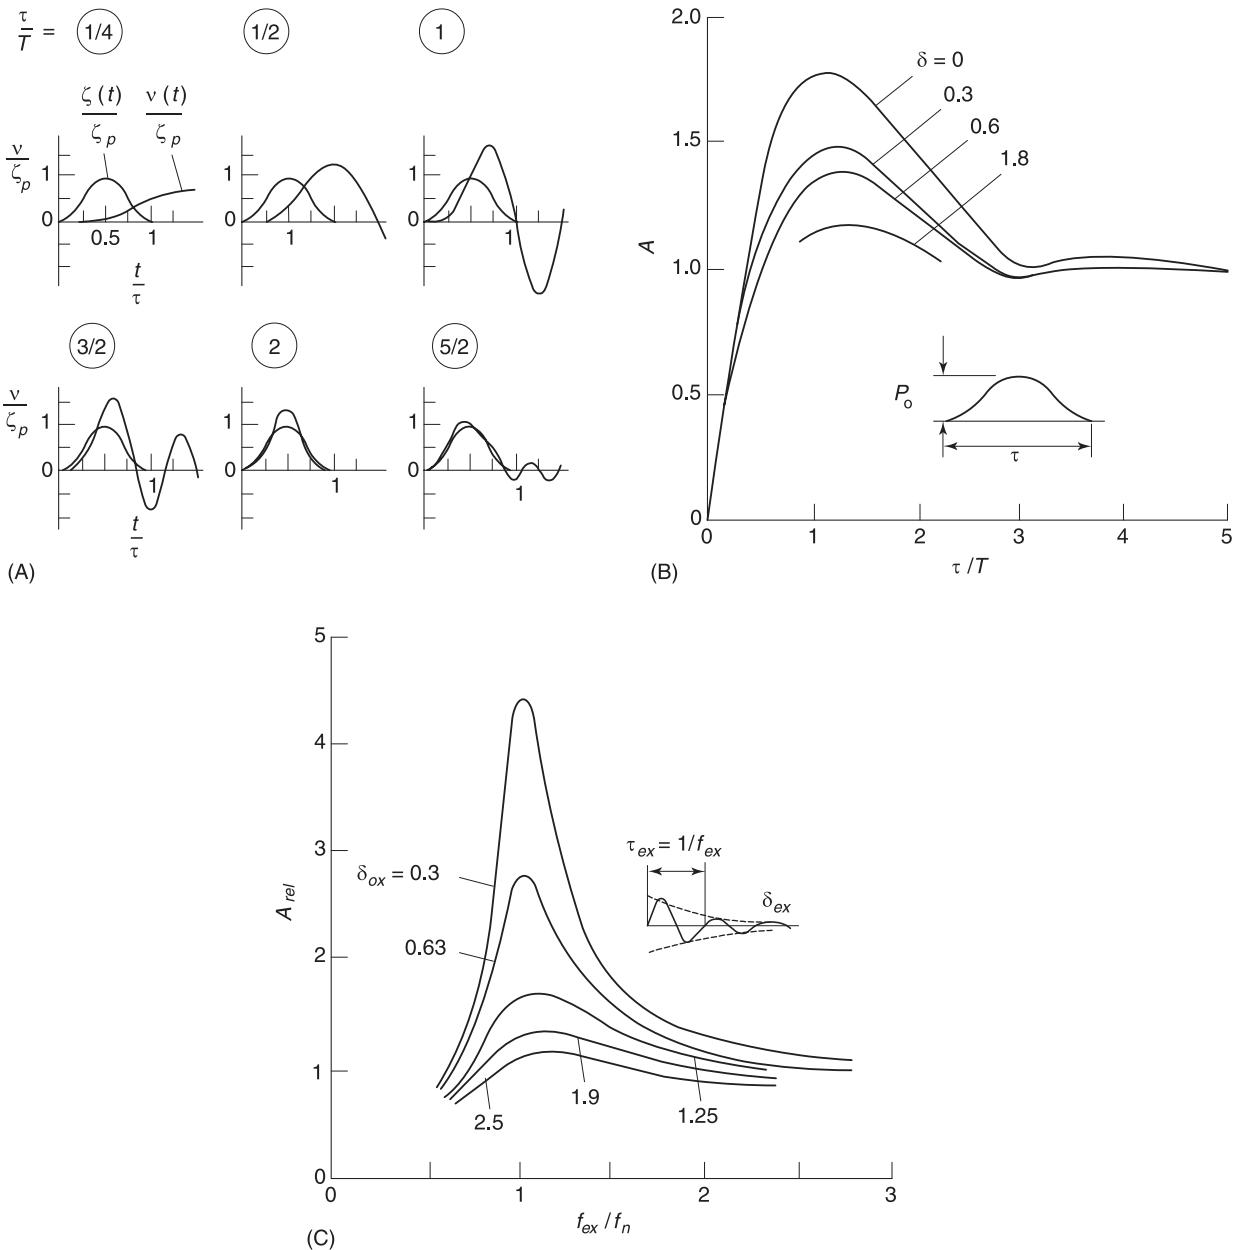

Figure 14 Response of SDOF system to various pulse excitations. (A) Time histories of response to versed-sine pulse; (B) absolute response 'shock' spectra of a SDOF system to versed-sine pulse; (C) same for decaying sinusoid pulse.

by calculating spectral content of the pulse excitation functions and its propagation within the dynamic system.

For undamped systems, shock spectra for half-sine (A_1) and versed sine (A_2) pulses can be expressed analytically as:

$$A_1 = \frac{(T_n/\tau_p) \cos(\pi\tau_p/T_n)}{(T_n/2\tau_p)^2 - 1} \quad [44]$$

$$A_2 = \frac{\sin(\pi\tau_p/T_n)}{1 - (\tau_p/T_n)^2} \quad [45]$$

For $\tau_p \ll T_n$ (e.g., the typical case for vibration isolation of forging hammers):

$$A_1 \cong \frac{4\tau_p}{T_n} \cos \frac{\pi\tau_p}{T_n} \quad [46]$$

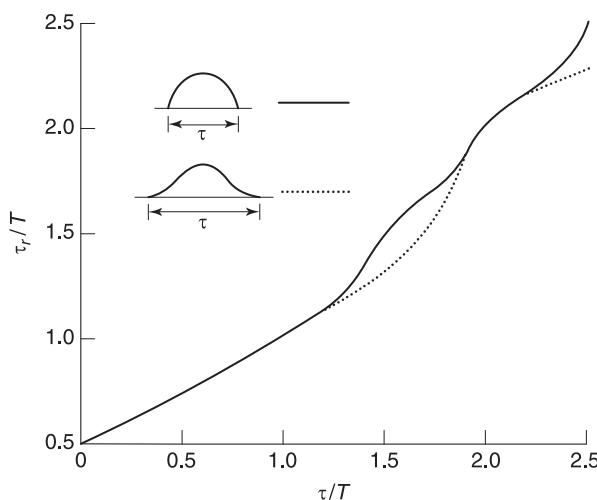

Figure 15 Duration τ_r of the response versed-sine pulse to half-sine and versed-sine excitation pulses (duration τ).

$$A_2 \cong \pi \tau_p / T_n \quad [47]$$

The presence of damping in the dynamic system under pulse excitation results, first of all, in fast decaying of the response at $t > \tau$, and in some, not very significant, reduction of the peak value of the response function. Within $\sim 5\%$, the influence of damping on the shock spectrum values for the half-sine and verse-sine pulses can be expressed as:

$$A_d \cong A_0(1 - 0.14\delta) \quad [48]$$

where A_d is shock spectrum value considering damping, and A_0 is the shock spectrum value without considering damping.

Nonlinearity in Vibration Isolation Systems

Nonlinearity in vibration isolation systems, like in other dynamic systems, is usually pronounced at large vibration amplitudes. However, steady vibration amplitudes in vibration isolation systems for stationary objects (production and measuring machines, internal combustion engines), as well as for aggregates on surface and air vehicles are usually much smaller than their static deformations. Thus, in most cases consideration of specifically nonlinear effects does not add much to the results of dynamic analysis performed in a linear approximation. Still, in some cases nonlinear effects have to be considered, such as: vibration isolation systems that can be subjected to high-level incidental intense impulse excitations may require snubbers introducing highly nonlinear

process; use of nonlinear isolators with low damping may result in such nonlinear effects as subharmonic resonances; an additional intermodal coupling may develop in the isolation system due to nonlinear effects.

Here ‘nonlinearity’ is used to indicate a nonlinear character of the load–deflection characteristic of isolators (‘static nonlinearity’). Other types of nonlinearity are dependencies of effective stiffness and damping of isolators on amplitude and frequency of vibration. The amplitude and frequency dependency can be a property of material of the flexible element, or it can be due to use of Coulomb friction connections in the isolator designs. The amplitude and frequency dependencies of both stiffness and damping are typical properties of elastomeric and plastic materials frequently used in vibration isolator designs. All types of such ‘dynamic nonlinearities’ can be pronounced and important in any amplitude ranges.

Snubbers in vibration isolation systems are, in addition to attenuation of deterministic vibratory forces, required to withstand severe incidental shocks. The typical case relates to the installation of a compressor producing near-harmonic excitation at 60 Hz. It should be attenuated 15-fold to protect adjacent precision instruments, thus requiring a low natural frequency ($f_n \cong 15$ Hz) and low damping isolation system. The system should also tolerate severe environmental shocks (a saw-tooth acceleration pulse with magnitude 50 g and duration 18 ms) and white-noise vibration input with 16.6 g RMS acceleration in the 0–2000 Hz range. For a conventional vibration system to survive such test conditions, it has to allow for unacceptably large deflections of the elastic element (spring). The proposed approach is to allow only such dynamic deflections of the isolation springs, which are adequate for performing the main task – protection of precision instruments. To accommodate the severe test conditions, the suspended object (compressor) comes in contact with relatively stiff and highly damped snubbers. Consequently, at high intensity excitations, the system is much stiffer and becomes a highly nonlinear vibro-impact system. The best dynamic quality of such system is at the minimum of a criterion:

$$\Pi = \dot{X}\ddot{X} = V^2\Psi(\zeta) \quad [48]$$

where \dot{X} and \ddot{X} are, respectively, the maximum velocity, acceleration of the object after impacting (and rebounding from) the snubber with velocity V , and $\Psi(\zeta)$ is the function of damping in the snubber which reaches its minimum when its damping ratio is $\zeta \cong 0.8$ (loss factor $\tan \beta \cong 0.4$, log decrement $\delta \cong 1.25$).

The most widely used vibration isolators with static nonlinearity are CNF isolators. Since the stiffness of such isolators varies in a very broad range with changing loads, they are ‘self-snubbing’ and provide for the same or better performance as the snubbers described in the above paragraph. Another interesting feature of nonlinear isolators is the fact that at large vibration amplitudes across such an isolator, the amplitude–frequency characteristic of the isolation system ‘bends’. This effect leads to some reduction of resonance amplitudes without adding damping to the system.

On the other hand, at high excitation amplitudes development of subharmonic vibrations in systems with nonlinear, e.g., CNF, elastic connectors is possible. Development of subharmonic regimes may result in deterioration of isolation effectiveness, especially for high frequency excitations. Subharmonic vibrations have been observed in vibration isolation systems with low damping CNF vibration isolators (based on conical springs). It is known, however, that subharmonic vibrations cannot develop if the damping in the system exceeds a certain critical value depending on the character and degree of nonlinearity and excitation amplitude.

Nonlinearity in the vibration isolators may lead to development of intermodal coupling in the system for which the decoupling conditions discussed above are satisfied. A study of the effects of the degree of cubic nonlinearity:

$$F_z = a(z + \varepsilon z^3) \quad [49]$$

as well as vibration amplitudes on the coupling has been carried out by Henry and Tobias. If a linear planar isolation system $z - \beta(a_z = 0)$ is decoupled, the minimum amplitude Z_{\min} of the z -direction vibration that excites rocking (β -direction) vibration in this system, is determined by the degree of nonlinearity (parameter ε), as well as by closeness between the natural frequencies f_z and f_θ :

$$f_\theta z_{\min} = \frac{1}{\sqrt{\varepsilon}} \sqrt{\left(\frac{4}{3} \frac{1 - n_{\beta z}^2}{3n_{\beta z}^2 - 1} \right)} \quad [50]$$

where $n_{\beta z} = f_\beta/f_z$ is a so-called ‘tuning factor’ characterizing the closeness of the natural frequencies.

Wave Effects in Vibration Isolators

Expressions for transmissibility in the SDOF vibration isolation systems above were derived assuming

that the isolator can be represented by a massless spring. Real-life isolators, made of metal and of other materials have some mass. As a result, wave effects may develop at high frequencies of transmitted vibrations whereas the dimensions of the isolators become commensurate with multiples of the half-wavelengths of the elastic waves passing through the flexible elements of the isolators. Figure 16 shows the transmissibility for two SDOF systems with low damped rubber flexible elements (one in shear and one in compression) and for one system with the steel spring, having even lower damping as well as much greater weight. There are intense high frequency peaks resulting in deterioration of transmissibility in the high frequency range. For the rubber cylinder in compression, the fundamental natural frequency is $f_n = 30\text{ Hz}$ and the high frequency peak at $f'_n = 500\text{ Hz}$, ($f'_n/f_n > 16$), and $\sim 47\text{ dB}$ below the fundamental peak. For the rubber isolator in shear, $f_n = 26\text{ Hz}$, $f'_n = 850\text{ Hz}$ ($f'_n/f_n = 33$), the difference in resonance peak heights $\sim 60\text{ dB}$. However, for the steel spring there are numerous high frequency resonances in the shown frequency range, with $f_n = 15\text{ Hz}$, a first high frequency peak at $f'_n = 83\text{ Hz}$ ($f'_n/f_n = 5.5$) and only 16 dB below the fundamental resonance peak.

High frequency wave resonances in vibration isolators develop at frequencies:

$$\omega_i = i\pi\omega_0\sqrt{\gamma} \quad [51]$$

where ω_0 is the fundamental natural frequency, $i = 1, 2, 3 \dots$ is the sequential number of the resonance, and $\gamma = M/M_f = M/\rho Al$ is the mass ratio between the mass M of the supported object associated with the flexible element, M_f is the total mass of the flexible element (ρ is its density, A is the cross-sectional area, l is the length). Transmissibility at the first high frequency resonance is:

$$\mu' = \frac{0.2}{\tan \beta} \frac{M_f}{M} = \frac{0.2}{\gamma \tan \beta} \quad [52]$$

Thus both the positioning and the intensity of the high frequency resonances caused by standing waves in the isolator are determined by the mass ratio between the isolator and the supported object and by damping in the isolator. If the high frequency transmissibility is of importance, steel springs are not the best choice. Rubber has about seven times lower density ρ than steel, and rubber isolators can be made very small for given natural frequency and load-carrying capacity.

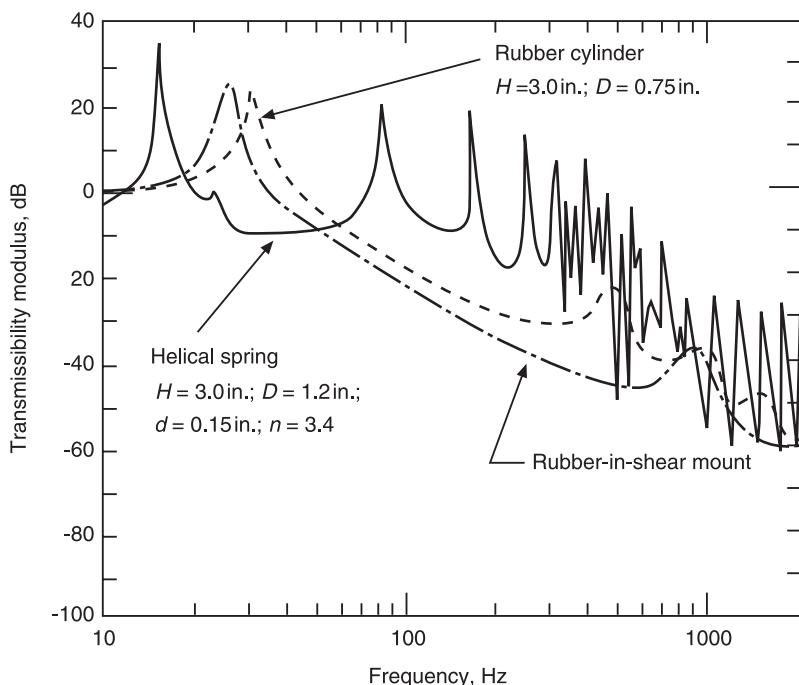

Figure 16 Transmissibility in a broad frequency range of a uniaxial vibration isolation system with isolator having rubber element in compression; rubber element in shear; and steel spring.

Nomenclature

c	damping coefficient
f	frequency
F	force
I	moment of inertia
k	stiffness constant
m	mass
M	moment
r	radius
T	torque
V	velocity
W	weight
μ	transmissibility
γ	friction angle

VIBRATION ISOLATION, APPLICATIONS AND CRITERIA

E Rivin, Wayne State University, Detroit, MI, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0181

Design of an optimal vibration isolation system is a complex problem due to the diversity of the requirements for the isolation of various objects in need of vibration isolation. Additional difficulties arise from the variety of working regimes and the internal configurations of some objects (such as cutting regimes in machine tools, position variations of heavy tables or gantries on machine tools and coordinate measuring machines (CMMs), etc.), as well as a variety of environmental conditions (dynamic characteristics of floor and foundation structures, presence of vibration producing and/or vibration sensitive equipment in the vicinity, etc.). While the development of special requirements for unique objects is warranted, a more appropriate way in many cases is to formulate generic criteria for four groups of similar objects:

1. Vibration-sensitive devices (precision machine tools, CMMs, electronic devices). The main goal of vibration isolation is to ensure that relative vibration in the ‘working’ or other critical area does not exceed permissible limits under given external and internal excitations.
2. Vibration-producing machines and devices (impact-generating machines, unbalanced rotors, reciprocating mechanisms). The main goal is to reduce intensity of dynamic exertions transmitted from the object to the supporting structure (foundation, floor, etc.).
3. General-purpose machinery and equipment, neither very sensitive to external vibratory exertions nor producing excessive dynamic forces (e.g., machine tools of ordinary precision). The main goals are to protect the object from accidental intense external shocks and vibrations; to protect the environment and adjacent precision devices, from occasional disturbances caused by the object (e.g., chatter or stick-slip vibrations); to reduce dynamic loads in bearings; to reduce noise and general vibration levels; to facilitate installation by eliminating the need to fasten or grout the objects to the floor.
4. Objects installed on nonrigid structures (upper levels of buildings, ships and surface vehicles, etc). Both internal and external dynamic excitations may be amplified due to the low dynamic stiffness of the supporting load-carrying structures. Thus, even small excitors produce severe vibrations of the supporting structures, creating the need for protection not only for precision but even for ordinary general-purpose objects.

The normal performance of the object should not be disturbed by vibration isolation, e.g., due to static instability or rocking motion of the isolated object or due to loss of required structural rigidity.

This classification is not absolute. A surface grinder or a CMM needs to be protected from floor vibrations, but reversals of heavy tables/gantries may produce intense dynamic loads disturbing nearby precision devices.

Isolation of Vibration-sensitive Objects

Sensitivity to external vibrations does not necessarily increase with increasing requirements for accuracy, since improvements in the accuracy of precision devices are usually accompanied by better designs.

Ambient Vibrations

Vibrations affecting vibration-sensitive devices can be transmitted from the supporting structures or through the air. Vibration isolators are usually intended to reduce the vibrations transmitted from the supporting structures. Floor vibrations are excited by the vibratory motions of nearby processing machines, motors, transformers, etc., by moving trains, trucks, carts, dollies, cranes, etc. For ultraprecision facilities, microseismic motions of the ground should be also considered. Structural vibrations of vehicles are due to engine excitations and to road disturbances (for surface vehicles). The character and levels of floor vibrations depend not only on the excitation, but also on the vibration-filtering effects of the dynamic system consisting of the soil, foundations, flooring, and other structural components of the building.

Floor vibrations are usually made up of a multitude of spectral components with randomly varying amplitudes and represent a nonstationary and nonergodic random process. The use of fast Fourier transform (FFT) spectrum analyzers in such conditions may give distorted results and smear the important difference between steady or quasisteady vibrations (when the amplitude of a harmonic component does not change significantly during 3–5 periods of vibratory motion) and transient vibrations with fast changing amplitudes. Envelopes of points representing absolute maximums at various frequencies of ground level floor vibration for manufacturing plants can be summarized as constant amplitudes of $\sim 3 \mu\text{m}$ in the frequency range 3–30 Hz for vertical vibrations and 25–30% less in a narrower frequency range of 2–20 Hz for horizontal vibrations. Outside these frequency ranges the amplitudes are much smaller. Vibrations on higher floors are ~ 1.5 –3 times more intense. The intensity of impulsive vibrations can be characterized by 30–60 μm magnitudes and 0.02–0.1 s duration of the versed-sine pulses.

The intensity of floor vibrations in precision manufacturing facilities (e.g., microelectronics) is usually much lower. Vertical vibrations for three typical clean room floors indicate that maximum displacement amplitudes do not exceed $0.05 \mu\text{m}$. Figure 1 shows generic vibration criterion (VC) curves by BBN Co. (Boston, MA, USA), frequently used to specify the vibration levels for newly constructed precision facilities. The displacement amplitudes are shown for critical points in Figure 1. The selection of

a particular VC and/or isolation system specifications makes a significant impact on the overall cost of the facility.

The most stringent ambient vibration parameters for electronic equipment are specified by military standards. Electronic devices must withstand without loss of performance a ‘white noise’ excitation with power spectral density of acceleration $S(\omega) = 0.1 \text{ g Hz}^{-1}$ in the frequency range 10–2000 Hz.

Detrimental Effects of Vibration

Many connections in precision devices are frictional joints tightened by bolts or by other means. One of the detrimental effects of vibrations is the destabilization of dimensional chains. Elements of these chains (e.g., guideways, screws, and clamps) are fastened in elastically strained conditions maintained by static friction forces. Vibratory variations of contact pressures and of friction forces in the joints lead to relaxation of the elastic strains and to possible ‘jumps’ in the dimensional chains. Such jumps may produce steps in machined surfaces, changes in dimensions within a batch of automatically machined parts, misalignments in optical systems, etc. Vibration-caused ‘jumps’ at joints of mounting systems (wedges, jack-screws) may lead to structural misalignments and deformations resulting in chatter, reduced accuracy, increased wear, etc.

Ambient vibrations may induce relative motions between the critical components of the device, such as between the cutting or measuring tool and the

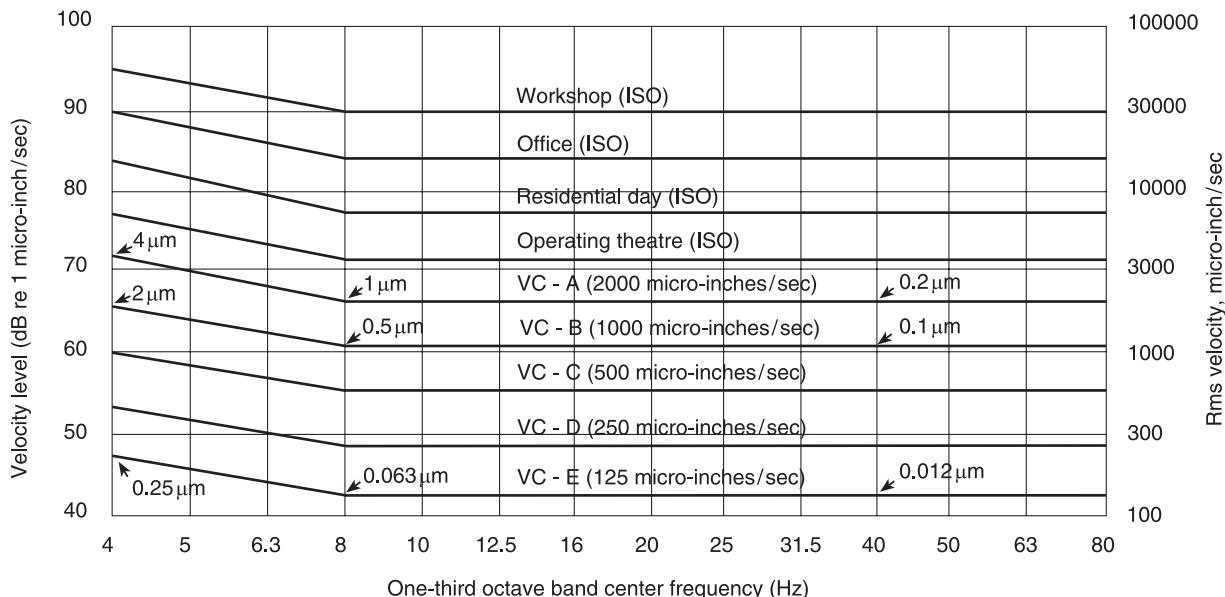

Figure 1 BBN floor vibration criteria for installation of precision equipment.

workpiece. These motions may cause waviness of the machined surface, out-of-roundness, erroneous measurement results, oscillatory misalignments between optical components, signal variations in proximity sensors, and deterioration in surface finish. Impulsive vibrations can lead to momentary misalignments, to erroneous measurements if occurring during the measurement process, and to local variations in the depth of cut (dents on the machined surfaces).

Model of Vibration Transmission

Ambient vibrations excite relative vibrations in the working (cutting/measurement) zone or in the joints comprising the dimensional set-up chain. Usually, these effects are only significant at the fundamental (seldom also at the second) natural frequency of the dynamic system. Often, the higher natural frequencies lie considerably above the frequency range of significant excitation amplitudes. The first natural frequency for grinders is between 30 and 70 Hz, the second natural frequency lies between 100 and 150 Hz, the range of greatly reduced floor amplitudes. While more intense high frequency vibrations are observed on the supporting structures of vehicles (spacecraft, aircraft, surface vehicles), the vibration-sensitive on-board devices usually have higher natural frequencies. Figure 2 shows vibration sensitivity curves for precision ‘projection aligner’ used in the production of electronic circuits. The minima on these plots represent structural natural frequencies of the devices. It can be seen that the lowest natural frequencies are between 10 and 30 Hz, and many of the higher natural frequencies lie between 30 and 70 Hz. At the higher frequencies, vibrations of floor/supporting structures usually undergo much higher attenuation by vibration isolation systems.

The dynamics of vibration transmission from the supporting structure into the working zone of a precision device can be approximated by three uncoupled two-mass systems, such as the one in Figure 3, one for each coordinate direction of the floor vibrations. Masses and springs in Figure 3 represent generalized inertias and stiffnesses of the unit, their values may be different for each coordinate direction. Here M_b represents the mass of the frame (bed) of the object; M_u is the mass of its upper structure (e.g., tool head or measuring head); k_m and c_m represent equivalent stiffness and damping of the internal structural components and joints; and k_v , c_v are the stiffness and damping, respectively, of the mounting devices (e.g., jacks or vibration isolators).

The effect of vibrations on an object may be described in terms of the ratio of the generalized relative displacement amplitude X_{grel} between masses M_u

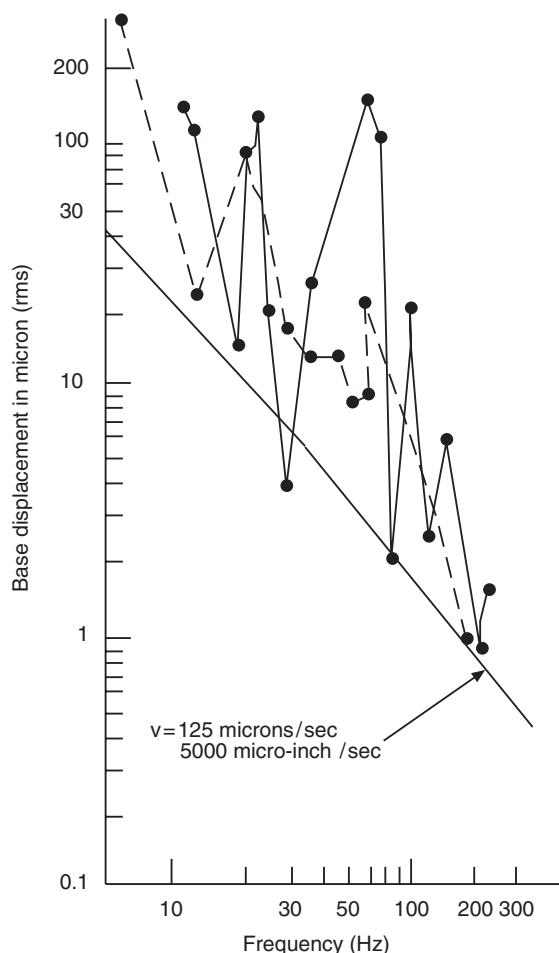

Figure 2 Vibration sensitivity for projection aligner Perkin-Elmer Microlign Mod. 341 for $0.1 \mu\text{m}$ image motion; (—) vertical floor vibration, (---) horizontal floor vibration.

and M_b to the displacement amplitude X_b of the frame M_b . This ratio is given as:

$$\frac{X_{grel}}{X_b} = -\frac{(f^2/f_m^2)}{\sqrt{[(1 - (f^2/f_m^2))^2 + [M_b/(M_u + M_b)](\delta_m^2 f^2/\pi^2 f_m^2)]}} = \mu_{rel} \quad [1]$$

where f is the frequency of interest, $f_m = (1/2\pi)\sqrt{(k_m/M_u)}$ is the (partial) resonance frequency of the upper structure, and δ_m is the log decrement of that system.

The actual relative displacement in the working area of the object is proportional to X_{grel} :

$$X_{rel} = \gamma X_{grel} \quad [2]$$

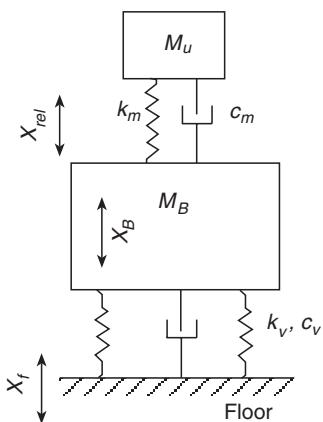

Figure 3 Two-mass dynamic model for vibration sensitivity of precision object in one principal direction.

and the proportionality design constant γ depends on geometry of the device. For example, for an upper structure represented by the model shown in Figure 4:

$$\gamma_{zx} = \frac{M_u b_1 c}{I_{O1}} = \frac{b_1 c}{\rho_y^2 + b^2 + c^2} \quad [3]$$

$$\gamma_{zz} = \frac{M_u c d}{I_{O1}} = \frac{c d}{\rho_y^2 + b^2 + c^2} \quad [4]$$

The first subscript on γ refers to the direction of the bed/frame vibration, and the second to the direction of motion of the upper structure relative to the bed; I_{O1} is its mass moment of inertia about the actual axis of rotation; and ρ_y is the radius of gyration about the principal y -axis. The dimensions b , b_1 , c , and d , as indicated in Figure 4, are measured from the center of gravity (CG) O_1 . The constant γ depends on the set up of the object, particularly on the position of the upper structure with respect to the bed. In Figure 4, the upper structure is attached by a torsional spring having infinite vertical stiffness. This is typical for structural designs of machine tools and measuring systems (guideways have high translational stiffness perpendicular to the motion direction, but significant angular deformations). Sensitivity of horizontal displacements in the work zone to vertical vibrations of the bed (γ_{zx}) can be reduced by reducing structural (design) dimensions c and b , by reducing overhang, or by adding counterweights to the back side of the structure. The sensitivity of vertical displacements in the work zone to vertical vibrations of the bed (γ_{zz}) can be reduced by reducing the design dimensions c and d .

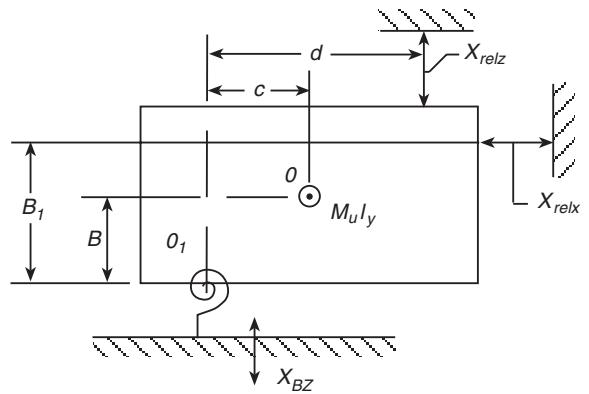

Figure 4 Dynamic model for influence of design parameters on relative vibration in working zone.

Similar machines may have very different (by one to two orders of magnitude) sensitivities to vibrations of their beds due to design differences.

The transmissibility, $X_{grel}/X_b = \mu_{rel}(f)$, from eqn [1] is a measure of the vibration sensitivity of the object as a function of the frequency f , and does not depend on the object's mounting, only on its design (structural natural frequency f_m and masses M_b , M_u). To obtain a ratio between the amplitudes of the relative vibrations within the working zone of the object and amplitudes of the floor vibrations, X_{rel}/X_b should be multiplied by the ratio of the bed vibration amplitudes to the floor vibration amplitudes (transmissibility of the mounting/isolation system), assuming that the dynamic coupling between the object structure and the vibration isolation system is weak, and that these systems can be considered to be independent. This assumption is justified since in most practical cases natural frequencies of the isolated bed in the three coordinate directions f_{vx} , f_{vy} , and f_{vz} , are considerably lower than the structural natural frequencies f_m , and the mass of the bed M_b is usually much larger than the mass of the upper structure M_u .

Principles and Criteria of Vibration Isolation

If a precision object is exposed to ambient vibrations characterized by a reasonably constant amplitude vibratory displacement, velocity, or acceleration in a certain frequency range, a resonance in the vibration isolation system is often inevitable. Accordingly, if the isolators have higher damping, natural frequencies of the isolation system (thus, stiffness values of the isolators) can be increased. The isolation system should satisfy the inequality:

$$\Phi_p^2 = f_v^2 / \delta_v < \frac{\Delta_0 f^2}{\pi X_f \mu_f} \quad [5]$$

where:

$$\Phi_p = \frac{f_v}{\sqrt{\delta_v}} = \frac{\sqrt{(k_v/(M_b + M_u))}}{\delta_v} \quad [6]$$

is the vibration isolation criterion for vibration-sensitive objects. The criterion Φ_p should be used instead of the natural frequency. It indicates that improvement in isolation can be achieved either by reducing the natural frequency f_v or by increasing the isolation damping δ_v . Such criteria can be specified for each coordinate direction of the isolation system. In eqns [5] and [6] k_v is the stiffness of the isolators, Δ_o , is the allowable vibration amplitude in the work zone, X_f is the maximum amplitude of the ambient vibration (same units, e.g., displacement or acceleration), and μ_f is the transmissibility from the object frame to the work zone at an arbitrary frequency, f .

Testing of numerous commercially produced vibration isolators for machinery and recommendations on their use based on a vast practical experience has shown that the recommendations are in good agreement with eqns [5] and [6].

The vibration isolation criterion eqn [6] also allows for a meaningful selection of resilient materials for vibration isolators. Both stiffness and damping of such materials usually depend upon amplitude a and frequency f of vibrations. The stiffness can be expressed as:

$$k = K_{dyn}(a, f)k_{st} \quad [7]$$

where k_{st} is the static stiffness of the isolator and K_{dyn} is the dynamic stiffness coefficient. Substitution of eqn [7] into eqn [6] yields

$$\Phi_p = \sqrt{\left(\frac{k_{st}}{M_b + M_u}\right)} \sqrt{\left(\frac{K_{dyn}(a, f)}{\delta_v(a, f)}\right)} \quad [8]$$

The static stiffness k_{st} of isolators for a given Φ_p can be increased (thus improving the stability of the isolated machine) by reducing K_{dyn}/δ_v . Since both K_{dyn} and δ_v depend upon frequency and, especially, the amplitude of vibrations, their ratio depends on material characteristics and vibration parameters. Optimum materials for vibration isolators for low ambient vibration amplitudes are very different from those for high amplitudes. Thus, wire-mesh and felt are more appropriate for high amplitudes, some rubber blends are preferable for smaller amplitudes, others for greater amplitudes.

The values of Φ_p for the three coordinate directions can be calculated using experimentally determined μ_f and given values for X_f and Δ_o . Then, using δ_v values for the selected isolators, the required natural frequencies in all three directions f_x , f_y , f_z can be calculated. Values of the permissible relative amplitudes Δ_o are chosen to correspond to one-half of the specified precision of the part being machined on a given machine tool. Values of the natural frequency ratios f_{vx}/f_{vz} , and f_{vy}/f_{vz} can be used to determine the required stiffness ratios of isolators in horizontal and vertical directions using the expression given in **Vibration isolation theory**. The results of the calculation of these parameters have been validated by the author by the successful installation of many thousands of precision machine tools.

Example If the vibration sensitivity $\mu(f)$ of a precision object is known (for example from the experimentally obtained plots as shown in Figure 2), then eqn [5] can be used to specify the vibration isolation parameters. For the case of Figure 2, $\Delta_o = 0.1\mu\text{m}$ is specified. Table 1 gives the values of $\mu(f)$ calculated for critical points from the plots in Figure 2 for vertical and horizontal directions, respectively. Table 1 also contains values of Φ_p calculated for these points using eqn [5] and assuming that for vertical direction $X_f(f) = \text{const.} = 3.0\ \mu\text{m}$ for frequencies in the range

Table 1 Vibration isolation synthesis for Figure 2

Vertical direction (Y-axis)									
f , Hz	11	12	20	25	30	32	41	70	80
$\mu(f)$	0.0083	0.010	0.087	0.0091	0.056	0.303	0.05	0.0077	0.010
Φ_1 , Hz	4.51	12.3	7.0	26.9	13.0	6.3	22.5	128	137
Φ_2 , Hz	12.9	36.6	26.9	116	61	29.7	106	601	644
Horizontal direction (X-axis)									
f , Hz	7	12	22	65	70	100	140	210	
$\mu(f)$	0.0033	0.05	0.0125	0.071	0.090	0.090	0.056	1.25	
Φ_1 , Hz	13.7	6.05	22.3	49.6	49.2	84	176	68.6	
Φ_2 , Hz	23.1	37.5	78	174	172	294	616	240	

3–30 Hz and $X_f(f) = 3.0 (30/f) \mu\text{m}$ for frequencies $f > 30 \text{ Hz}$; for the horizontal direction $X_f(f) = \text{const.} = 2.5 \mu\text{m}$ for frequencies of 2–20 Hz, and $X_f(f) = 2.5(20/f) \mu\text{m}$ for frequencies $f > 20 \text{ Hz}$. The values of Φ_{p2} were calculated using floor vibration levels corresponding to line VC-B in Figure 1 (both for vertical and horizontal directions). Values of Φ_{p1} are given only for comparison, since high precision microelectronic production equipment is never used in conventional plant facilities, only in specially designed buildings complying with some of VC curves.

It can be seen from Table 1A that the lowest value of Φ_{p1} for vertical direction is 4.51 Hz. If vibration isolators with medium damping $\delta_v = 0.6$ are used, then from eqn [6] the required vertical natural frequency $f_v = 4.51\sqrt{(0.6)} = 3.04 \text{ Hz}$. However, if isolators made of rubber with high damping $\delta_v = 1.2$ are used, then $f_v = 5.0 \text{ Hz}$, which can be realized by passive isolators. Much stiffer isolators can be used to comply with values of Φ_{p2} , which represent floor conditions at microelectronics industry installations.

A similar situation is seen in Table 1B, however, realization of natural frequencies corresponding to $\Phi_{p1}(4.7 \text{ Hz}$ for $\delta_v = 0.6$, 6.63 Hz for $\delta_v = 1.2$) in horizontal directions with passive isolators does not present any difficulty; even much lower values can easily be realized. Use of Φ_{p2} gives even more latitude in selecting isolator parameters.

In some cases, isolation from short duration (impulsive or shock) motions of the floor or other supporting structure is required. Such excitations are less troublesome due to their short durations. Accordingly, the permissible peak relative displacement Δ_{op} in response to floor shocks can be taken to be ~ 3 times the value of Δ_o permissible for steady-state vibrations. For an object subjected to shock excitation the shock spectrum approach (see **Vibration isolation theory**) can be used to obtain:

$$\Delta_p = A_{rel}a_b\gamma = A_1A_{rel}\gamma a_f \quad [9]$$

where a_b denotes the peak displacement of the bed caused by shock motion of the floor with displacement magnitude a_f , A_1 represents the shock spectrum corresponding to a versed-sine pulse acting on the vibration isolation system, and A_{rel} represents the shock spectrum for relative displacement in the work area corresponding to a versed-sine motion of the bed (Figure 5).

If γ and Δ_{op} are known, as well as the pulse magnitude a_f and duration τ_f (e.g., from **Vibration isolation theory**), then the values of the natural frequency f_{vp} of the isolation system that are necessary

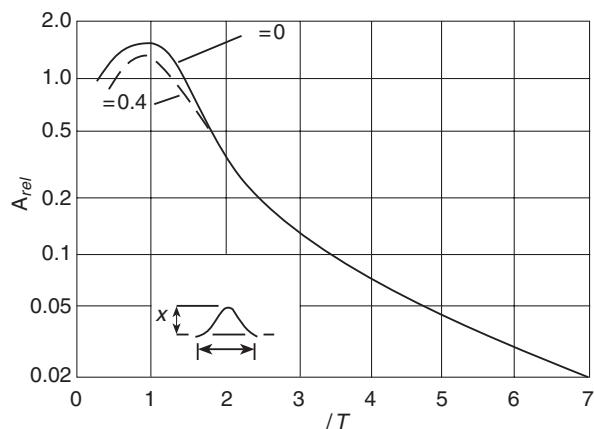

Figure 5 Maximum response amplitudes (shock spectrum) of generalized relative displacements in working zone for versed-sine pulse-motion of frame (t – pulse duration, T – natural period of object structure).

for adequate isolation may be determined from the foregoing expression by trial and error. The isolator damping has less effect on transmission of shocks than of steady motions. Values of f_{vp} for the z -direction that have been determined in this manner have been given elsewhere for a number of precision machine tools. These values are close to the natural frequency values f_v that are necessary with $\delta_v = 0.5$ to provide sufficient isolation of steady-state vertical vibration according to the Φ_{pz} criterion. This correlation holds for machine tools with very different and diverse design structures, it can be extrapolated to other precision devices. However, modern ultrahigh-precision equipment is always installed far from sources of intensive impulsive loads, and $30\text{--}60 \mu\text{m}$ displacement magnitudes of floor motions would never occur in the controlled environment facilities for high-precision equipment.

Vibration Isolation Systems

Required parameters of vibration isolation systems for various units of precision equipment are usually calculated with the assumption that there is no dynamic coupling between the vertical and horizontal vibrations of the object. However (see **Vibration isolation theory**), use of conventional constant-stiffness vibration isolators results in strong coupling of vibratory processes in various directions. This coupling can be caused by substantially nonuniform mass distribution in typical objects, difficulties in determining the CG positions and calculating weight distribution between the mounting points, large differences in nominal stiffnesses between sequential models of vibration isolators in a given isolator design line, and large deviations of the stiffness values from the

nominal values due to manufacturing tolerances. The undesirable coupling problem can be alleviated considerably by use of constant natural frequency (CNF) isolators, in which stiffness in both vertical and horizontal directions is proportional to the weight load on the isolator. Use of such isolators results in a system with very low degree of coupling between vertical and horizontal coordinates without the need to determine the CG position, to calculate the weight load distribution between the mounting points, etc. Such isolators also have a significantly reduced sensitivity to manufacturing tolerances. The effect of using CNF isolators is illustrated by Figure 6 which shows the frequency response of relative displacements between the grinding wheel and the table of a surface grinder caused by vertical floor vibrations of $5\text{ }\mu\text{m}$ amplitude in the 7–38 Hz range. Use of CNF isolators providing a 20 Hz natural frequency in the vertical (z) direction resulted in much better isolation than the best constant-stiffness isolators with a much lower 15 Hz natural frequency in the z -direction. The difference between vertical natural frequencies of 15 and 20 Hz is equivalent to approximately doubling the isolator stiffness for $f_{vz} = 20\text{ Hz}$.

Side Issues for Vibration-isolated Precision Equipment

Vibration isolation using passive isolators results in a reduced stiffness of the connection between the isolated object and the supporting structure (foundation). This can lead to rocking motions of the object if it contains internal massive moving units (e.g., tables in surface grinders, gantries in CMMs), and

to reduction of the effective rigidity of the equipment frame not structurally tied to the rigid foundation. These issues may be important for any device installed on flexible mounts, but are especially important for vibration sensitive precision devices.

The rocking motion of isolated precision machines may become objectionable if it does not settle until the next cycle of operation (next grinding pass on a surface grinder or next measurement event on CMM) and low frequency but intense rocking vibrations are transmitted into the working zone. The rocking may be reduced by installing the machine rigidly on massive foundation blocks and placing vibration isolation means under these blocks. This approach is expensive and time consuming for installation and, especially, for relocation of the object/machine. Often the direction of maximum vibration sensitivity is at a right angle to that of the internal excitation, and use of anisotropic isolators with optimized stiffness ratios can be beneficial. A higher stiffness of the isolators in the direction of internal excitation reduces the amplitudes and increases the frequency of the rocking motion. The latter leads to faster decaying of the rocking motion. Increased distances between isolators in the direction of the internal excitations reduce the angular motion component (associated with large amplitudes of motion) and increase the translational component, thus significantly improving the stability of the object. The increased distances between isolators can be achieved by installing isolators under a plate or rails attached to the frame/bed of the object. Increased damping of the vibration isolators reduces the settling time, especially in the direction of the rocking motion.

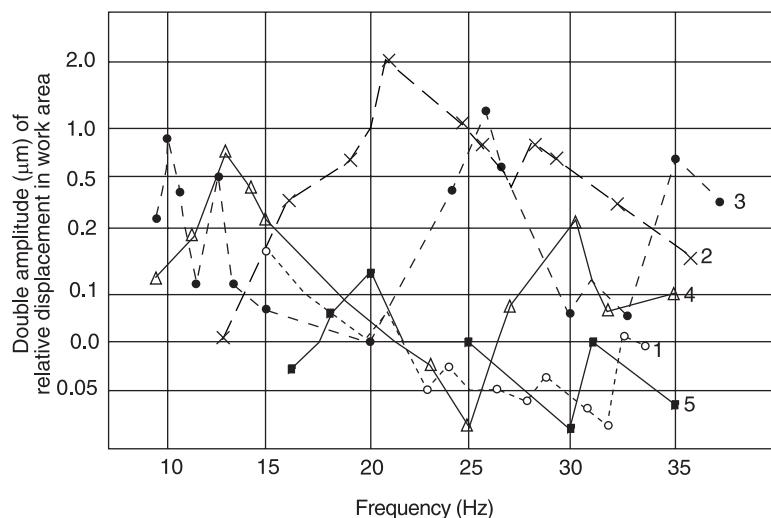

Figure 6 Amplitudes of relative motion in working area (between grinding wheel and table) of 3B71 surface grinder excited by $5\text{ }\mu\text{m}$ amplitude floor vibration for the machine installed on various isolators: (1) rubber-metal CNF isolators, $f_{vz} = 20\text{ Hz}$; (2) steel wedges, $f_{vz} = 27\text{ Hz}$; (3) wire-mesh isolators, $f_{vz} = 25\text{ Hz}$; (4) plastic pads, $f_{vz} = 30\text{ Hz}$; (5) rubber-metal isolators, $f_{vz} = 15\text{ Hz}$.

Usually, smaller precision devices do not require the addition of a foundation to enhance the rigidity of their frames, whereas larger devices (e.g., machine tools weighing over 10 t) usually do, unless they are specially designed to be mounted on three supporting points. For machines of intermediate weight (5–10 t), judicious placement of the vibration isolation mounts using the ‘Bessel’s points’ principle may reduce static deflections of the frame, thus effectively making it act as if it were more rigid. Another way of stiffening the frames of precision equipment units is to attach them to rigid plates or specially designed rigidizing frames.

Isolation Requirements for Vibration-producing Objects

Objects Producing Single Frequency Excitations

A frequency ratio $f/f_{vz} = 4–5$ is usually recommended for isolation of objects generating a single frequency (f) dynamic force (e.g. created by rotating unbalanced parts), where f_{vz} is the vertical natural frequency of the isolation system. This brings a 15–25 times reduction of transmission of the vertical component of the dynamic force, but f_{vz} can become rather low, such as $f_{vz} = 5–6$ Hz for rotors with a rotational speed of 1500 rpm, 3–4 Hz at 900 rpm, and therefore steel-spring isolators are frequently used. They have low damping and poor performance in a high-frequency range, $f > \sim 10f_{vz}$, thus high frequency excitations due to inaccuracies of bearings, clearances, etc., are not attenuated and may be amplified.

The frequency ratio can be reduced by considering the transmissibility in all of the modes of the isolation systems. The critical cases are ones where the largest components of the dynamic force are vertical. Horizontal force components are easier to isolate since low natural frequencies of horizontal (and/or rocking) vibrations are not associated with the instability of the isolated object, unless the vertical natural frequency is low. Objects containing horizontal (or inclined) unbalanced rotors are usually associated with generation of intense vertical dynamic forces.

Two principal force components are z , component (F_z), and x , component (F_x). The transmissibility for F_z is determined by the natural frequency f_{vz} , and for F_x , by the natural frequency $f_{x\beta}$ of the lower rocking mode.

The transmissibility for an oscillatory torque T_y is mostly determined by the higher rocking mode $f_{\beta x}$. For a z -axis rotor the correspondence is: $F_x - f_{x\beta}$; $F_y - f_{yx}$; where the oscillatory torque is f_γ . Modal coupling is not considered.

The effectiveness of vibration isolation depends on attenuation of all dynamic force and torque components. Orthogonal components of the dynamic forces are phase-shifted by $\pi/2$. If for a z -axis rotor F_o is the centrifugal force amplitude, then:

$$\begin{aligned} F_x &= F_o \sin 2\pi ft \\ F_y &= F_o \sin(2\pi ft - \pi/2) \\ F'_x &= F'_{xo} \sin 2\pi ft \\ F'_y &= F'_{yo} \sin(2\pi ft - \pi/2) \end{aligned} \quad [10]$$

$$\begin{aligned} \mu_{F_x} &= F'_{xo}/F_o; \quad \mu_{F_y} = F'_{yo}/F_o \\ \mu_F &= \frac{\sqrt{\left(F'_{xo} \sin 2\pi ft\right)^2 + \left(F'_{yo} \cos 2\pi ft\right)^2}}{F_o} \end{aligned} \quad [11]$$

Here $'$ denotes components on the output side of vibration isolators; μ_{F_x} and μ_{F_y} are transmissibilities along the respective axes; and μ_F is the overall force transmissibility. The amplitude of the trigonometrical expression $(A \sin \phi)^2 + (B \cos \phi)^2$ is equal to $\max(A^2, B^2)$, and the overall transmissibility is:

$$\mu_F = \frac{\max(F'_{xo}, F'_{yo})}{F} = \max(\mu_{F_x}, \mu_{F_y}) \quad [12]$$

The effectiveness of vibration isolation is determined by the transmissibility in the highest mode for force. Usually, only one significant factor (force or torque) is present, thus transmissibility in only one mode can be considered. If both factors are present, then the ‘effective transmissibility’ μ , or their weighted average can be used. For the z -axis and y -axis rotors:

$$\begin{aligned} \mu_z &= \frac{1}{2}(W_F \mu_F + W_T \mu_T) \\ &= \frac{1}{2} \left[W_F \max(\mu_{F_x}, \mu_{F_y}) + W_T \max(\mu_{T_x}, \mu_{T_y}) \right] \end{aligned} \quad [13]$$

$$\mu_y = \frac{1}{2} \left[W_F \max(\mu_{F_z}, \mu_{F_x}) + W_T \max(\mu_{T_z}, \mu_{T_y}) \right] \quad [14]$$

where weighting factors $W_F W_T = 2$. In general, transmission of torque is less dangerous. With widely

spaced isolators the forces creating the output torque are small, with narrow spaced isolators action of the torque on the supporting structure is local. Thus, $W_F = 2W_T$ can be assumed. Eqns [13] and [14] are conservative since reactions of the isolators due to forces and torques should be added up as vector quantities.

Example Validation on a vertical-axis hammer crusher ($f = 12 \text{ Hz}$; $f_{x\beta} = f_{y\alpha} = 1.66 \text{ Hz}$; $f_{\beta x} = 3.5 \text{ Hz}$; $f_{xy} = 4.0 \text{ Hz}$, and $\mu_{F_x} = 0.02$; $\mu_{T_x} = 0.093$; $\mu_{T_y} = 0.125$). From eqn [13] with $W_F = 2W_T = 1.33$, we obtain $\mu = 0.042$. By measuring floor vibrations with and without isolators, we obtained $\mu = 0.0355$.

From eqns [13] and [14], the necessary natural frequencies can be determined for a required attenuation μ . Typical values for vibration isolation systems for machinery are: $\eta_{x,y} = k_z/k_{x,y} = 4.0$; $f_{x\beta}, f_{y\alpha} = 0.45f_z$; $f_{\beta y}, f_{xx} = 1.2f_z$; $f_y = 1.15f_z$. For these values and the required $\mu = 0.20$ (five times attenuation, which is adequate in most cases), the necessary frequency ratios are: from eqn [13] for z -axis rotors $f/f_z > \sim 2.0$; from eqn [14] for x -axis rotors $f/f_z > \sim 2.6$.

Objects Producing Polyharmonic Excitations

Isolation of polyharmonic dynamic forces depends on the spectral content of the excitation, absolute values of the lowest frequencies of dangerous components, dynamic characteristics of the structures and equipment to be protected, etc. When inertia blocks and highly damped isolators (with internal damping which does not significantly impair postresonant transmissibility) are used, resonance (not of the most dangerous spectral component) could be a permissible working regime.

Objects Producing Conservative Impact Excitations

Typical objects are stamping presses. Reaction moments generated by the production pulse loads excite the lower rocking mode in the $x-z$ plane. Stamping presses generate ‘versed-sine’ pulses. Typical working conditions of crank presses generate pulses with duration $\tau = \sim 0.1t_c$ for automatic operation and $\tau = \sim 0.05t_c$ for manual operation (single strokes). Here t_c is the time of one working cycle (one crank revolution). The nominal pulse duration for synthesis of the vibration isolation system is calculated for n_{\max} , the maximum rate of strikes-per-minute (spm):

$$\tau_{\text{nom}} = 0.1(60/n_{\max}) = 6/n_{\max} \quad [15]$$

With the press rigidly attached to the floor, the lower rocking modes are at $f_{x\beta}, f_{y\alpha} = 15-25 \text{ Hz}$. For presses with $n_{\max} = 60-200 \text{ spm}$, dynamic loads to the floor may be amplified by a transmissibility factor 1.2–1.5, in accordance with the ‘shock spectrum’ for the versed-sine pulse; see **Vibration isolation theory**. Sometimes, presses are fastened to inertia (foundation) blocks whose mass is about equal to the press mass. This reduces the dynamic pulse transmission to the environment by $\sim 50\%$, thus the transmissibility factor is about $\mu = 0.6-0.75$. The required degree of attenuation of the pulse magnitude by vibration isolation is $\mu = 0.5$ since installation of the press on vibration isolators would attenuate the most objectionable high frequency components of the pulse much more than the magnitude of the pulse. For damping in the isolators $\delta_v = 0.6$, the required rocking natural frequency:

$$f_v = f_{x\beta} = n_{\max}/30(\text{Hz}) \quad [16]$$

For high CG/narrow base presses an intense rocking of the machine can occur. It can be corrected by extending distance between mounts in the rocking direction by mounting the press on a frame or rails.

Some production machines (cold heading machines, injection molding machines, etc.) generate intensive dynamic loads of the conservative nature in a horizontal direction. Such machines have heavy reversing masses generating large horizontal inertia forces in addition to conservative pulses associated with the production process. This may result in intense rocking of the machine on vibration isolators. Reduction of the undesirable rocking can be achieved by increasing vertical stiffness of the isolators.

Objects Generating Pulses of Inertial Nature

Forging hammers and casting mold conditioning machines are the most hazardous industrial sources of vibration. Hammers are installed on massive foundation blocks supported by compliant steel springs. Damping is provided by viscous friction units or large rubber cubes, but is usually low, $\delta = 0.2-0.3$. Oak beams or reinforced rubber belting pads under the anvil are the first stage of vibration isolation. **Figure 7** is a schematic model for an isolated forging hammer; m represents the mass of dropping tup with the upper die, m_2 is the anvil, $m_3 = m'_3 + m''_3$ represents frame m'_3 attached to foundation block m''_3 , m_4 is the foundation box.

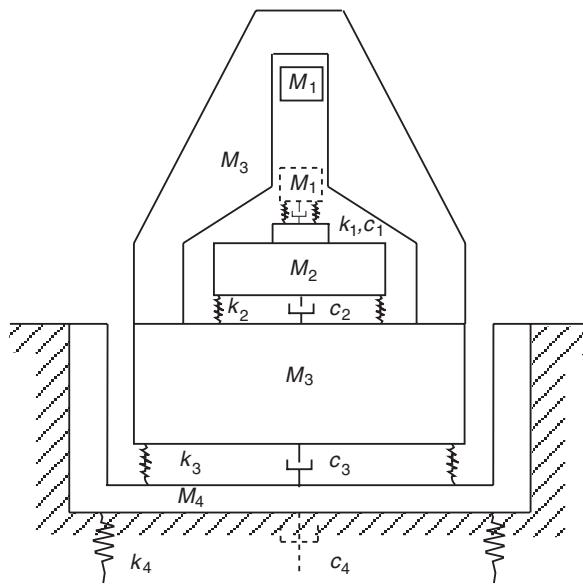

Figure 7 Dynamic model of forging hammer isolation system.

The stiffness and damping, respectively, of the die-billet subsystem are k_1 , c_1 ; of the first isolation stage between the anvil and the foundation block k_2 , c_2 ; of main isolators k_3 , c_3 ; and the effective stiffness and damping coefficients for the surrounding soil are k_4 , c_4 . Partial natural frequencies for typical vibration isolated hammers are: for $m_2 - k_2 - m_3$, ~ 50 Hz; for $m_3 - k_3 - m_4$, between 2 and 7 Hz; for the foundation box-soil subsystem $m_4 - k_4$ and usually $f_{n4} = 15 - 20$ Hz.

The impact pulse in forging hammers is a half-sine pulse; its magnitude P_o and duration τ_p depend on the billet material, its temperature, design and the size of the die. For the worst case (impact of the upper die against the lower die without billet material inside) the pulse parameters are given in Table 2.

Analysis of the propagation of the impact pulse through the system in Figure 7 resulted in the transmissibility expression:

$$\frac{P_{3\max}}{P_{o\max}} \cong 6.9 \sqrt{\left(\frac{m_3 m_4^2}{(m_3 + m_4)(m_1 + m_2 + m_3)(m_1 + m_2 + m_3 + m_4)} \right) \tau_p f_n} \quad [17]$$

where $P_{3\max}$ is the magnitude of the force pulse transmitted to the foundation box, and the fundamental natural frequency of the isolated hammer is:

$$f_n = \frac{1}{2\pi} \sqrt{\left(\frac{k_3(m_1 + m_2 + m_3 + m_4)}{(m_1 + m_2 + m_3)m_4} \right)} \\ = f_{n3} \sqrt{\left(\frac{(m_1 + m_2 + m_3 + m_4)m_3}{(m_1 + m_2 + m_3)(m_3 + m_4)} \right)} \quad [18]$$

Thus, for the short pulse excitation the transmitted force $P_{3\max}$ is proportional to the natural frequency of the isolation system, while in cases of isolation of steady (e.g., sinusoidal) vibrations the transmitted force is proportional to the second power of the natural frequency. However, in the latter case the vibration transmitted to the supporting structure is at the excitation frequency, while for the pulse excitation the transmitted vibration has a less hazardous low frequency equal to the natural frequency f_{n4} . Within the assumed approximations, the effectiveness does not directly depend on the stiffness k_2 of the auxiliary isolation system.

The amplitude of the foundation box is approximately equal to its static deflection under $P_{3\max}$, since $f_n = 2 - 7$ Hz is substantially lower than the natural frequency f_{n4} . The soil stiffness k_4 is nonlinear; the effective stiffness k_4 can be calculated as:

$$k_4 = 4\pi^2 f_{n4}^2 m_4 \quad [19]$$

Table 2 Impact pulse parameters for forging hammers

	1	2	3	5	5.5	10	15	20
Dropping mass (tup + upper die), m_1 , t								
Pulse duration, τ_{p1} , ms	1.0	1.26	1.44	1.69	1.75	2.07	2.45	2.64
Load magnitude, P_o , kN	1925	2830	3700	5130	5500	7500	10890	12400

The amplitude of soil vibration in the first approximation is:

$$a_s = \frac{P_{3\max}}{k_4} = \frac{P_{3\max}}{4\pi^2 f_{n4}^2 m_4} = 0.17 \sqrt{\left(\frac{m_3 m_4^2}{(m_3 + m_4)(m_1 + m_2 + m_3)(m_1 + m_2 + m_3 + m_4)} \right) \frac{\tau_{pl} f_n}{f_{n4}^2}} \quad [20]$$

Example For a hammer with $m_1 = 5000 \text{ kg} = 5 \text{ t}$, $m_2 = 20m_1$, $m_3 = 60m_1$, $m_4 = 40m_1$, $\tau_{pl} = 0.0017 \text{ s}$, $f_n = 4.5 \text{ Hz}$, $P_{0\max} = 5.1 \times 10^6 \text{ N}$, from eqn [17] $P_{3\max} = 0.0165 P_{0\max} = 0.083 \times 10^6 \text{ N}$. From eqn [20], $a_s = 2.3 \times 10^{-4} \text{ m}$. The measured amplitude of the foundation box vibration was $a_s = 1.8 \times 10^{-4} \text{ m}$. The discrepancy ($\sim 24\%$) is due to: less severe impact conditions during the test (a billet was forged rather than rigid dies coimpacted); damping c_2 , c_3 , c_4 , as well as the nonlinearity of soil behavior were not considered in the analysis; etc.

The fundamental natural frequencies of industrial and residential buildings (2–4 Hz) are in the range of the natural frequencies of the spring-isolated foundations, thus quasiresonant amplification of building vibrations may occur due to slow decay of soil vibrations resulting from one hammer blow.

The increased damping in both anvil and main isolators would reduce (but not very significantly), the transmissibility described by eqn [17]. In addition, the increased damping accelerates decaying of the foundation vibrations and thus reduces adverse vibration effects on humans, on precision equipment, and on structures. Considering both effects, the principal parameter of the vibration isolation system for an object generating inertial pulses, such as forging hammers, becomes not its main natural frequency f_n , but a shock isolation criterion:

$$\Phi_{sh} = \frac{f_n}{\delta^{0.25}} \quad [21]$$

Increasing damping in both main and anvil isolators to $\delta = 1-1.25$ allows us to increase the natural frequency of the vibration isolation system by a factor of ~ 1.5 , from $f_n = 2-6 \text{ Hz}$ to $3-9 \text{ Hz}$ with the same isolation effectiveness. Stiffer springs and/or reduced mass m_3 of the foundation block can be used without degrading the system stability but significantly cutting costs. These conclusions were validated by testing a 0.75 t hammer on the foundation block supported by rubber isolating mats ($f_n = 7 \text{ Hz}$, $\delta = 0.8$). The system performance was satisfactory, similar to the performance of spring-suspended foundations having lower natural frequencies.

General Purpose Machinery and Equipment

Selection of the isolation system parameters for this large and diversified group is influenced by the dynamic stability and vibration level of the machine, and dynamic loads in the joints (especially bearings).

Influence of Mounting Conditions on Dynamic Stability

Working processes in production machinery, especially the cutting processes, may, in effect, introduce negative damping into the structure. When the total damping balance in the system machine/production process becomes negative, chatter appears. Fastening the machine bed by stiff mounts to a rigid foundation improves the dynamic stiffness of the machine structure and its chatter resistance. Compliant mounts (vibration isolators) may not have such an effect. The influence of natural frequency and damping of the isolation system on the dynamic stability of the production process can be analyzed by considering the dynamic coupling in the system. If the dynamic stability of a machine is sensitive to mounting conditions, their effect is determined by the magnitude of the dynamic stability criterion:

$$\Phi_{ds} = f_v^3 \delta_v \quad [22]$$

This criterion states that a small reduction of the natural frequency of the mounting or vibration isolation system can only be compensated by a substantial increase in damping of the mounting system.

Vibration isolators influence the chatter resistance of a machine tool only when its structural stiffness k_m and/or structural damping δ_m are low, or other structural or process features are not optimal. Stiff machine tools are usually not noticeably influenced by mounting conditions. Sensitivity to the mounting condition may change as a result of changing its internal configuration (position of the tool carriage in a lathe, position of the gantry on a plano-milling machine, etc.).

Example The dynamic stability criterion (eqn [22]) was validated by extensive tests performed on a

medium-sized lathe. Chatter resistance (the maximum depth of cut without chatter t_{lim}), was measured with different sets of mounts, both all-metal jack mountings and CNF isolators with rubber flexible elements, providing various natural frequencies and degrees of damping of the installation/vibration isolation system. Figure 8 shows that the values of t_{lim} for different mounting conditions are closely correlated with values of Φ_{ds} .

Vibration Levels of General Purpose Machines

Vibrations with the natural frequencies of the mounting system may interfere with the normal performance of general purpose machines. A real machine has a multitude of vibration sources acting in different directions and with different frequencies; the dynamic characteristics of the floors and other supporting building structures may also affect the vibration levels. While nonexcessive vibration levels may not be detrimental for performance, they may cause annoyance and discomfort to operators. Though only an experimental selection of isolators is reliable, the semi-qualitative analytical criteria listed below can be useful.

The most common vibration source is centrifugal forces from rotating unbalanced components, such as gears, pulleys, flanges, etc. The amplitude of the centrifugal force is proportional to the second power of the rotational frequency f . However, tolerances on the unbalance values become stricter for higher f . Allowable F_{cf} is proportional to $f^{0.5}$ for rotors of electric motors; to $f^{0.5}$ for grinding wheels; to $f^{0.5} - f^{-0.5}$ for unbalanced blanks for machining

on lathes, such as forgings, castings, etc. It can be assumed that the rated amplitudes of the centrifugal forces do not depend on frequency. This is often true for other sources of machine vibrations. The most pronounced spectral amplitudes of vibratory displacement for several types of machine tools, determined during idling and averaged over an ensemble can be considered as frequency independent in the 10–100 Hz range. Thus, resonances in the system ‘machine on its mounts’ are very probable for both rigid and soft mounting elements. The maximum amplitudes of relative displacement in the working area with the above assumptions do not depend on the natural frequency of the isolation system, but only on its damping which could be considered as a vibration level criterion:

$$\Phi_{vl} = \delta_v \quad [23]$$

Often the vibratory velocity level is considered as an indicator of the machine vibration status. An equally hazardous or annoying action of vibration on personnel corresponds to an equal vibratory velocity level at frequencies higher than 2–8 Hz (International Standard, ISO 2631). Comparison of alternative mounting systems can be performed by the vibratory velocity level criterion:

$$\Phi_{vv} = f_v \delta_v \quad [24]$$

Thus, to reduce the vibratory velocity level of an isolated object, increase of the natural frequency and of damping have similar effects.

Influence of Vibration Isolation on Bearing Loads

In many cases the useful life of bearings inside the machine installed on vibration isolators is lengthened. Dynamic loads acting on bearings are due mainly to the centrifugal force from the supported unbalanced rotor. While the main effect of vibration isolation is reduction of transmission of the unbalanced force $F(t)$ to the foundation, the secondary effect of vibration isolation is change of dynamic load $R(t) = R_o \cos \omega t$ in the bearing. The influence of the isolators on the dynamic load amplitude R_o can be expressed as the influence function:

$$W = (R_o)_v / (R_o)_r \quad [25]$$

where $(R_o)_v$ is the dynamic load amplitude in the bearings of the isolated object comprising the rotor, and $(R_o)_r$ is the same for the rigidly installed object. In a broad frequency range, both force transmissibility $\mu_F < 1$, and $W < 1$, thus vibration isolation is accompanied by reduction of dynamic loads in bearings.

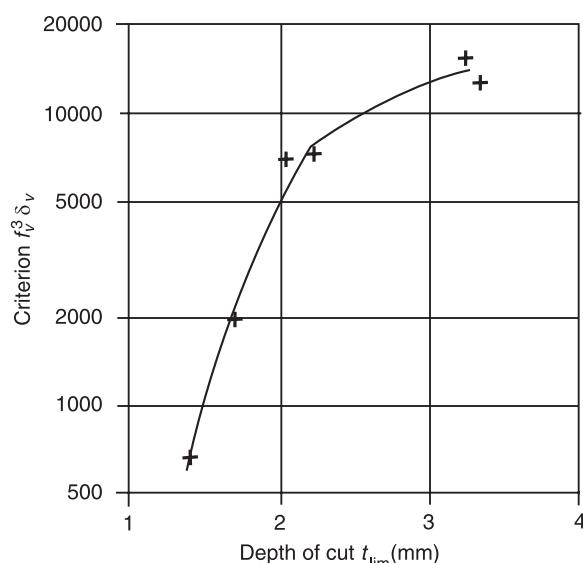

Figure 8 Maximum stable depth of cut t_{lim} vs criterion $f_v^3 \delta_v$.

Figure 9 shows μ_F and W vs the frequency ratio f/f_v , where f_v is the natural frequency of the vibration isolation system, for a case of light rotor ($M_1/M_2 = 0.1$), **Figure 9A**, and for a case of heavy rotor ($M_1/M_2 = 1.0$), **Figure 9B**. Here M_1 is the mass of the rotor, M_2 is the mass of the machine, k_1 is the stiffness of the bearing; k_2 is the stiffness of the isolators. The stiffness ratio for both cases is $k_1/k_2 = 10$ and the damping ratios for both the rotor subsystem $M_1 - k_1 - M_2$ and for the vibration isolation subsystem $M_2 - k_2$, are $\zeta_1 = \zeta_2 = 0.005$. The frequency ranges within which both μ_F and $W < 1$ are quite broad.

Influence of Vibration Isolation on Noise

Vibration isolation reduces the transmission of high frequency vibrations across structures and thus should result in reduction of noise in spaces which are adjacent to an isolated vibration-producing device, but separated from this device by structural

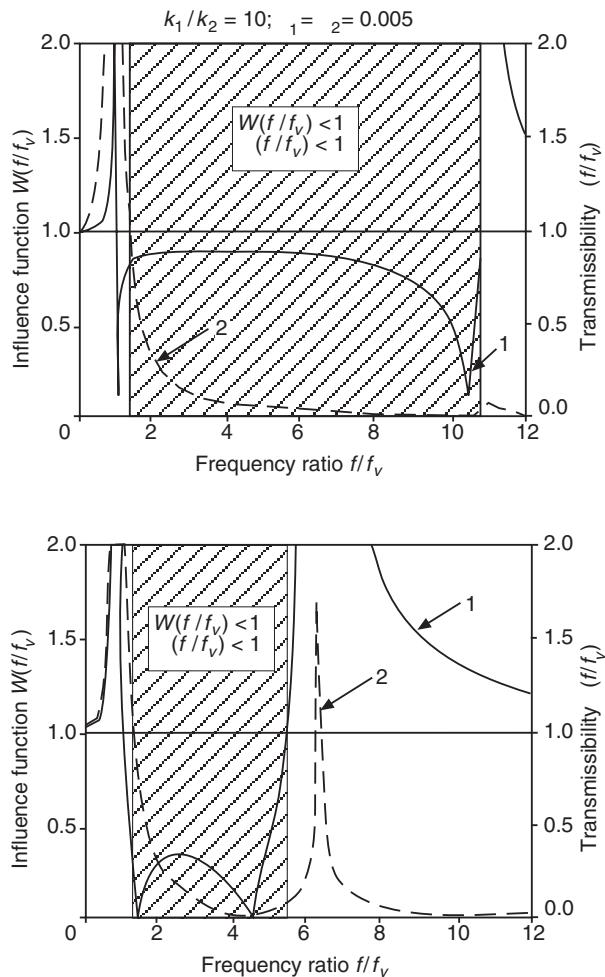

Figure 9 Frequency dependence of influence function W (1) and transmissibility μ_F (2). (A) light rotor ($M_1/M_2 = 0.1$); (B) heavy rotor ($M_1/M_2 = 1.0$).

partitions. An example of such transmission reduction is illustrated in **Figure 10**. It is less obvious what happens in the near-field at the device itself. **Figure 10** shows that noise level at the device may decrease or increase. Noise levels measured at a stamping press sometimes are reduced when the press is installed on vibration isolation mounts.

A noticeable noise reduction results if the majority of production machinery in a shop is installed on vibration isolators, most probably due to reduction of floor-radiated noise. In a shop with ten operating lathes, the sound pressure level reduction was 2 dB(A) (87.5 dB(A) for vibration isolated machines vs 89.5 dB(A) for rigidly installed machines) after rigid attachment to the floor (cement grouting) was replaced by installation on CNF isolators, $f_{vz} = \sim 20$ Hz. Even more significant, 4–5 dB(A) reduction was measured in the most annoying high frequency range.

Vibration Isolated Objects Installed on Nonrigid Supporting Structures

Stationary (e.g., production and measuring) equipment is usually attached by vibration isolators to rigid supporting structures (foundation plates, individual foundation blocks). However, in some cases both vibration-sensitive and vibration-producing devices are installed on nonrigid structures, such as floors over the basement or on higher floors of multistory buildings. This is always the case for objects installed

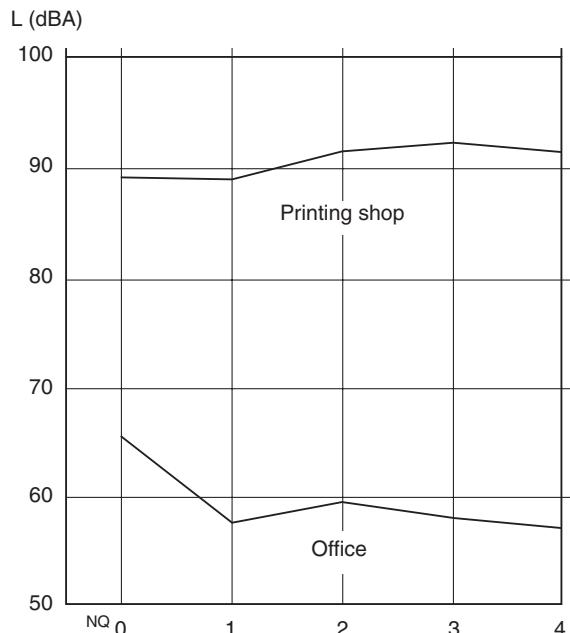

Figure 10 Noise level readings vs mounting conditions for knife-type paper folding machine on the second floor; the office is at the ground floor underneath the machine.

on vehicles, such as car engines, machinery on surface and underwater ships, aircraft, etc.

This problem can be analyzed by modeling the dynamic characteristics of the isolated object, the supporting structure, and the impedances of the vibration isolators. In most cases, the mass of the isolated object is substantially greater than the ‘effective mass’ of the supporting structure significantly involved in the vibratory process associated with the object. On the other hand, the effective stiffness of the supporting structure in the vicinity of the object is substantially greater than the stiffness values of the isolators. Thus, the main influence of the nonrigid supporting structure is usually modification (usually reduction) of the effective damping in the system. The situation may be significantly different in the high (acoustical) frequency range where the supporting structure, the isolated object, and the isolators (considered as distributed parameters system with corresponding high frequency resonances) are interacting dynamically. The system ‘car engine–engine mounts’ has been analyzed for the case of rigid foundation and for the case of actual supporting conditions on the low-stiffness vehicle sub-frame. Figure 11 shows force transmissibility for a rigid foundation and for the actual ‘flexible’ supporting structure. The lines are similar; the resonance peaks of transmissibility are at the same frequencies (engine rpm) in both cases. Some peaks have increased height (reduced damping), some have reduced height (increased damping), and one peak is the same for both cases.

Some general considerations for vibration isolation of objects on nonrigid structures, based on analyses of simple models can be formulated as follows:

Installation of vibration-sensitive devices The upper floor vibration levels are usually 1.25–1.7 times higher than those of the ground floor, thus the vibration isolation criterion Φ_p from eqn [6] should be 1.4–1.7 times less than it would be for the same device on the ground floor. Since a corresponding reduction of natural frequency may create instability or excessive rocking motions, the proper approach is to increase damping while not significantly reducing isolator stiffness.

Installation of a vibration producing or a general purpose machine The response of the nonrigid supporting structure to excitation is amplified because of its small damping. Use of compliant isolators may lead to instability or to excessive rocking motions. But since the effective mass of the floor ‘attached’ to the installed machine is $\sim 1.5\text{--}2.5$ times less than the mass of the machine (for floor structures made of prestressed concrete plates). Thus, the dynamic characteristics, especially damping, of the floor structure can be controlled by using highly damped isolators. It is possible to increase the effective damping of the floor (or other nonrigid supporting structure, such as vehicle structure) 2.5–4 fold and thus correspondingly reduce its sensitivity to external excitations.

Experimental Selection of Isolators

The above criteria do not consider the dynamic data of the floor; specific features of machine vibrations in different modes of the isolation system; dynamics of the machine itself and isolators in a high-frequency range; the real character of exciting forces; various

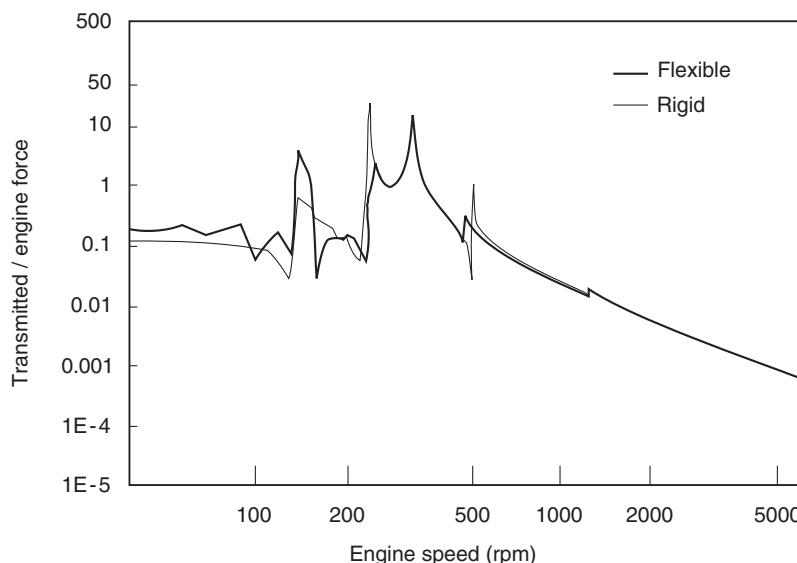

Figure 11 Transmissibility for rigid and flexible foundation models for engine mounted in vehicle (at transmission mount location).

regimes of machine performance, etc. The selection of isolators that consider these factors could provide substantial advantages. However, an analytical approach for individual objects seems to be impractical. The best way is to compare several alternatives of the machine installation, with specific reference to the specified requirements, when each alternative is characterized by a single-rated parameter (selection criterion). Since reinstallations of the objects, especially large ones, is a time- and labor-consuming procedure, variable-stiffness isolators can be useful.

When the object to be vibration isolated is used in different modes of operation (e.g., a machine tool with many spindle and feed speeds, a car engine operating in a broad rpm range), a 'common sense' approach can be used, or the selection criterion can be:

$$B_{\Sigma} = \alpha_1 \beta_1 B_1 + \cdots + \alpha_i \beta_i B_i + \cdots \quad [26]$$

where B_i is the selection criterion for the i th mode of operation, α_i is the weighting factor assigned to the i th mode, and β_i is a fraction of full working time during which the device is used in the i th mode of operation.

Example The 'common sense' selection of vibration isolators was applied for a knife-type folding machine installed on the second floor of the printing shop. The goal was to reduce noise transmission from the machine into the office room downstairs. Figure 10 gives noise level readings in dBA in the office and in the printing shop for the machine on metal jack mounts (#0) and on rubber mounts providing different f_v (26 Hz – #1; 20 Hz – #2; 16 Hz – #3; 10 Hz – #4). Unexpectedly, the #1 alternative (the stiffest isolators) was judged optimal (it gave the same noise level in the office as for #4 isolators, but lower noise in the printing shop and less rocking of the machine).

Nomenclature

f	frequency
F	force
I	inertia
M	mass
O_1	center of gravity
T	torque

W	weighting factor
X	amplitude
δ_m	log decrement
δ_v	isolation damping
τ	duration

$$\alpha_r = \frac{Z_1 - Z_2}{Z_1 + Z_2} \quad [2]$$

$$\alpha_t = \frac{2Z_1}{Z_1 + Z_2} \quad [3]$$

Introduction

The propagation of vibration in complex connected structures transmits and reflects elastic waves at junctions between different structural members of that structure. These junctions represent structural discontinuities, be it a geometrical change of shape, a change in the type of the element, a change in the cross-sectional area, density or elasticity, or changes introduced externally such as blocking masses, elastic springs, and boundary conditions.

Since these changes at a junction will cause reflection and transmission of the incident waves at that junction, part of the incident vibration mechanical power is transmitted through, giving rise to attenuation of vibrational power across that junction. In this section, the reflection or transmission coefficients will be presented for structural members undergoing longitudinal, torsional or flexural vibration.

Longitudinal Vibration

Change of Cross-section

Consider an infinite elastic bar or plate, $\infty < x < \infty$, whose density, Young's modulus, Poisson's ratio and cross-section are ρ_1 , E_1 , v_1 , and A_1 , for $x < 0$ and ρ_2 , E_2 , v_2 , and A_2 for $x > 0$. An incident longitudinal wave traveling in the $x < 0$ region in the positive x direction impinges at the junction $x = 0$ and causes a reflected wave in the $x < 0$ region and a transmitted wave in the $x > 0$ region. Defining the impedance for sections $x < 0$ or $x > 0$ as Z_1 and Z_2 , respectively:

$$Z_1 = A'_1 \sqrt{(\rho_1 E'_1)} \quad [1]$$

and

$$Z_2 = A'_2 \sqrt{(\rho_2 E'_2)}$$

where $E' = E$ for beams and $E' = E/(1 - v^2)$ for plates and $A' = A$ for beams and $A' = b$ for plates, then the transmission and reflection coefficients α_r and α_t , respectively, are given by:

Since the vibrational power is proportional to the impedance and the velocity squared, the reflection and transmission efficiencies τ_r and τ_t are given by:

$$\tau_r = |\alpha_r|^2 \quad [4]$$

$$\tau_t = \frac{Z_2}{Z_1} |\alpha_t|^2 \quad [5]$$

Note that the reflected and transmitted efficiencies add up to unity. The formulae given in eqns [3] and [5] represent the transmission loss factors for changes due to density, elasticity or cross-sectional area.

Blocking Mass on an Infinite Bar

Consider a blocking mass M attached to an infinite uniform bar at $x = 0$, the reflection and transmission coefficients are:

$$\alpha_r = \frac{i\omega M/2Z}{1 + i\omega M/2Z} \quad [6]$$

$$\alpha_t = \frac{1}{1 + i\omega M/2Z} \quad [7]$$

$$\tau_r = \frac{\omega^2 M^2 / 4Z^2}{1 + \omega^2 M^2 / 4Z^2} \quad [8]$$

$$\tau_t = \frac{1}{1 + \omega^2 M^2 / 4Z^2} \quad [9]$$

where $Z = A' \sqrt{(\rho E')}$

Torsional Vibrations

Since torsional wave propagation in elastic torsion members obeys the same wave equation as longitudinal vibrations, one could rewrite the formulae, eqns [2]–[5], for torsional vibration reflection and transmission across a junction by redefining the impedances. Let ρG and J represent the density, shear modulus and cross-sectional polar moment of inertia

of a circular torsional member, respectively, then define the moment impedances as:

$$Z_1 = J_1 \sqrt{(\rho_1 G_1)}$$

and

$$Z_2 = J_2 \sqrt{(\rho_2 G_2)}$$

The reflection and transmission coefficients then are given by eqns [2]–[5]. If the cross-section is rectangular, the polar moment of inertia must be modified.

Flexural Vibrations

The reflection and transmission coefficients for flexural waves in two semi-infinite beams ($x < 0$ or $x > 0$) joined at the junction $x = 0$ can be evaluated for an incident bending wave traveling in the $x < 0$ region in the positive x direction. The bending waves reflected or transmitted at $x = 0$ have a propagating component and an exponentially decaying near-field component. Thus, there is a near-field and far-field reflection and transmission coefficients. For flexural waves in beams and plates, let the flexural wave number k and flexural wave speed c be given by:

$$k^4 = \frac{\rho A' \omega^2}{D'} \quad [10]$$

$$c^4 = \frac{\rho D' \omega^2}{A'} \quad [11]$$

where the cross-sectional area:

$$\begin{aligned} A' &= A \text{ for beams} \\ &= b \text{ for plates} \end{aligned}$$

and the bending stiffness:

$$\begin{aligned} D' &= EI \text{ for beams} \\ &= Eb^3/12(1-\nu^2) \text{ for plates} \end{aligned}$$

and where A and I are the cross-sectional area and moment of inertia of a beam, and b is the thickness of a plate. Define the radius of gyration ‘ r ’ of a cross-section as:

$$\begin{aligned} r^2 &= I/A \text{ for a beam} \\ &= \frac{1}{12}b^2 \text{ for a plate} \end{aligned}$$

Define a nondimensional wavenumber:

$$\bar{k} = \sqrt{(12)kr} \quad [12]$$

Define a nondimensional linear spring of stiffness K by:

$$\bar{\beta} = \frac{K}{\rho c^2} \quad [13]$$

Define a nondimensional helical spring of rotational stiffness γ by:

$$\bar{\alpha} = \frac{\gamma}{\rho A \sqrt{(12)rc^2}} \quad [14]$$

Define a nondimensional blocking mass M by

$$\bar{\mu} = \frac{M}{\sqrt{(12)\rho Ar}} \quad [15]$$

Change of Cross-section

Consider two semi-infinite uniform beams (plates) joined at $x = 0$, each having cross-sectional area A , moment of inertia I , Young’s modulus E , and Poisson’s ratio ν . The near-field reflection α_{nr} and transmission α_{nt} coefficients are defined as the reflected or transmitted amplitude at $x = 0$, respectively:

$$\alpha_{nr} = \frac{\zeta(1 - \eta^2) - 2i\zeta(1 - \eta) + 2(1 - \zeta^2)\eta}{\zeta(1 + \eta)^2 + 2\eta(1 + \zeta^2)} \quad [16]$$

$$\alpha_{nt} = \frac{2(1 + \zeta)(1 + \eta) - 2i(\zeta + i)(1 - \eta)}{\zeta(1 + \eta)^2 + 2\eta(1 + \zeta^2)} \quad [17]$$

and the far-field reflection and transmission coefficients α_{fr} and α_{ft} are given by:

$$\alpha_{fr} = \frac{2\eta(1 - \zeta^2) - i\zeta(1 - \eta)^2}{\zeta(1 + \eta)^2 + 2\eta(1 + \zeta^2)} \quad [18]$$

$$\alpha_{ft} = \frac{2(1 + \zeta)(1 + \eta)}{\zeta(1 + \eta)^2 + 2\eta(1 + \zeta^2)} \quad [19]$$

where:

$$\zeta^4 = \frac{\rho_2 A'_2 D'_1}{\rho_1 A'_1 D'_2} \quad [20]$$

and:

$$\eta^2 = \frac{\rho_2 A'_2 D'_2}{\rho_1 A'_1 D'_1} \quad [21]$$

The reflection and transmission efficiencies can be computed from:

$$\tau_r = |\alpha_{fr}|^2 \quad [22]$$

$$\tau_t = 1 - |\alpha_{fr}|^2 \quad [23]$$

Infinite Beam on Simple Support

Consider a uniform infinite beam (plate) with a simple support at $x = 0$. The conditions at support point are that the slopes and moments are continuous and the displacement is zero. The near-field and far-field reflection and transmission coefficients are given by:

$$\begin{aligned}\alpha_{nr} &= -1 \\ \alpha_{nt} &= 0 \\ \alpha_{fr} &= -\frac{1+i}{2} \\ \alpha_{ft} &= -\frac{1-i}{2} \\ \tau_r &= \frac{1}{2} \\ \tau_t &= \frac{1}{2}\end{aligned}$$

Two Semi-Infinite Beams Joined by a Hinge

Consider two semi-infinite uniform and identical beams (plates) joined at $x = 0$ by a hinge such that the displacements and shears are continuous but the moments are zero at $x = 0$. The near-field and far-field reflection and transmission coefficients are:

$$\begin{aligned}\alpha_{nr} &= -i \\ \alpha_{nt} &= 1-i \\ \alpha_{fr} &= -\frac{1+i}{2} \\ \alpha_{ft} &= -\frac{1-i}{2} \\ \tau_r &= \frac{1}{2} \\ \tau_t &= \frac{1}{2}\end{aligned}$$

Infinite Beam with a Sliding Support

Consider an infinite uniform beam (plate) where a sliding support exists at $x = 0$ such that the displacements and shears are continuous but the slopes are zero. The near-field and far-field reflection and transmission coefficients are:

$$\begin{aligned}\alpha_{nr} &= 0 \\ \alpha_{nt} &= 1 \\ \alpha_{fr} &= \frac{1-i}{2} \\ \alpha_{ft} &= \frac{1+i}{2} \\ \tau_r &= \frac{1}{2} \\ \tau_t &= \frac{1}{2}\end{aligned}$$

Two Semi-Infinite Beams Joined by a Hinge and Helical Spring

Consider two semi-infinite beams (plates) joined by a hinge and connected through a helical spring of rotational stiffness γ at $x = 0$. Here the displacements, moments and shears are continuous at $x = 0$ and the moment is given by the helical spring stiffness times the difference of the slopes of the two beams at $x = 0$:

$$\alpha_{nr} = -\frac{1+i}{1-i(1+4\bar{k}\bar{\alpha})} \quad [24]$$

$$\alpha_{nt} = -\frac{2i(1+2\bar{k}\bar{\alpha})}{1-i(1+4\bar{k}\bar{\alpha})} \quad [25]$$

$$\alpha_{fr} = -\frac{1}{1-i(1+4\bar{k}\bar{\alpha})} \quad [26]$$

$$\alpha_{ft} = -\frac{i(1+4\bar{k}\bar{\alpha})}{1-i(1+4\bar{k}\bar{\alpha})} \quad [27]$$

$$\tau_r = \frac{1}{1+(1+4\bar{k}\bar{\alpha})^2} \quad [28]$$

$$\tau_t = \frac{(1+4\bar{k}\bar{\alpha})^2}{1+(1+4\bar{k}\bar{\alpha})^2} \quad [29]$$

Plots of $|\alpha_{fr}|$, $|\alpha_{ft}|$, $|\alpha_{nr}|$, and $|\alpha_{nt}|$ in dB scale are shown in Figures 1–4, respectively, vs non-dimensional wave number \bar{k} for various values of the nondimensional helical spring stiffness $\bar{\alpha} = 0.1, 1, 10$, and 100 .

An Infinite Beam Resting on a Linear Spring

Consider a uniform infinite beam (plate) resting on a linear spring at $x = 0$ of linear stiffness K :

$$\alpha_{nr} = -\frac{(1-i)\bar{\beta}/\bar{k}}{\bar{\beta}/\bar{k} - i(\bar{\beta}/\bar{k} + 4)} \quad [30]$$

$$\alpha_{nt} = -\frac{4i}{\bar{\beta}/\bar{k} - i(\bar{\beta}/\bar{k} + 4)} \quad [31]$$

$$\alpha_{fr} = -\frac{\bar{\beta}/\bar{k}}{\bar{\beta}/\bar{k} - i(\bar{\beta}/\bar{k} + 4)} \quad [32]$$

$$\alpha_{ft} = -\frac{i(\bar{\beta}/\bar{k} + 4)}{\bar{\beta}/\bar{k} - i(\bar{\beta}/\bar{k} + 4)} \quad [33]$$

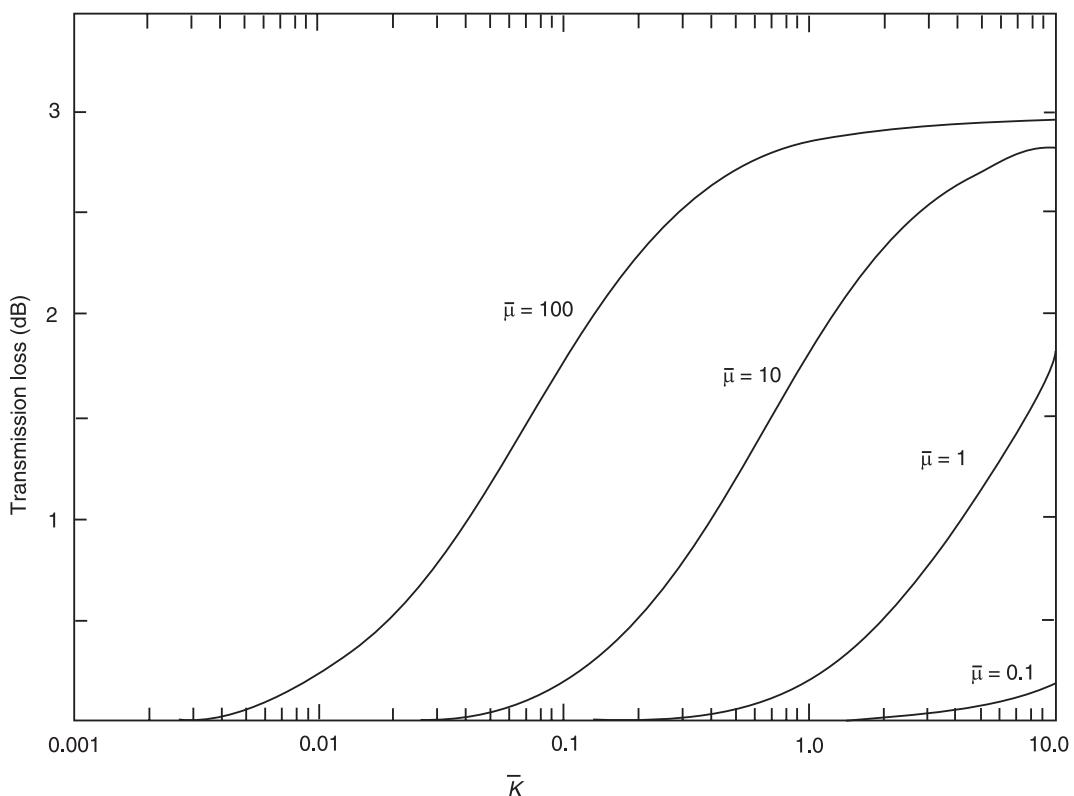

Figure 1 Far-field reflection coefficient for hinge with helical spring.

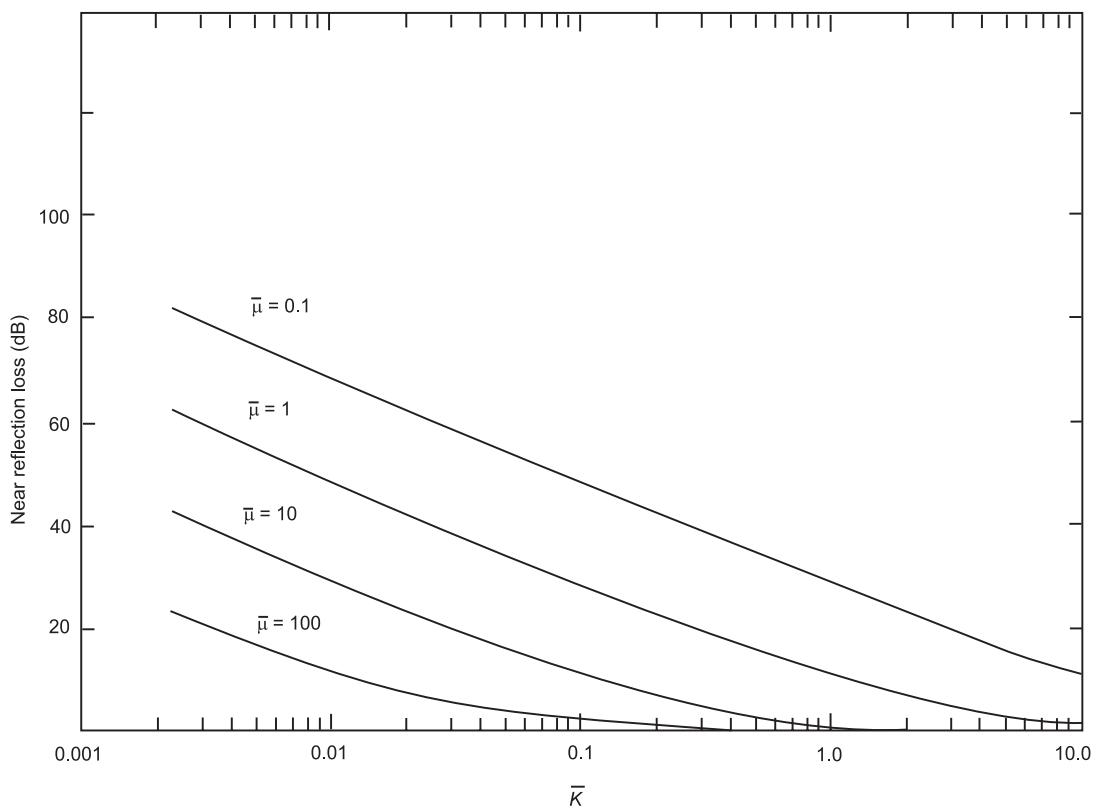

Figure 2 Far-field transmission coefficient for hinge with helical spring.

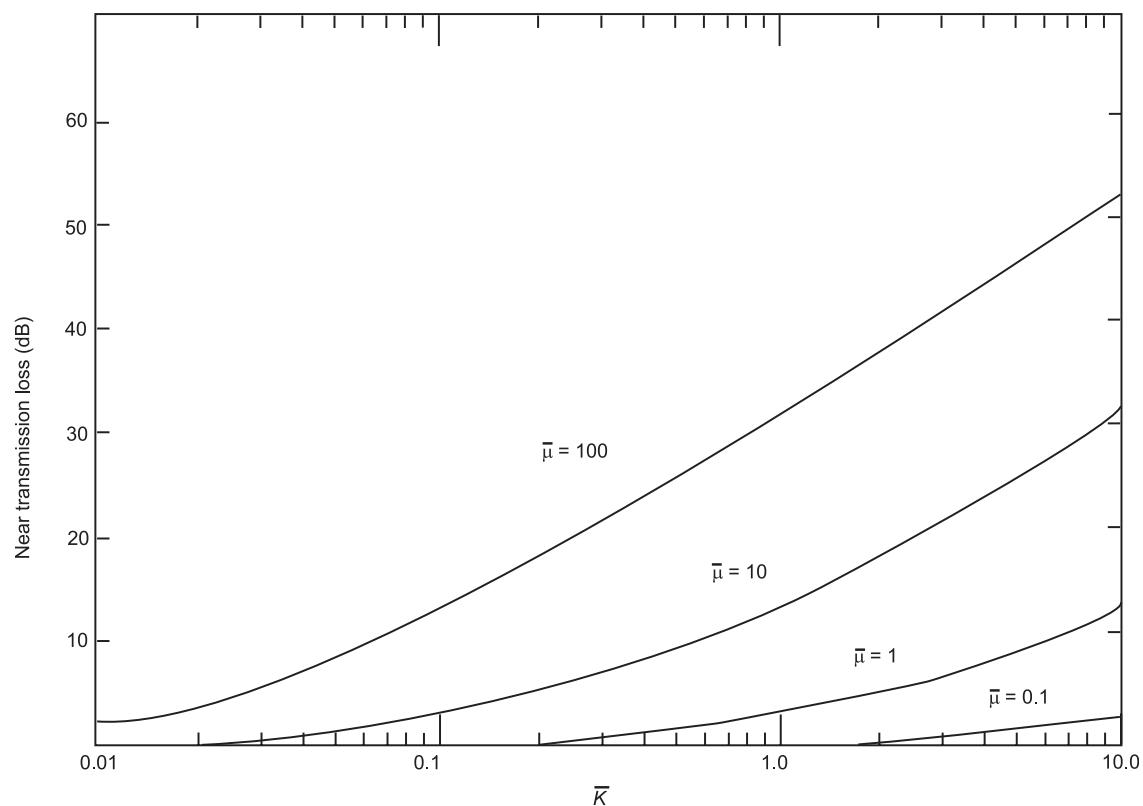

Figure 3 Near-field reflection coefficient for hinge with helical spring.

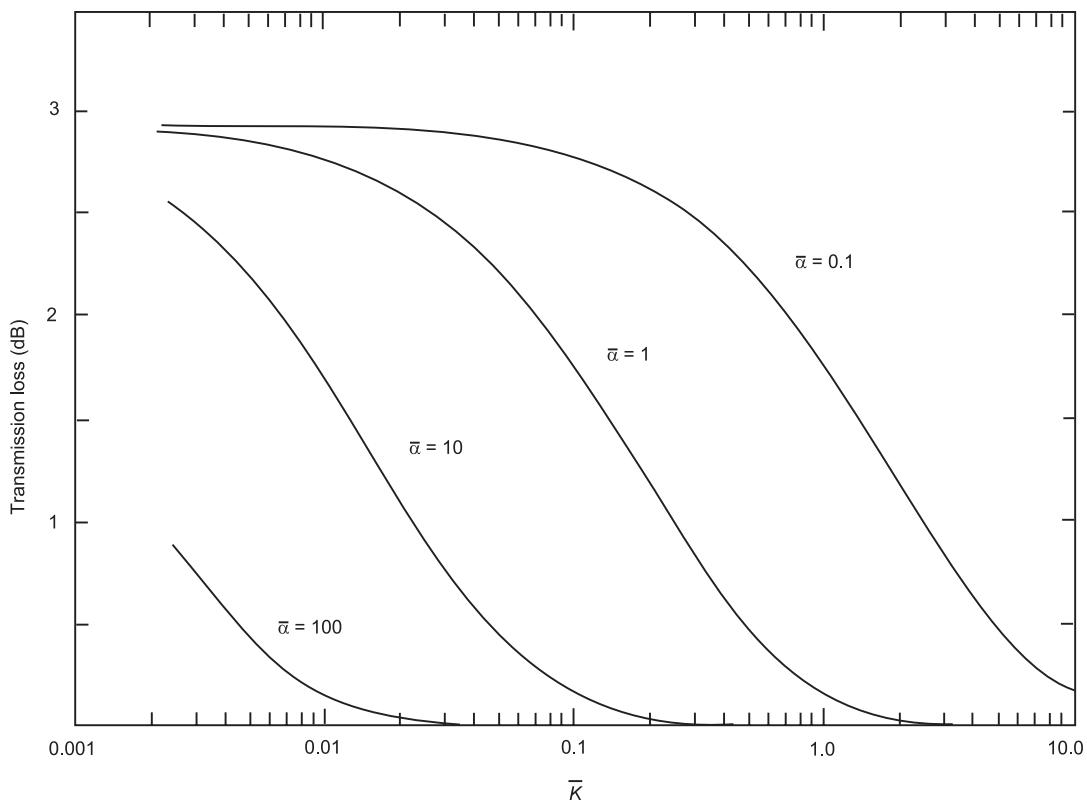

Figure 4 Near-field transmission coefficient for hinge with helical spring.

$$\tau_r = \frac{(\bar{\beta}/\bar{k})^2}{(\bar{\beta}/\bar{k})^2 + (\bar{\beta}/\bar{k} + 4)^2} \quad [34]$$

$$\tau_t = \frac{(\bar{\beta}/\bar{k} + 4)^2}{(\bar{\beta}/\bar{k})^2 + (\bar{\beta}/\bar{k} + 4)^2} \quad [35]$$

Plots of $|\alpha_{fr}|$, $|\alpha_{ft}|$, $|\alpha_{nr}|$, and $|\alpha_{nt}|$ are shown in Figures 5–8, respectively, vs nondimensional wave number \bar{k} for various values of the nondimensional spring stiffness $\bar{\beta} = 0.1, 1, 10$, and 100 .

Infinite Beam with a Blocking Mass

Consider an infinite uniform beam (plate) with a blocking mass (line mass) M located at $x = 0$:

$$\alpha_{nr} = -\frac{(1-i)\bar{\mu}\bar{k}}{\bar{\mu}\bar{k} - i(\bar{\mu}\bar{k} + 4)} \quad [36]$$

$$\alpha_{nt} = -\frac{4i}{\bar{\mu}\bar{k} - i(\bar{\mu}\bar{k} + 4)} \quad [37]$$

$$\alpha_{fr} = -\frac{\bar{\mu}\bar{k}}{\bar{\mu}\bar{k} - i(\bar{\mu}\bar{k} + 4)} \quad [38]$$

$$\alpha_{ft} = -\frac{i(\bar{\mu}\bar{k} + 4)}{\bar{\mu}\bar{k} - i(\bar{\mu}\bar{k} + 4)} \quad [39]$$

$$\tau_r = \frac{(\bar{\mu}\bar{k})^2}{(\bar{\mu}\bar{k})^2 + (\bar{\mu}\bar{k} + 4)^2} \quad [40]$$

$$\tau_t = \frac{(\bar{\mu}\bar{k} + 4)^2}{(\bar{\mu}\bar{k})^2 + (\bar{\mu}\bar{k} + 4)^2} \quad [41]$$

Plots of $|\alpha_{fr}|$, $|\alpha_{ft}|$, $|\alpha_{nr}|$, and $|\alpha_{nt}|$ are shown in Figures 9–12, respectively vs nondimensional wave-number \bar{k} for values of nondimensional mass $\bar{\mu} = 0.1, 1, 10$, and 100 .

VIBRO-IMPACT SYSTEMS

doi:10.1006/rwvb.2001.0045

The motion of mechanical systems with impacts is strongly nonlinear due to sudden changes of the system parameters and the motion quantities, when

the impacts of moving bodies appear. Impacts influence the system behavior so expressively, that the weak nonlinearities, acting on the system during the impactless motion, can often be neglected. Such systems are thought of as piecewise linear or systems with discontinuities.

The simplest motion with impacts can be studied using mechanical models shown in Figures 1B and 1C. The mechanical oscillator in Figure 1A is

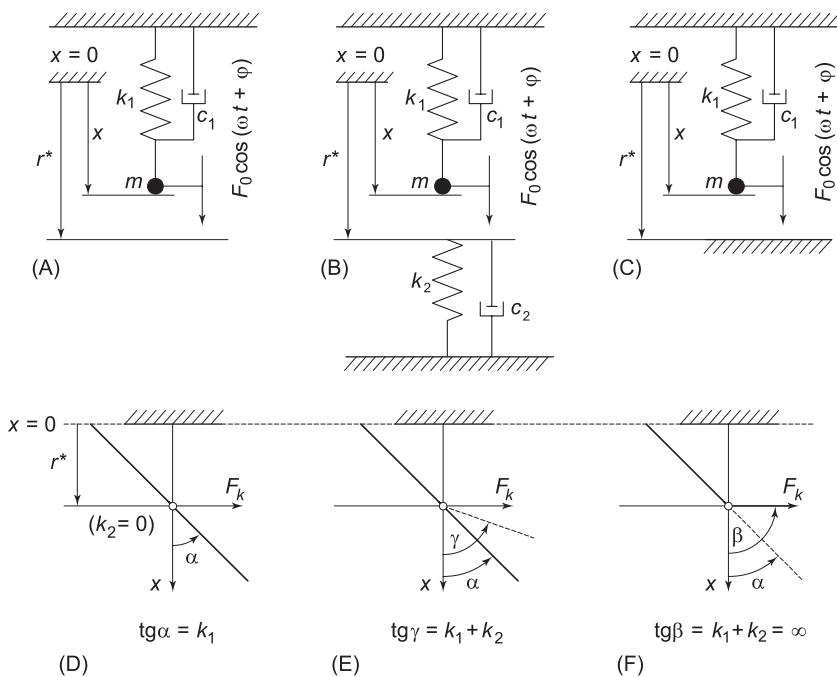

Figure 1 Schemes of linear and nonlinear oscillators.

composed from the mass element m , which is suspended on the stiffness element k_1 , the spring force-deflection diagram $F_k(x)$ of which is shown in Figure 1D. The motion is excited by the periodic force of amplitude F_0 and damped by a linear damping element c_1 . Figure 1B shows the mechanical model of the oscillator with soft impacts. When the displacement x of mass m exceeds the static clearance r^* , then elements k_2 and c_2 will influence the oscillator motion. They represent the elastic and damping contact forces of impacting bodies. There exist many linear, piecewise linear and non-linear models of soft impacts. The linear force-displacement characteristics $F_k(x)$ – the Kelvin–Voigt model – is in Figure 1E. When stiffness k_2 increases to infinity (Figure 1F), then the classic impact oscillator (Figure 1C) is obtained. It corresponds to the motion with hard impacts of the body against the rigid stop. Such motion can be described by the elementary Newton theory of direct and centric impact. Direct means that bodies move before the impact along a straight line and centric means that the resulting normal contact forces act on the straight line, connecting the centroids of impacting bodies. The duration of impact is assumed negligibly short and the change of velocity of body and the energy loss at impact can be expressed by restitution coefficient:

$$R = -\frac{v_+}{v_-} \quad [1]$$

where v_+ and v_- are after-impact and before-impact velocities of body m , respectively. The interval $0 \leq R \leq 1$ embraces impacts from absolutely plastic ($R = 0$) to absolutely elastic ($R = 1$).

When Newton's impact of two bodies arises (Figure 2), then after-impact velocities v_{1+} and v_{2+} can be expressed in the form:

$$\begin{aligned} v_{1+} &= v_p - \frac{m_2}{m_1 + m_2} R v_{\text{rel}-} \\ v_{2+} &= v_p + \frac{m_1}{m_1 + m_2} R v_{\text{rel}-} \end{aligned} \quad [2]$$

where $v_p = (m_1 v_{1-} + m_2 v_{2-}) / (m_1 + m_2)$ is the the velocity of bodies after the plastic impact, $v_{\text{rel}-} = v_{1-} - v_{2-}$ is the the relative velocity of bodies just before the impact. Equation [2] follows from the assumption of fixing the momentum of bodies during the impact:

$$m_1 v_{1-} + m_2 v_{2-} = m_1 v_{1+} + m_2 v_{2+} \quad [3]$$

and from the definition of restitution coefficient:

$$R = -(v_{1+} - v_{2+}) / (v_{1-} - v_{2-}) \quad [4]$$

The kinetic energy E_i lost at impact is determined by formula:

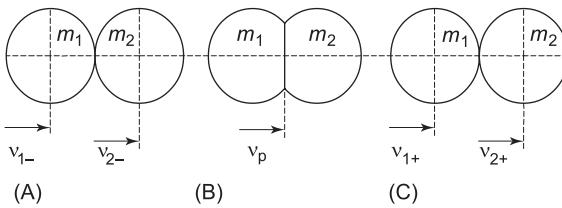

Figure 2 Direct and centric impact of two bodies: (A) state just before impact; (B) state at the instant of maximum deformation of bodies at impact; (C) state just after impact.

$$E_i = \frac{1}{2} \frac{m_1 m_2}{m_1 + m_2} (1 - R^2) v_{\text{rel}-}^2 \quad [5]$$

and it changes into:

$$E_i = \frac{1}{2} m (1 - R^2) v_-^2 \quad [6]$$

for the single impact oscillator (Figure 1C), when $m_1 = m$, $m_2 = \infty$, $v_{1-} = v_-$ and $v_2 = 0$.

Selected Examples of Vibro-impact Systems

Impacts accompany the vibration of many types of machines and devices. They are important in the forming, drilling, compaction, milling, crashing, vibration damping or control of motion, etc. They can be also undesirable, e.g., in mechanisms with clearances, where they increase the noise and the mechanical stress by impact impulses. Such impacts decrease the reliability and durability of machines and they can cause serious failures.

Examples of mechanical schemes of vibro-impact systems are shown in the following figures (Figures 3–8).

Complex impact interactions can appear in vibratory systems. The study of the systems behavior is based on the selection of a proper model of vibro-impact system and on its theoretical, simulation and experimental investigation.

Fundamental problems of the vibro-impact systems dynamics will be explained on the dynamical analysis

of the single impact oscillator with one-degree-of-freedom.

Dynamics of the Single Impact Oscillator

The Existence Boundary of Impactless Periodic Motion (Grazing Bifurcation)

The first step in the investigation of the dynamics of impact oscillators is the determination of a boundary, beyond which the impactless motion cannot exist, because the bodies begin to touch the stops or the other moving bodies and impacts should appear. This boundary is named the *existence boundary* or the *grazing bifurcation boundary*. It is the most important condition, which limits the existence of not only impactless motion but generally the existence of every periodic impact motion.

The impactless motion of the oscillator (Figure 1C) is described by the ordinary differential equation:

$$m \frac{d^2x}{dt^2} + c_1 \frac{dx}{dt} + k_1 x = F_0 \cos(\omega t + \varphi) \quad [7]$$

Its solution is:

$$x(t) = e^{-b\Omega t} A \cos(\Omega_d t + \psi) + \rho_0 x_{\text{st}} \cos(\omega t + \varphi - \alpha) \quad [8]$$

$$v(t) = dx/dt \quad [9]$$

where: $b = c_1/2\sqrt{(k_1 m)}$ is dimensionless damping, $\Omega = \sqrt{(k_1/m)}$ is angular frequency of undamped free vibration, $\Omega_d = \Omega\sqrt{(1 - b^2)}$ is the angular frequency of damped free vibration, A , ψ are the integration constants depending on initial conditions $x(0)$ and $v(0)$, $\rho_0 = 1/\sqrt{[(1 - \eta^2)^2 + (2b\eta)^2]}$ is the dimensionless amplitude of forced vibration, $\eta = \omega/\Omega$ is the dimensionless excitation frequency, $x_{\text{st}} = F_0/k_1$ is static displacement, and $\alpha = \arctan[2b\eta/(1 - \eta^2)]$ is the phase shift between excitation force and forced vibration.

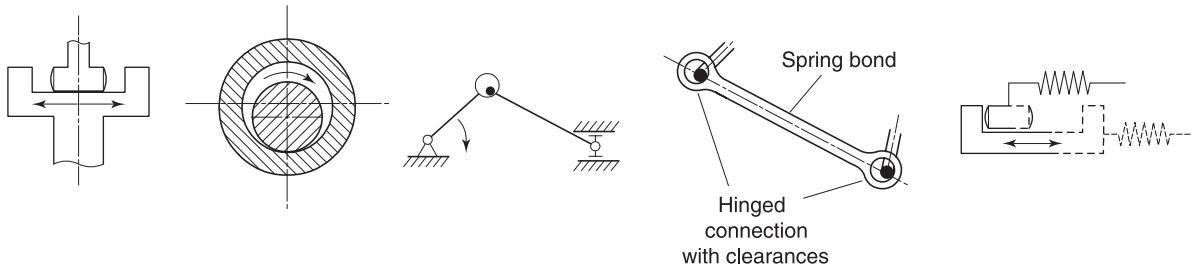

Figure 8 Mechanisms with clearances, forks, bearings, journals, and gearing.

Figure 9 shows the frequency amplitude characteristics $\rho_0(\eta)$ of the impactless motion for damping $b = 0.05$. This curve represents the grazing bifurcation boundary, where the moving body begins periodically to touch the stop (see Figure 10, where $X = x/x_{st}$ and V are the dimensionless displacement and velocity, respectively).

When condition:

$$0 < r < \rho_0 \quad [10]$$

($r = r^*/x_{st}$ is the dimensionless static clearance) is met, then impactless motion ends its existence and some impact motion should appear.

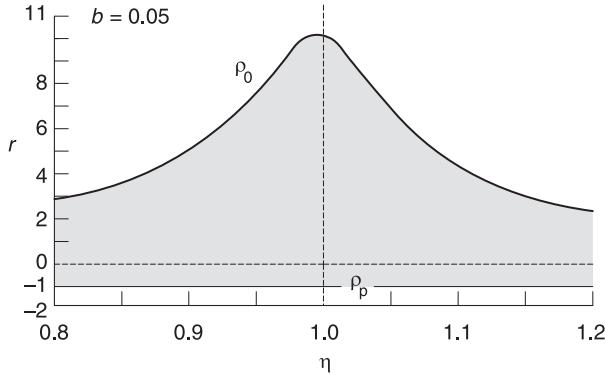

Figure 9 Region of necessary onset of an impact motion.

The negative clearance r represents a state, when body m is prestressed to the stop in the static position by the force:

$$F_p = |r|F_0 \quad [11]$$

When the prestress force $F_p < F_0$, then body m repeatedly disconnects from the stop and the impacts subsequently will arise. The impact motion should therefore appear in the region of the necessary onset of an impact motion (see dark region in Figure 9):

$$\rho_p < r < \rho_0 \quad [12]$$

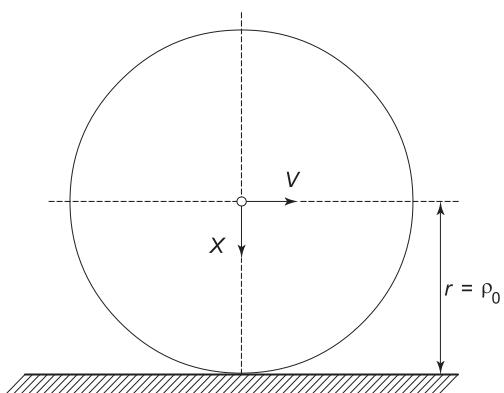

Figure 10 Phase trajectory of impactless motion on the grazing bifurcation boundary.

On boundary $r_p = -1$ the body m begins to disconnect during the decrease of prestress force F_p .

Every impact introduces new initial motion conditions and the two-dimensional set of these conditions makes possible a large variety of excited impact motions. Nevertheless steady-state vibro-impact motions can exist also outside region [12], but they should be called forth, e.g. by special motion initial conditions, by a change of system parameters, etc.

Classification of Impact Motions

The response of the impact oscillator on a periodic excitation is periodic or chaotic. Periodic motions are definitely characterized by quantity:

$$z = p/n \quad [13]$$

where p is the number of impacts and n is the number of excitation periods $T = 2\pi/\omega$ in one period of motion. This quantity also characterizes chaotic impact motions and it refers to the mean value of impacts related to one period T .

Figure 11 introduces several series of motions classified according to quantity z for harmonic and periodic rectangular excitation forces $F(t)$. **Figure 11A** shows the first four motions of fundamental series $z = 0, 1, 2, 3, \dots$. Motions repeat with the excitation period $T(n=1)$ and they differ by the number $p = 0, 1, 2, 3, \dots$ of impacts. The impactless motion ($z = 0$) belongs to this series. Series in **Figures 11B** and **11C** show periodic subharmonic impact motions. Their period is the integer multiple of $T(n > 1)$. The first series (in **Figure 11B**) is typical by one impact ($p = 1$), which repeats after $n = 2, 3, 4, 5, \dots$ periods T . In the second series (in **Figure 11C**) repeat $p = 1, 3, 5, 7, \dots$ impacts with period $2T(n=2)$. **Figure 11D** shows the series $z = 1/2 - 1; 1/3 - 1; 1/4 - 1; 1/5 - 1, \dots$ of chaotic impact motions.

Chaotic impact motion is the unpredictable state of the impact oscillator in the range of a strange attracting set. This set can be imagined, e.g., as a special configuration in the phase space of the system, the dimension of which is less than the dimension of the phase space.

Regions of Existence and Stability of Impact Motions

Every periodic impact motion has a region of existence and stability in the space of the system parameters. There are two important parameters η and r of the impact oscillator and regions of impact motions will be illustrated in the plane $(\eta \times r)$.

Examples of regions are shown in **Figure 12** for two periodic excitation forces $F(t)$ and for constant

restitution coefficient $R = 0.6$ and linear damping $b = 0.05$. The region of each fundamental periodic motion ($n = 1; z = 0, 1, 2, 3$) is bounded from below by the existence (grazing bifurcation) boundary ($\rho_0, \rho_1, \rho_2, \rho_3$). This boundary appears at every periodic impact motion, when impactless loop of the motion phase trajectory begins to touch the stop and a new impact should arise.

Regions of impact motions $z = 1, 2, 3$ are bounded from above by stability boundaries s . Stability boundaries s and existence boundaries ρ of neighboring periodic motions (e.g., $z = 0$ and $z = 1$ or $z = 1$ and $z = 2$, etc.) mutually intersect and create two types of transition regions. They are named as hysteresis and beat-motion regions and they are illustrated as black and white regions, respectively, in **Figure 12**. Points of intersection of boundaries divide the stability boundaries s on two different parts, s_{+1} , which corresponds to the saddle-mode bifurcation and s_{-1} , which corresponds to the period-doubling bifurcation. Both neighbor periodic motions can exist in hysteresis regions, because the two-fold response of the system exists. Beat-motion regions contain subregions of periodic subharmonic and chaotic impact motions, because the fundamental z motion cannot exist and the neighbor ($z + 1$) motion is not stable there. Values z of impact motions in beat-motion regions are in the interval $\langle z, z + 1 \rangle$ and $n > 1$.

The configuration of mentioned subregions inside the beat-motion region is shown in more detail in **Figure 13**, which is section (a) of **Figure 12**.

It follows from **Figure 12** that the structure of impact-motion regions is independent of the type of periodic excitation. Regions which correspond to the rectangular excitation, differ from regions for the harmonic excitation only quantitatively. The rectangular exciting force can be supplemented by the series of odd subharmonics, so subharmonic resonances of order $1/3$ and $1/5$ appear in **Figure 12**.

Regions of Subharmonic and Impact Motions

Fundamental $z = 1$ impact motion loses its stability on boundary s_{-1} (**Figure 13**) and changes into $z = 2/2$ motion after period doubling bifurcation. One impact in the motion period $2T$ disappears on the saddle-node stability boundary $(s_1)_{2/2}$ and subharmonic $z = 1/2$ impact motion stabilizes. This motion transits into $z = 1$ or $z = 2/2$ impact motion on the grazing bifurcation boundary $\rho_{1/2}$. It means that between boundaries $(s_1)_{2/2}$ and $\rho_{1/2}$ exists the hysteresis region of neighbor motions $z = 1/2$ and $z = 2/2$ or $z = 1$.

Subharmonic motions $z = 1/2, z = 1/3, z = 1/4, \dots$ lose their stability, with increasing clearance r , on

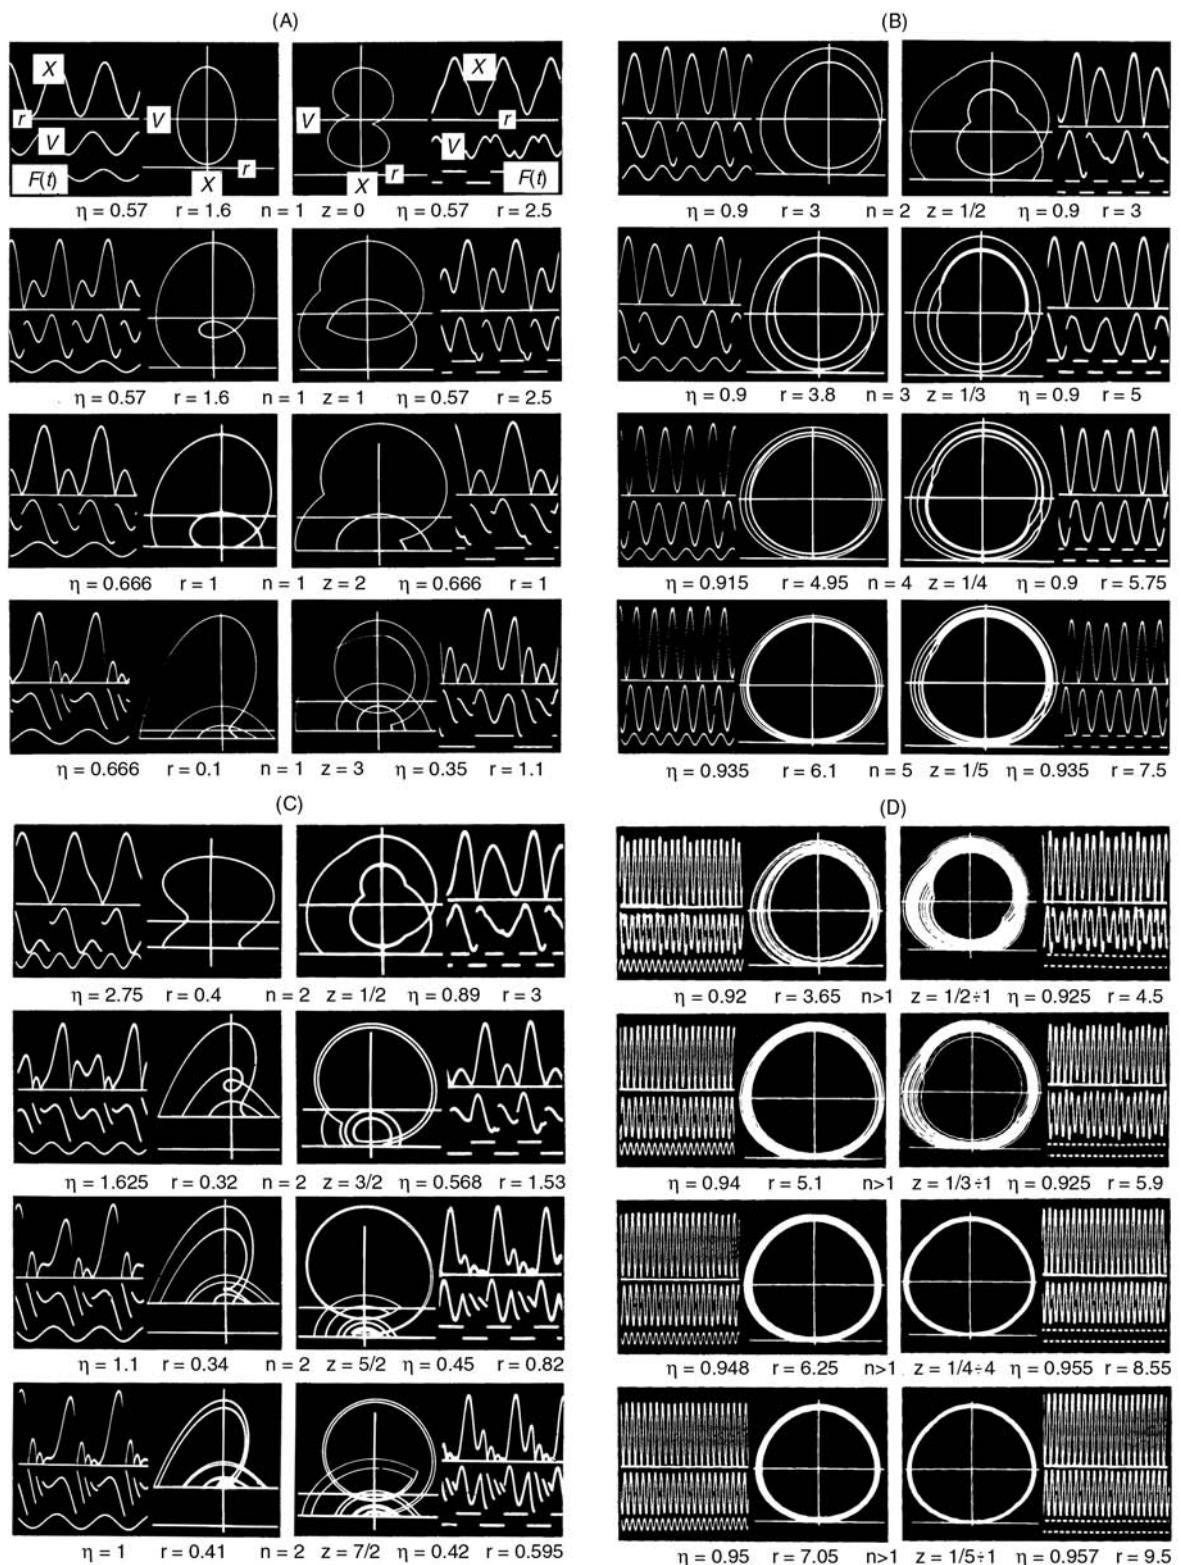

Figure 11 Examples of periodic and chaotic impact motions.

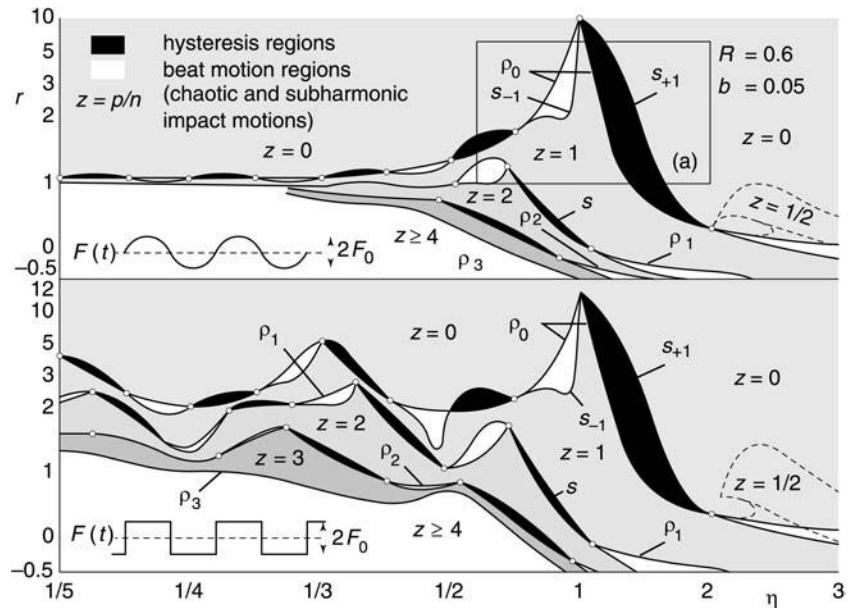

Figure 12 (see plate 52). Regions of stability and existence of impact motions for the periodic harmonic and rectangular excitations.

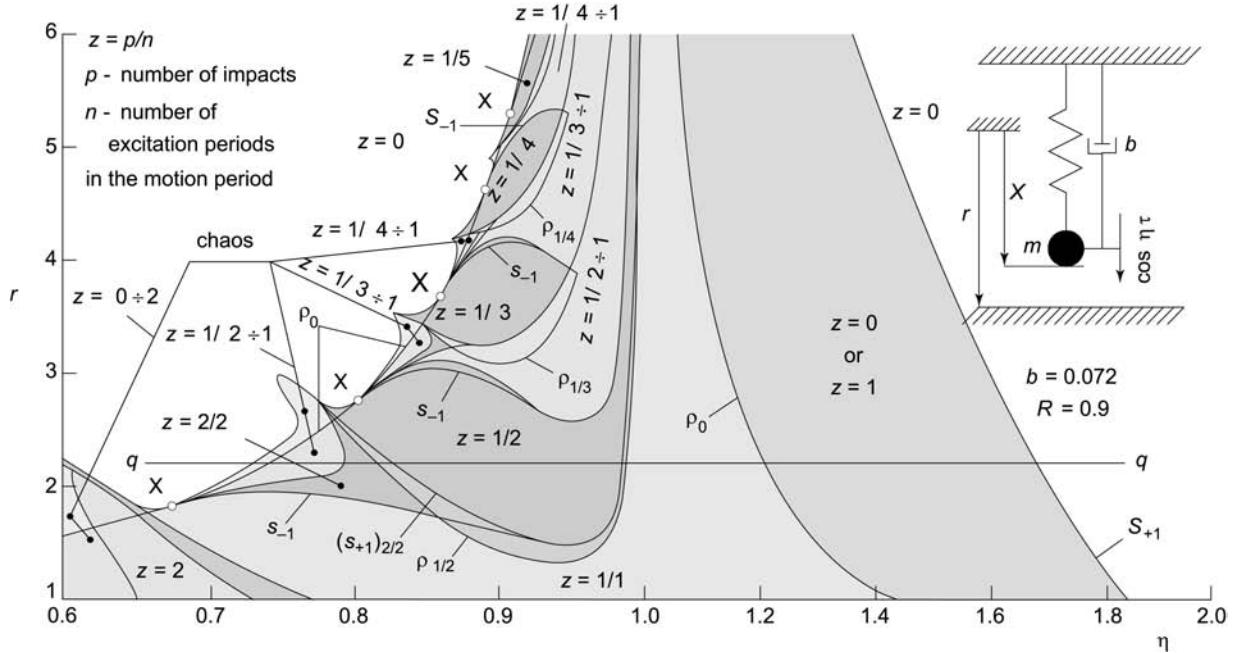

Figure 13 (see plate 53). Regions of periodic and chaotic impact motions near the resonance of the linear oscillator.

period doubling bifurcation boundaries s_{-1} and then they transit into regions of chaotic impact motions $z = 1/2 - 1, z = 1/3 - 1, z = 1/4 - 1, \dots$. Hysteresis regions exist also between subharmonic motions $z = 1/3, 1/4, 1/5, \dots$, and chaotic motions $z = 1/2 - 1, z = 1/3 - 1, z = 1/4 - 1, \dots$ (see dark blue subregions in Figure 13). Hysteresis regions

are also salients of beat-motion regions into the region of impactless motion $z = 0$, over the boundary ρ_0 , but their magnitude decreases with increasing damping b .

Similar configuration of regions of subharmonic and chaotic impact motions exist in beat-motion regions between neighboring z and $z + 1$ ($z = 0, 1, 2, 3, \dots$) periodic motions.

Bifurcation Diagrams

The useful tools for qualitative and quantitative evaluation of impact motions are bifurcation diagrams. They display the selected samples of motion, when system parameters are changed. One example is shown in Figure 14. Every before-impact velocity V_- and minimum displacement X_m , evaluated in every excitation period T , is plotted, while parameters η, r are changed along line q in Figure 13. Arrows along bifurcation diagrams express the direction of frequency η change. Diagrams expressive explain the system behavior, when line q crosses different bifurcation boundaries in Figure 13.

Quantity $z = p/n$ can be directly determined according to the number of branches of diagrams $V_-(\eta)$ and $X_m(\eta)$ for certain periodic impact motions.

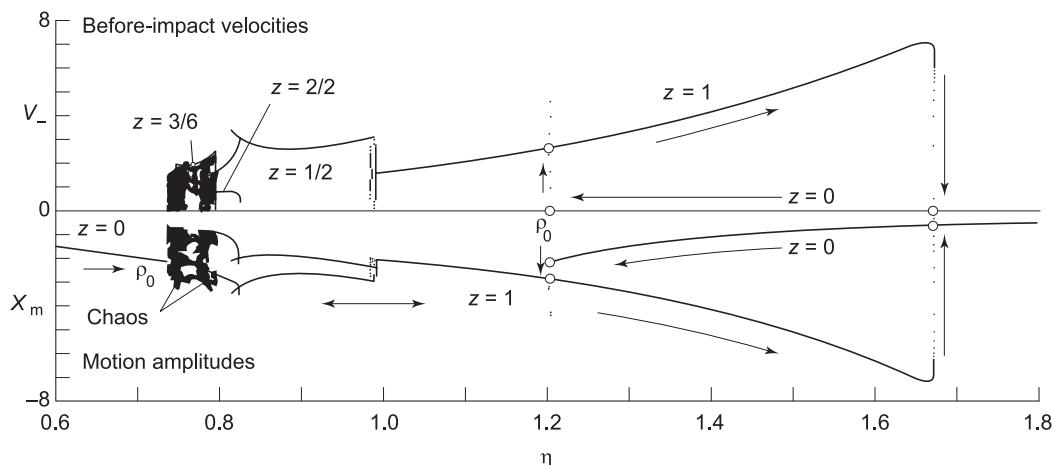

Figure 14 Bifurcation diagrams along line q in Figure 13.

Exact Theoretical Solution of Periodic $z = 1/n$ Impact Motions and their Local Stability

The theoretical solution of periodic impact motions can be obtained in the explicit form only for the simplest mechanical systems and simple regimes of motion. The procedure will be shown on the example of the impact oscillator in Figure 1C, without the damping element c_1 . The scheme of the series of periodic motions $z = 1/n$ is shown in Figure 15.

The solution of motion differential eqn [7] for $b = 0$ is:

$$\begin{aligned} x &= A \cos (\Omega t + \psi) + \rho_0 x_{st} \cos (\omega t + \varphi) \\ v &= -A \Omega \sin (\Omega t + \psi) - \rho_0 x_{st} \omega \sin (\omega t + \varphi) \end{aligned} \quad [14]$$

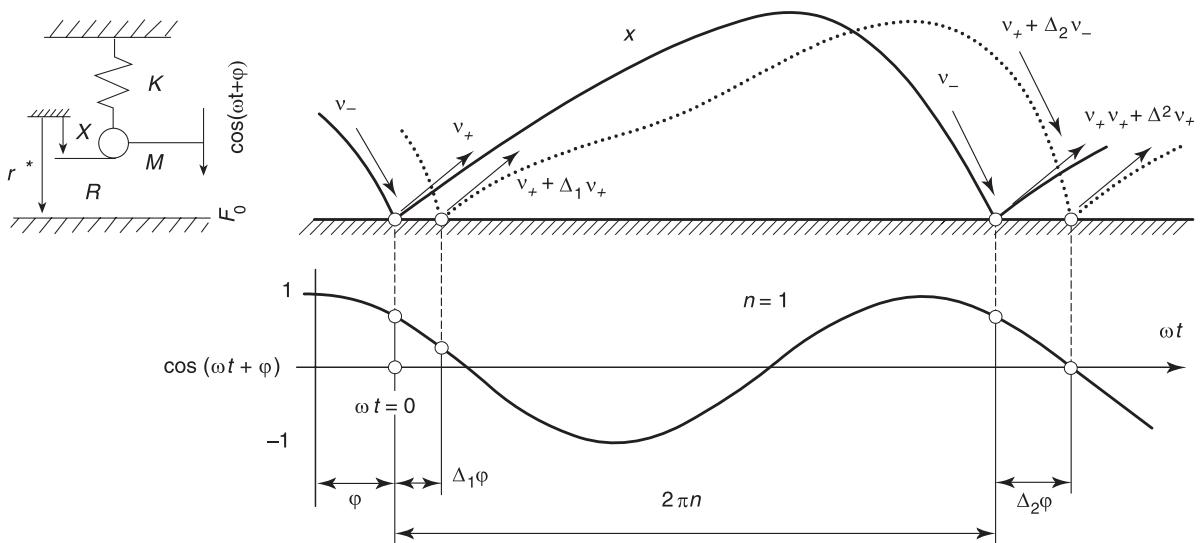

Figure 15 Scheme of periodic $1/n$ impact motions ($n = 1, 2, 3, 4 \dots$) of the impact oscillator and their perturbation.

where constants A , ψ of the general solution – free vibration – depend on the motion initial conditions and the particular solution – forced vibration – has the dimensionless amplitude:

$$\rho_0 = \frac{1}{|1 - \eta^2|} \quad [15]$$

and it is the grazing bifurcation boundary of the impactless motion.

Periodicity Conditions

The solution of periodic $z = 1/n$ -impact motions in their motion period nT ($0 < t < 2\pi n/\omega$) is derived from the periodicity conditions (Figure 15):

$$\begin{aligned} x(0) &= x(2\pi n/\omega) = r^*, \\ v_+ &= v(0) = -Rv(2\pi n/\omega) = -Rv_- \end{aligned} \quad [16]$$

in the form (14), where:

$$\psi = -\frac{\pi n}{\eta} = -\alpha, \quad A = \frac{1+R}{1-R}\eta B \frac{\sin \varphi}{\sin \alpha} \quad [17]$$

$$[\cos \varphi]_{I,II} = \frac{-1}{B(1+K^2)} \{r \pm K\sqrt{[B^2(1+K^2) - r^*]^2}\} \quad [18]$$

$$\begin{aligned} [\sin \varphi]_{I,II} &= \frac{1}{B(1+K^2)} \{-rK \pm \sqrt{[B^2(1+K^2) - r^*]^2}\} \\ B &= \frac{1}{1-\eta^2} x_{st}, \quad K = \frac{1+R}{1-R}\eta \cot \alpha \end{aligned} \quad [19]$$

The before-impact velocity v_- depends on system parameters according to equation:

$$v_- = \Omega x_{st} \frac{2}{1-R} \frac{\eta}{\eta^2 - 1} \sin \varphi \quad [20]$$

Impenetrability Conditions

There exist two different solutions, I , II , of the assumed periodic impact motions, $z = 1/n$. These solutions should be verified by the impenetrability conditions:

$$v_- = v(2\pi n/\omega) \geq 0$$

and

$$x(t) < r^* \text{ (for } 0 < t < 2\pi n/\omega) \quad [21]$$

which express the conditions of physical validity of theoretical results. A limit case:

$$x(t) = r^* \quad [22]$$

which appears between periodic impacts, corresponds to the grazing-bifurcation boundaries $\rho_{1/n}$ of these periodic impact motions (Figures 12 and 13). These boundaries cannot be derived in explicit form. They should be found numerically, using simulation or experimentally.

Stability Conditions

A periodic impact motion should also satisfy the stability conditions. The stability analysis is based on the assumption that small initial motion perturbations Δ_1 of the system at the instant of the periodic impact (see Figure 15) will develop at next l impacts according to the relation:

$$\Delta_l = \gamma^l \Delta_1 \quad [23]$$

The stability condition is expressed in the form:

$$|\gamma| < 1 \quad [24]$$

Stability boundaries correspond to the condition:

$$|\gamma| = 1 \quad [25]$$

The quantity γ depends on system parameters and it is the solution of the second-order characteristic equation, the roots of which are generally complex. Two types of stability boundaries, s_{+1} , and, s_{-1} , can be distinguished according to the real value of quantity γ on the unit circle [25]:

values of γ	absolute value of the stability boundary	stability conditions	
1) $\gamma = 1$	$s_{+1} = \rho_0 \sqrt{(1+K^2)}$	$r < s_{+1}$ (for $K < 0$) and $r > -s_{+1}$ (for $K > 0$)	[26]

2) $\gamma = -1$	$s_{-1} = \rho_0 \frac{ V - 1 - K^2 }{\sqrt{[(V - 1)^2 + K^2]}}$	$r > -s_{-1}$ (for $K < 0$) and $r < s_{-1}$ (for $K > 0$)	[27]
------------------	--	--	------

where:

$$V = \frac{2(1+R^2)}{(1-R)^2 \sin^2 \alpha}$$

Summary of Theoretical Analysis

Resulting regions of the existence and stability of assumed $z = 1/n$ -impact motions in the plane of system parameters r, η are hatched in Figure 16 and they correspond to the solution I of the periodic impact motions (see signs + in eqns [18] and [19]). They are bounded by stability boundaries s_{+1}, s_{-1} , which link up at points X and by grazing bifurcation boundaries ρ .

The bifurcation boundaries s_{+1} and s_{-1} have the following simplified mathematical expression:

1. The motion disturbances Δ at the successive impacts begin to increase on the stability boundary s_{+1} with the same polarity ($\gamma=1$ in eqn [26]). This process leads to the jump change from the unstable $z = 1/n$ impact motion to the impactless or another impact motion and it corresponds to the saddle-node bifurcation boundary.

2. The motion disturbances Δ begin to increase on the stability boundary s_{-1} and their sign alternates ($\gamma = -1$ in eqn [27]). This process stabilizes in the near limit cycle, which period is double. Stability boundary s_{-1} corresponds to the period-doubling bifurcation boundary.

Point X are also points of boundaries ρ_0 and $-\rho_0$ (Figure 16) for $K = 0$, as follows from eqns [26] and [27]. Quantity $K(\eta)$ is a tangential function (19), which divides the frequency interval $0 \leq \eta \leq \infty$ on nl ($n = 1, 2, 3, \dots$ $l = 0, 1, 2, 3, \dots$) subintervals, which boundaries are determined by frequencies $\eta = n/l$, where $K = \pm\infty$. Corresponding points $X(K = 0)$ have coordinates $\eta = n/(l + 1/2)$.

Resulting regions of stability and existence of $z = 1/n$ impact motions create infinite series of regions $n = 1, 2, 3, 4, \dots$, in every l frequency subintervals η for fundamental impact motion $n = 1$, which are denoted by dot-and-dash lines in Figure 16.

The transition from impactless ($z = 0$) motion into the neighbor $z = 1/n$ impact motion is never continuous and stable, except singular points X of grazing bifurcation boundary ρ_0 . Both neighboring motions

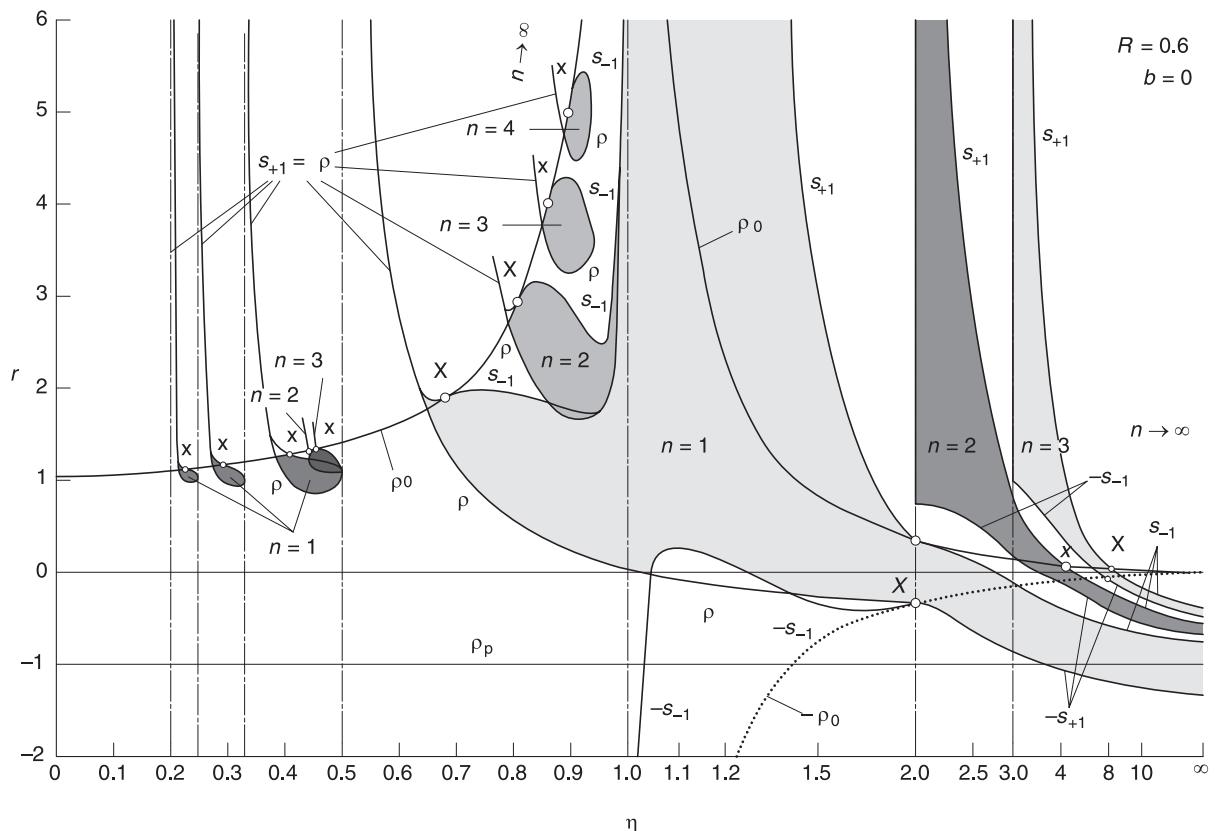

Figure 16 Resulting regions of existence and stability of $1/n$ impact motions obtained by the theoretical analysis.

are identical and both motions are stable in the neighborhood of these points. The impactless motion with the periodic touches of mass m and the rigid stop is identical with the $z = 1/n$ impact motion, the before-impact velocity V_- of which degenerates into zero (Figure 10).

It follows from Figure 16, that $z = 1/n$ impact motions are stable and can exist outside the region [12] of the necessary onset of an impact motion (see region between boundaries ρ_0 and ρ_p). They are named hysteresis regions of impact motions into the region of the impactless motion. Assumed $z = 1/n$ impact motions do not describe impact regimes in remaining white regions inside the region [12], where impact motion should appear. The simulation of the system motion and physical experiments have explained, that in these regions exist more complex periodic and chaotic impact motions (see the description of Figures 12 and 13).

Figure 16 expresses results of the simplified analytical solutions of periodic $z = 1/n$ impact motions. It describes only partially the behavior of impact oscillators, as it follows from the comparison of regions $z = 1/n$ in Figures 13 and 16. Forms of comparable

regions, especially hysteresis regions, are influenced by different values of damping b of the impactless motion.

Four Ways from Periodic Motions into the Chaos

A special question of the dynamics of vibro-impact systems is the better understanding of chaotic motion and reasons of their appearance, so called ways into the chaos. Four different kinds of change from periodic into chaotic motions for the impact oscillator have been found. They will be explained using Figure 17A, where color regions of chaotic impact motion are shown for the system without viscous damping ($b = 0$). Four types of color boundaries of the chaotic motion regions correspond to four different ways into chaos and black segments of boundaries express only output from the chaos into periodic motions. The motion on boundaries of chaotic motion regions will be explained in more detail by bifurcation diagrams, time histories and phase trajectories of motion, when parameters η , r will change

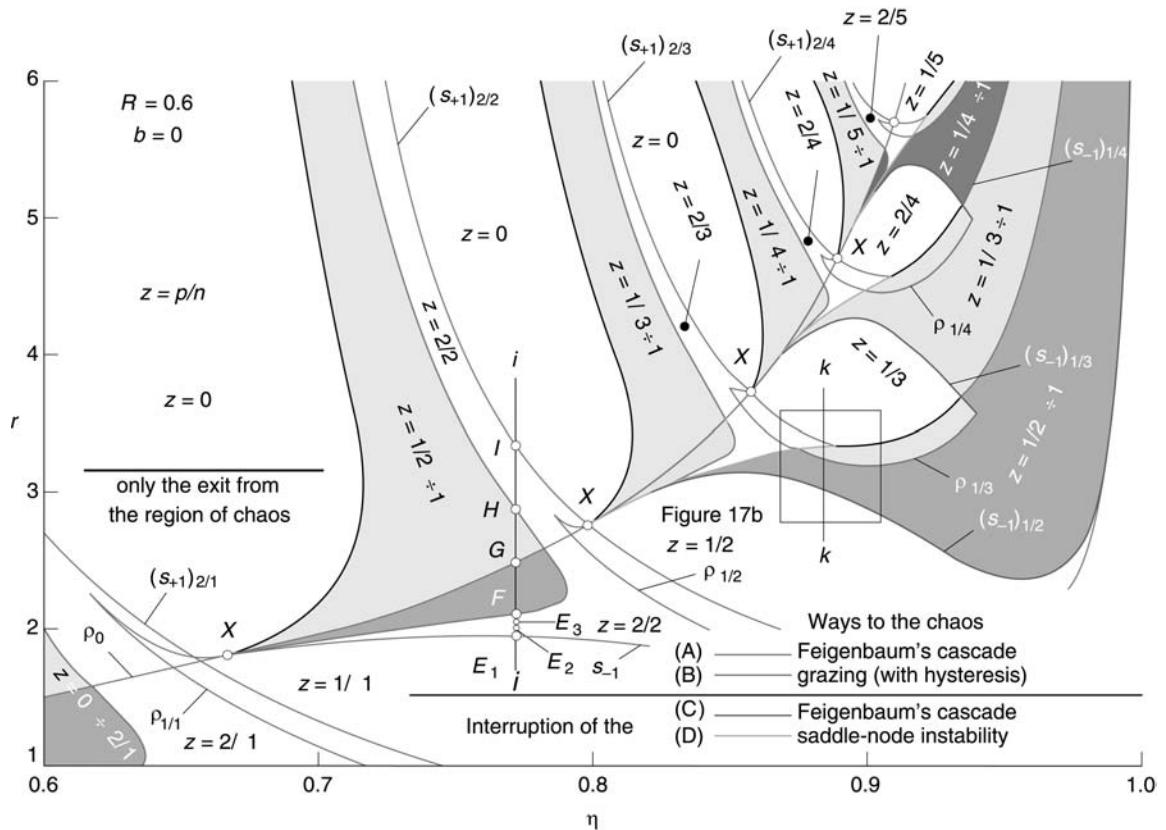

Figure 17A (see plate 54). Regions of chaotic impact motions and classification of their boundaries (four types of way into and from chaos and one type of exit from chaos).

along lines i, k crossing the boundaries. Ways to chaos are characterized in Table 1.

Feigenbaum's Cascade of Period Doublings

Line i ($\eta = 0.77$) in Figure 17A crosses the red boundary of chaotic motion $z = 1/2 - 1$ in points F, H . Bifurcation diagrams $X_m(r), V_-(r)$ are shown in Figure 18 and typical phase trajectories of the system motion in clearances (A) to (H) are shown in Figure 19. Fundamental $z = 1$ impact motion (Figure 19A) loses the stability in point E_1 ($r = 1.95$) on boundary s_{-1} and the $z = 2/2$ impact motion (Figure 19B) stabilizes. Next splitting appears in point E_2 ($r = 2.07$), when $z = 4/4$ impact motion (Figure 19C) begins to exist. The cascade of splitting or motion period doubling continues (see, e.g., point E_3 ($r = 2.1$) in Figure 17A for $z = 8/8$ motion – Figure 19D) and ends in point F , where it changes into the chaos (Figure 19E).

Typical features of this way into the chaos are:

1. reversible changes of the system motion, without hysteresis phenomena,
2. constant values z during the way into the chaos (e.g., $z = 1, 2/2, 4/4, 8/8, \dots$); it means that no impact vanishes or appears in corresponding excitation periods T .

When system parameters penetrate more deeply into the region of chaotic impact motion, then impacts can vanish in some period T and number z decreases (e.g., motion $z = 1/2 - 1$ in Figure 19G). There exist also ‘windows’ of more complex periodic impact motions inside the region of chaotic motions (e.g., $z = 3/5, 4/5$ motions in Figure 18 and Figure 19F).

The inverse Feigenbaum’s cascade appears with further increase of clearance r over the point H in Figures 17 and 18, but this cascade is not complete, because $z = 2/2$ motion loses its stability in point I on stability boundary $(s_1)_{2/2}$ and impactless motion stabilizes after the jump transition process.

Jump Transition into the Chaos on Segments of Grazing Bifurcation Boundaries Exhibiting Hysteresis Phenomena

When clearance r decreases along line i in Figure 17A, then impactless motion changes suddenly into the

chaotic impact motion in point G on the green segment of grazing bifurcation boundary ρ_0 (bifurcation diagrams with decreasing clearance r are represented by light grey in Figures 18 and 20).

Point G is placed inside the region $z = 1/2 - 1$ of the chaotic motion, so the return into the impactless motion is possible with remarkable hysteresis. The system motion has similar character along all green segments beginning in points X on boundary ρ_0 (Figure 17A).

Two Types of Interruption of the Instability Development of Subharmonic Impact Motions, Caused by Additional Impacts

Special ways into the chaos have been found for the series of $z = 1/n, z = 2/2n$ and $z = 2/(n+1)$ of subharmonic impact motions ($n \geq 2$). They will be explained using the quasistationary change of clearance r along line k ($\eta = 0.885$) in Figure 17B and by bifurcation diagrams in Figure 20.

Figure 17B is the enlarged rectangular segment of Figure 17A and line k crosses regions of periodic $z = 1/2; 1/3, 2/4, 2/3$ impact motions and the region of the chaotic $z = 1/2 - 1$ impact motion.

Interruption of Feigenbaum’s Cascade

When clearance r increases, line k crosses the stability boundary $(s_{-1})_{1/2}$ of $z = 1/2$ impact motion (Figure 21A) in point A (Figure 17B) and motion changes to $z = 2/4$ impact motion (Figure 21B). The splitting of phase trajectories (extremes 1, 2, 3, split into extremes 1a, 1b, 2a, 2b, 3a, 3b in Figure 21) increases up to point B on grazing bifurcation boundary $\rho_{2/4}$ (Figure 17B), where impactless loop 3b begins to touch the stop and the additional impact should appear. Additional impact turns the system motion towards the state, which corresponds to the nonsplitted motion (Figure 21A), i.e., it eliminates the splitting. The nonsplitted motion is unstable, so the splitting increases and an additional impact appears again. The system is continuously in transition processes between the depression and development of the splitting. The motion of the impact oscillator is chaotic (see dark area in Figure 21C), because the intensity and the instant of additional impact are unpredictable.

Table 1 Summary of characteristic features of different ways into the chaos

The way into chaos	Bifurcations	Hysteresis phenomena	Quantity z
A – Feigenbaum’s cascade of period doublings	Period doublings cascade	Absent	is constant
B – Segments of grazing bifurcation boundaries	Grazing	Exist	increases
C – Interruption of development of Feigenbaum’s cascade	Period doublings and grazing	Absent	increases
D – Interruption of saddle-node instability development	Saddle-node	Absent	decreases

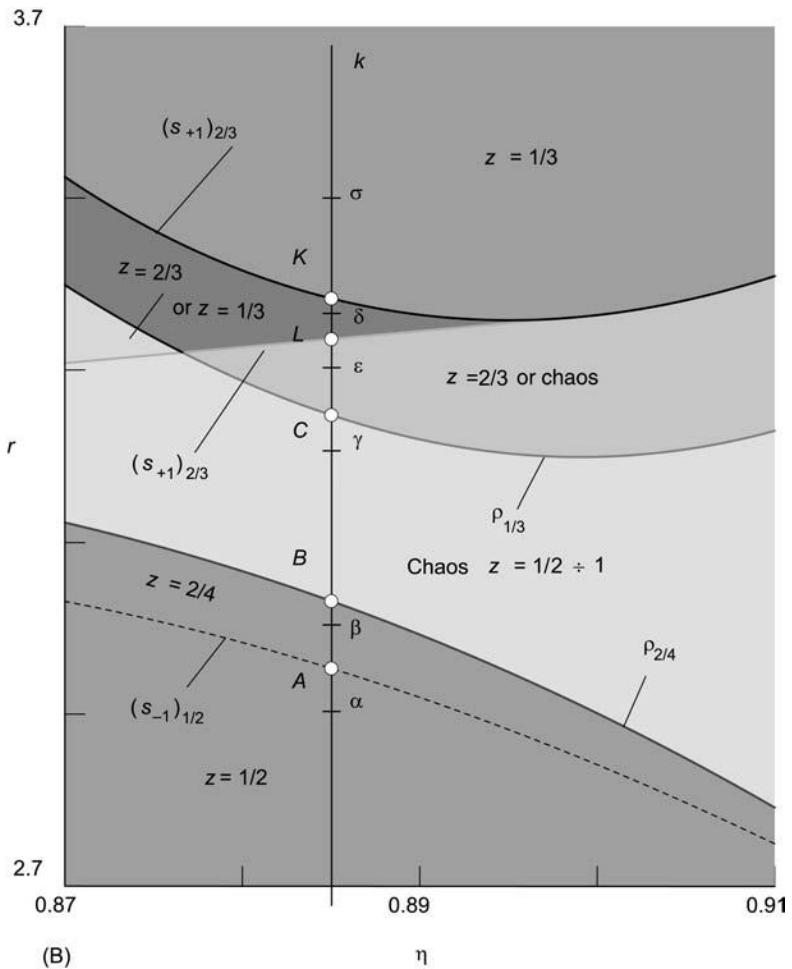

Figure 17B (see plate 55). Regions of periodic and chaotic impact motions in enlarged rectangular subregion of **Figure 17A**.

When the impenetrability condition [21] is omitted for previously impactless loops 3b of phase trajectories of $z = 2/2n$ impact motions, then the splitting of motions can increase over the level of the stop (**Figure 21C**) and the Feigenbaum cascade is not interrupted.

This way into chaos is typical by the increase of quantity z of the chaotic motion (e.g., $z = 2/4 \rightarrow z = 1/2 - 1$) due to the additional impacts. The transition cross the grazing bifurcation boundaries $\rho_{2/2n}$ is reversible, without hysteresis phenomena.

Interruption of the Saddle-node Instability Development

Periodic $z = 2/3$ impact motion (see points δ in Figures 17B, 20 and 21D) loses its stability in points K , L , which are both points of saddle-node bifurcation boundaries $(s+1)_{2/3}$ (**Figure 17B**). The weaker of two periodic impact (point v in **Figure 21D** and curve

v in **Figure 20**) vanishes in point K and the system stabilizes by the jump into $z = 1/3$ impact motion (**Figure 21F**). On the other hand, the stronger impact (point μ in **Figure 21D** and curve μ in **Figure 20**) weakens and vanishes and the weaker strengthens near point L and $z = 1/3$ impact motion (**Figure 21F**) stabilizes. This change can be accomplished, only when an additional impact is omitted. It appears at the end of this process on previously impactless loops of $z = 2/3$ motion (see development of impactless loop 2 in **Figure 22**, where clearance r is repeatedly increased for Δr and two penetrations per stop are allowed). This process is explained in more detail in **Figures 21D** and **21F** and **Figure 22** by the:

1. development of the position of extremes 1–4;
2. appearance of new extreme 5;
3. development of impact velocities v, μ ,
4. disappearance of impact μ .

An additional impact, which is not of the grazing character, turns the system motion more or less into

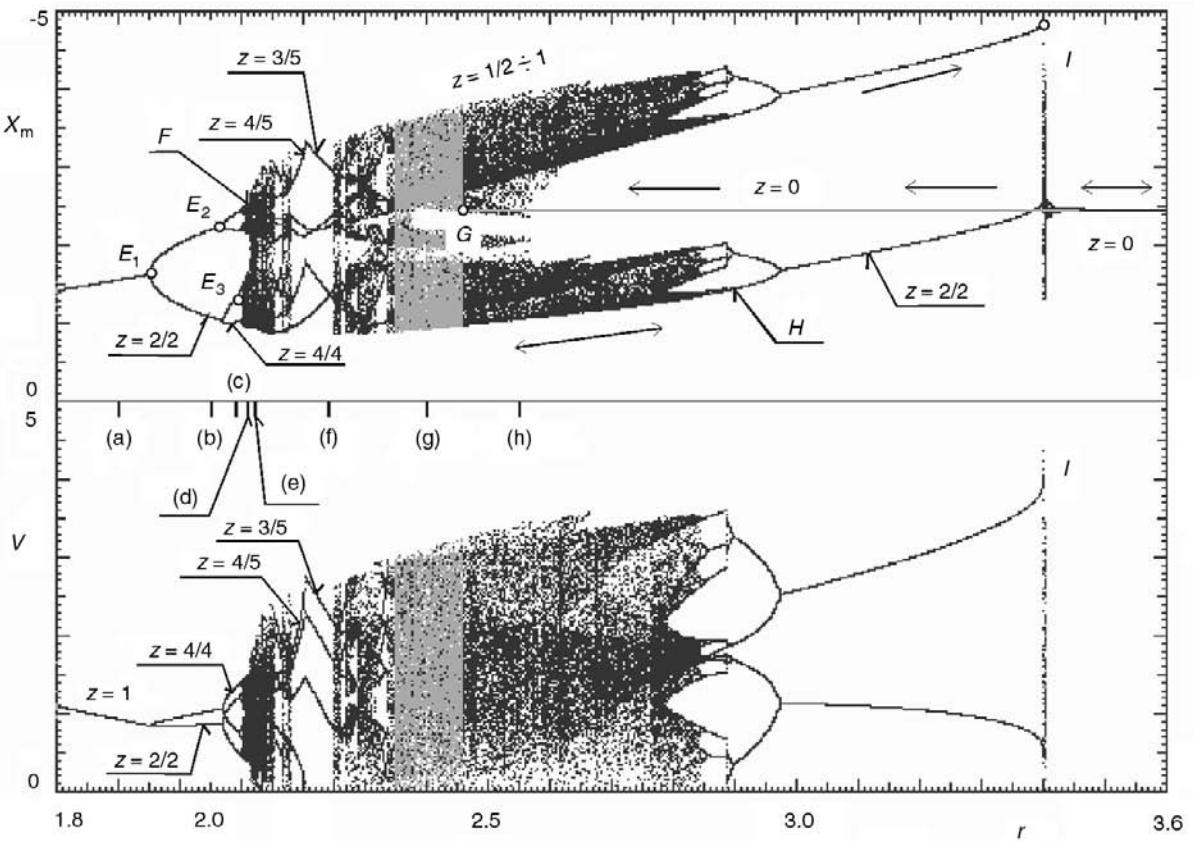

Figure 18 Bifurcation diagrams along line i in Figure 17.

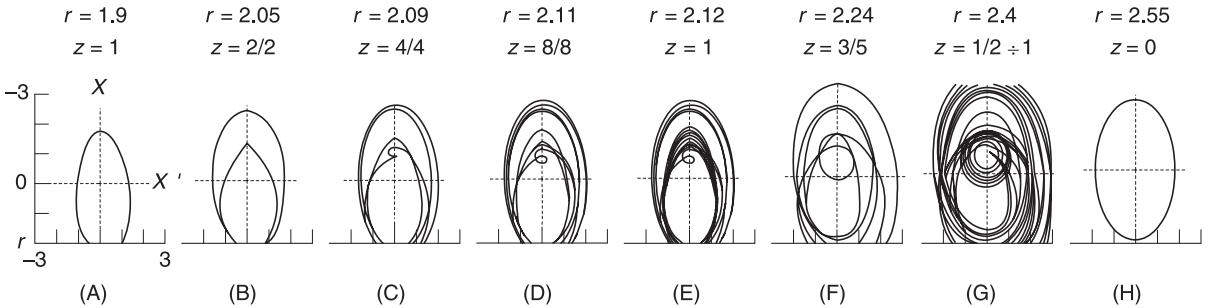

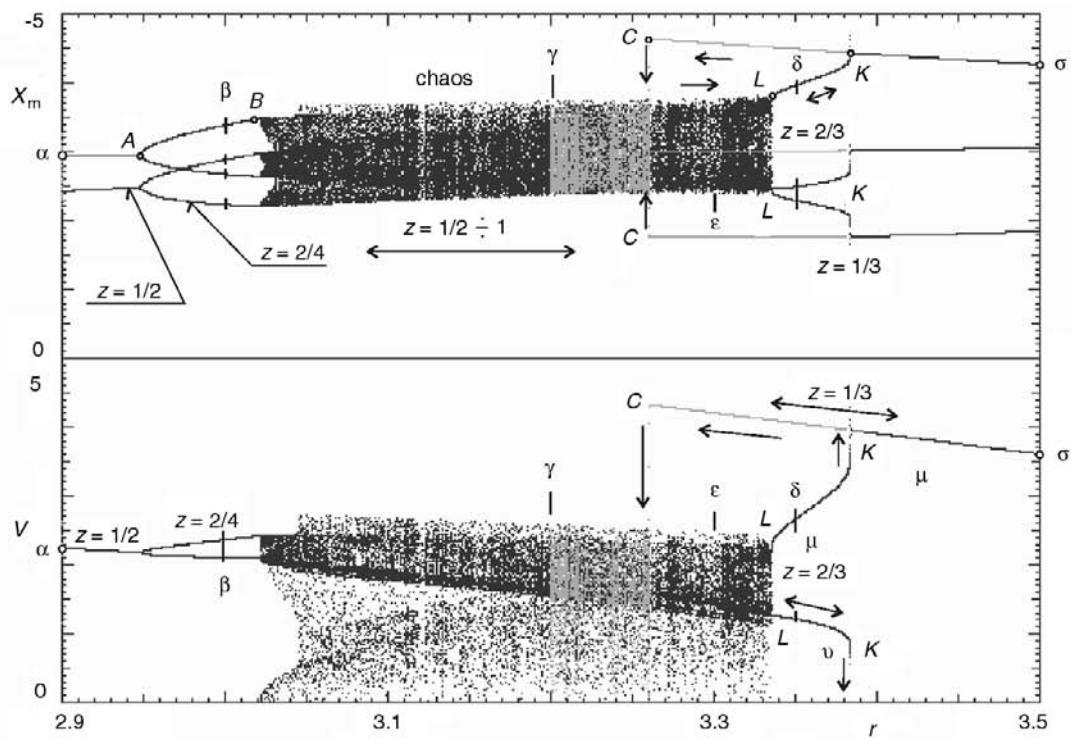

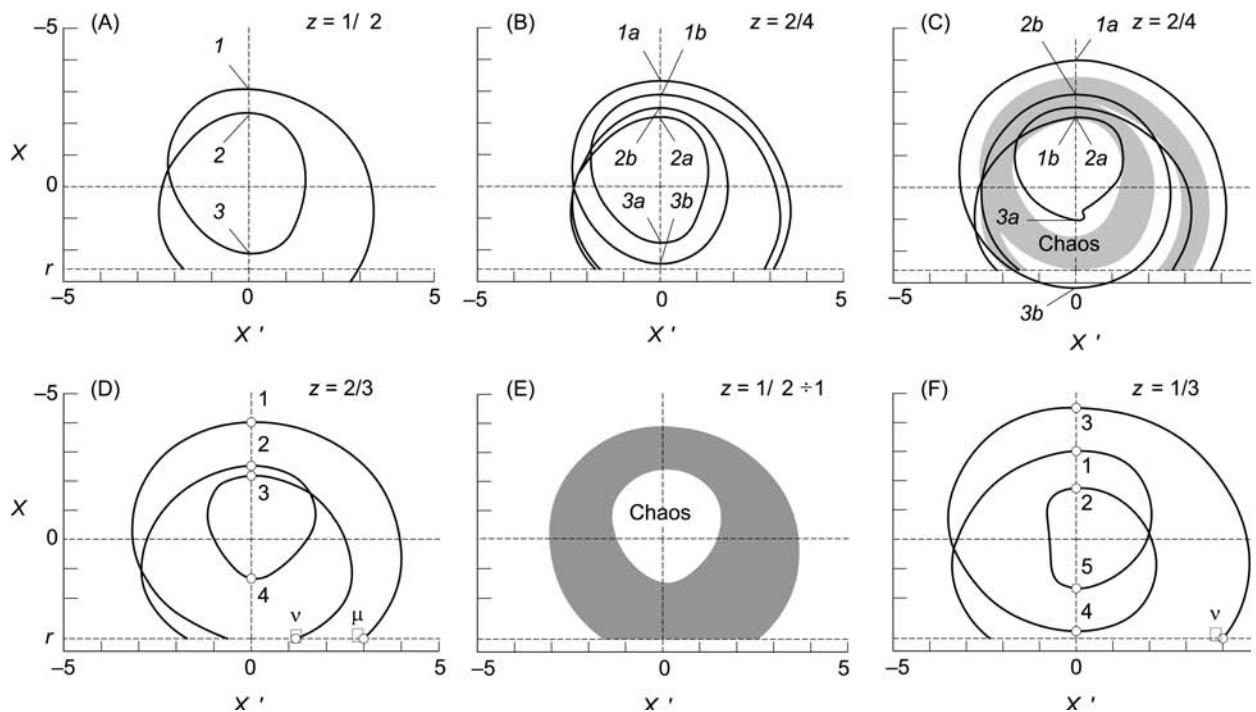

Figure 19 Phase trajectories of motions along line i in Figure 17A.

the state before the stability loss (Figure 21D), similarly as in the case of the interruption of the Feigenbaum cascade (see way C in Figure 17), and the instability of $z = 2/3$ impact motion develops to new additional impact. The intensity and appearance of an additional impact are unpredictable and the chaotic motion of the intermittency character arises (see Figure 23A), where time series of extremes 1–4 and impact velocities μ, v are displayed in the time interval ($0 < T < 500$).

Time intervals of $z = 2/3$ impact motion during the intermittency are longer, the nearer are system

parameters to the saddle-node stability boundary $(s_{+1})_{2/3}$. For example, point L on this boundary (Figures 17B and 20) has coordinate $r = 3.3342$ and the intermittency in Figure 23A was simulated for $r = 3.334$. The chaotic impact motion in Figure 23B corresponds to point $\varepsilon(r = 3.3)$ and time intervals of $z = 2/3$ impact motion are short.

This way into the chaos can be found in other $z = 2/n$ ($n > 3$) subharmonic impact motions. It is characterized by very sharp boundary $(s_{+1})_{2/n}$ between periodic $z = 2/n$ and chaotic $z = 1/(n-1) \div 1$ impact motions and quantity z decreases.

Figure 20 Bifurcation diagrams along line k in Figure 17B.Figure 21 Phase trajectories of motions along line k in Figure 17.

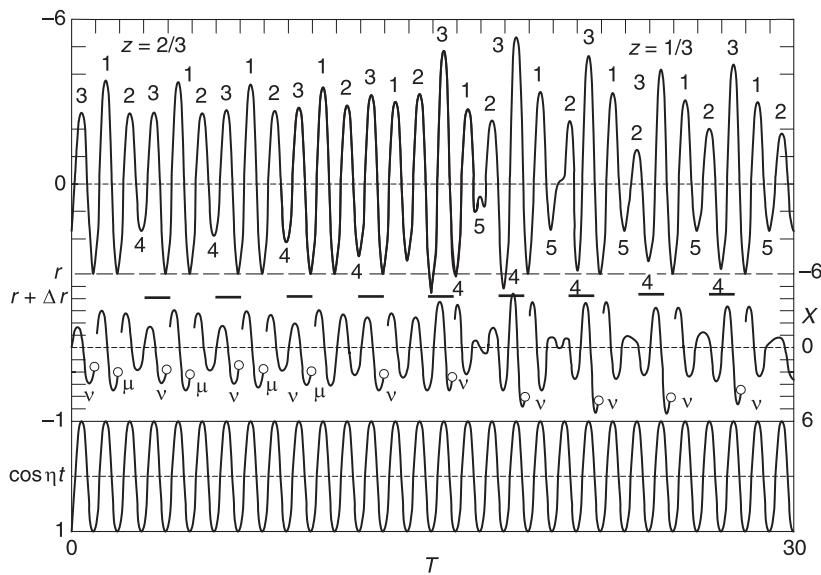

Figure 22 The last stage of development of saddle-node bifurcation and the elision of additional impacts.

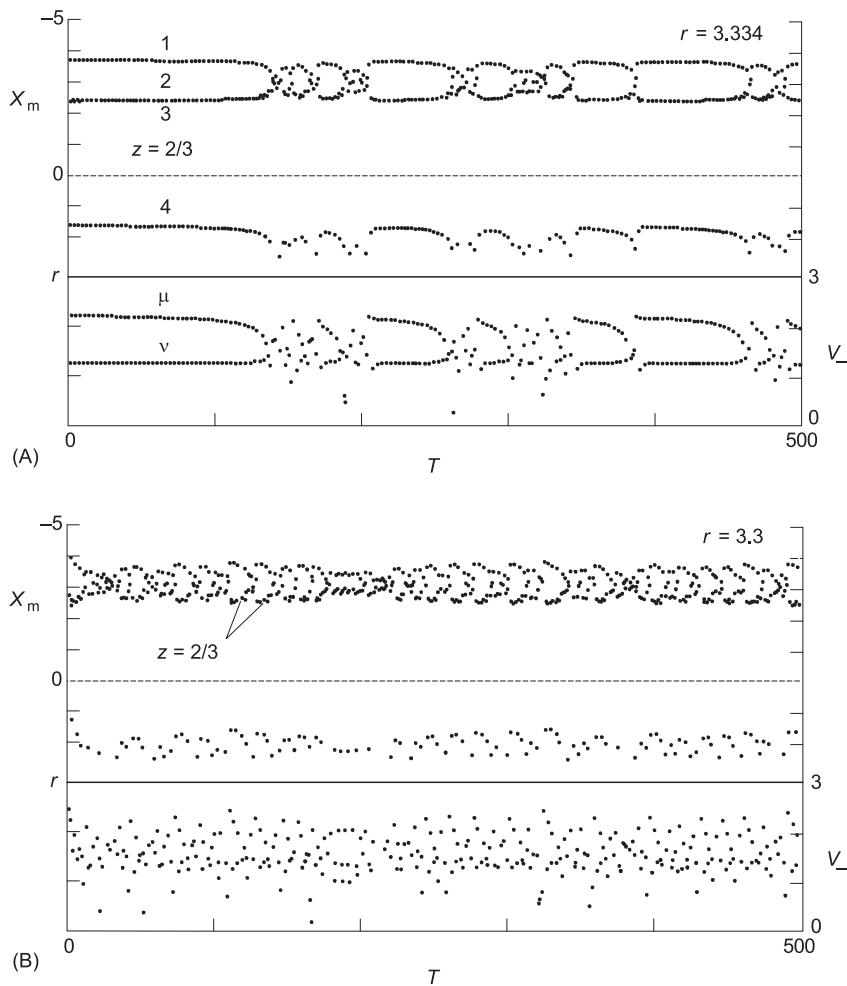

Figure 23 Intermittency (A) near point L and (B) in point ε in **Figure 17B**.

When clearance r decreases, e.g., from point σ in Figure 17B, then $z = 1/3$ impact motion (Figure 21F) ends its existence in point C on grazing bifurcation boundary $\rho_{1/3}$ and the system jumps inside the region of chaotic $z = 1/2 - 1$ motion (Figure 21E). It corresponds to way B (see Figure 17) into the chaos (see also points C in Figure 20).

There are other procedures, which throw light on the chaotic motion, e.g., stroboscopic or Poincaré's mappings, Lyapunov's exponents, autocorrelation functions, frequency power spectra, chaotic attractors and their dimensions, etc.

Conclusion

Explained dynamics of the simplest impact oscillator has shown the complexity and diversity of its behavior. The more complex the mechanical system and the higher the number of impacting bodies, the less and smaller are regions of periodic impact motions and the larger are regions of chaotic impact motions. Theoretical analysis of complicated impact oscillators is difficult and the effective tools for their investigation are simulations of the systems motion. They show the real behavior of chosen mathematical models of the mechanical system with impacts.

VISCOUS DAMPING

F Gandhi, The Pennsylvania State University, University Park, PA, USA

doi:10.1006/rwvb.2001.0016

Vibratory systems with discrete degrees-of-freedom are typically comprised of inertial, elastic, and viscous elements, and can undergo oscillatory motions under transient or periodic loading conditions. The inertial element (mass) stores kinetic energy, and the elastic element (spring) stores strain energy. In the absence of a viscous element (dashpot or damper), which generates a force proportional to velocity, the system would in principle continue to oscillate indefinitely when subjected to an initial

perturbation. However, if a viscous dashpot was present, it would dissipate the energy in the system, thereby causing the oscillations to decay with time (see **Critical damping**).

When the vibratory system is subjected to a sustained sinusoidal excitation force, it will eventually reach a steady-state oscillatory behavior, with the force of the viscous damper $C\dot{x}$ (C is the viscous damping constant), influencing the amplitude and the phase of the steady-state response. For the vibratory system:

$$m\ddot{x} + C\dot{x} + Kx = F(t) = F_0 \sin \Omega t \quad [1]$$

it can be shown that the steady-state response x is given as:

$$x(t) = x_0 \sin(\Omega t - \phi) \quad [2]$$

where

$$x_0 = \frac{F_0}{\sqrt{((K - m\Omega^2)^2 + (C\Omega)^2)}} \quad \phi = \tan^{-1} \frac{C\Omega}{K - m\Omega^2} \quad [3]$$

Away from the resonance condition (when the excitation frequency Ω is not close to the system's natural frequency), the $K - m\Omega^2$ term is large (and overshadows the $C\Omega$ term associated with viscous damping). In that case, viscous damping has little influence on the amplitude, x_0 , and the phase, ϕ , of the response (eqn [3]). However, near resonance conditions, viscous damping has a significant influence on both the response amplitude and the phase. Since $(K - m\Omega^2) \rightarrow 0$, it is seen from the expression for x_0 that in the absence of viscous damping the oscillation amplitude could become extremely large; and it is in fact the viscous damping in the system that attenuates the resonant amplitude (Figure 1A). The phase difference between the excitation force and the response amplitude, ϕ (which assumes a value of 0° or 180° in the absence of viscous damping), varies continuously with excitation frequency, Ω , when viscous damping is present in the system (Figure 1B).

Once the system with viscous damping has reached steady-state oscillatory behavior under the harmonic excitation force ($F_0 \sin \Omega t$), the work done by this force over every cycle can be calculated as follows:

$$\begin{aligned} W &= \int_0^{2\pi/\Omega} F dx = \int_0^{2\pi/\Omega} F \dot{x} dt \\ &= \int_0^{2\pi/\Omega} \{F_0 \sin \Omega t\} \{x_0 \Omega \cos(\Omega t - \phi)\} dt \\ &= \pi F_0 x_0 \sin \phi = \pi C \Omega x_0^2 \end{aligned} \quad [4]$$

and this is equal to the energy dissipated over the cycle by the viscous damper. The energy dissipated could also be calculated as the work done over any cycle by the viscous damping force (rather than the excitation force). Thus:

$$\begin{aligned} W &= \int_0^{2\pi/\Omega} C \dot{x} dx = \int_0^{2\pi/\Omega} C \dot{x}^2 dt \\ &= \int_0^{2\pi/\Omega} C \Omega^2 x_0^2 \cos^2(\Omega t - \phi) dt = \pi C \Omega x_0^2 \end{aligned} \quad [5]$$

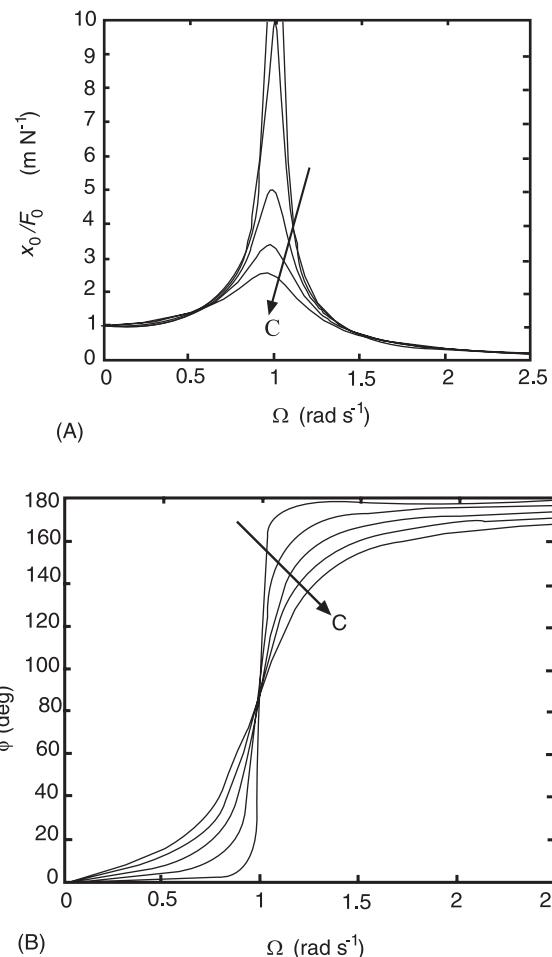

Figure 1 Response amplitude under harmonic excitation force. ($m = 1 \text{ kg}$, $K = 1 \text{ N m}^{-1}$, $C = 0.02, 0.1, 0.2, 0.3$ and 0.4 N s m^{-1} .)

While the work done or the energy pumped into the system by the external excitation force is dissipated by the viscous damper, the remaining stored energy in the system switches between kinetic and potential over every oscillatory cycle in the steady state.

For a harmonic excitation force, $F_0 \sin \Omega t$, and a steady-state harmonic response (eqns [2] and [3]), eqn [1] can also be expressed as:

$$F = (K - m\Omega^2)x \pm (C\Omega)\sqrt{(x_0^2 - x^2)} \quad [6]$$

This expression for force as a function of displacement produces the hysteresis loops shown in Figure 2. This is a fairly typical hysteresis cycle associated with oscillatory systems subjected to a steady harmonic excitation force. The area enclosed in the hysteresis loops is simply a measure of the energy dissipated per cycle, $\pi C \Omega x_0^2$, due to the viscous damping in the system.

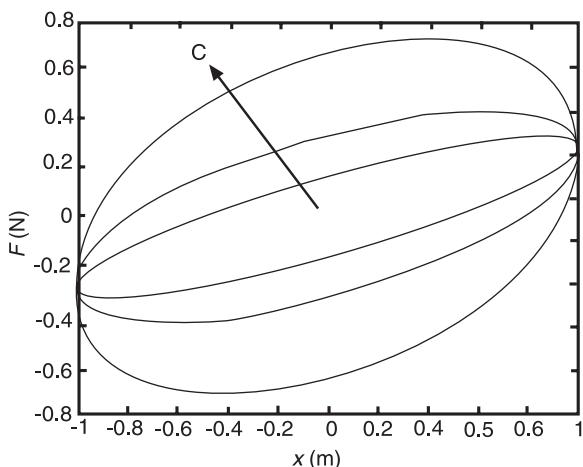

Figure 2 Hysteresis loop under harmonic excitation. ($m = 1 \text{ kg}$, $K = 1 \text{ N m}^{-1}$, $C = 0.2$, 0.4 and 0.8 N s m^{-1} , $\Omega = 0.85 \text{ rad s}^{-1}$.)

The transient response of a system in the presence of viscous damping is not addressed in this article as it has been extensively covered elsewhere (see **Critical damping**).

WAVE PROPAGATION

Guided Waves in Structures

M J S Lowe, Imperial College of Science, Technology and Medicine, London, UK

doi:10.1006/rwvb.2001.0173

Definition of Guided Waves (and Guided-wave Modes)

A guided wave is one whose propagation is guided by a structural form or boundary. The structure both guides the direction of the wave and determines its characteristics. In the context which is discussed here, the guided waves are elastodynamic; their propagation characteristics therefore depend on the density and the elastic properties of the material, as well as on the nature of the boundaries. A well-known example of such waves is the seismic wave created by an earthquake, which propagates along the surface of the earth. The sound (or vibration) which can easily be made to propagate along a tensioned wire is also a guided wave, as are the ‘whispering gallery’ waves which are guided around a circular enclosure by the wall.

Guided waves are natural properties of a structure, and are directly analogous to the natural vibration properties of a structure. The natural vibration properties of a plate of certain dimensions of thickness, length, and width are the unforced natural frequencies and mode shapes and can readily be calculated. For example, these natural vibration modes include a series of bending modes and in-plane extensional modes. But if the plate is assumed to be infinite in length and width, then these natural frequencies and mode shapes do not exist in the same way. Instead then, the natural properties of the plate are the guided waves which can propagate indefinitely along the plate. These, again, are unforced properties. They also have particular characteristics of spatial form (shape), such as bending and extension, which are found in the vibration modes of a finite bounded

structure, and they are often referred to as the guided-wave modes. So, a guided-wave mode is a particular type of wave which has its own properties of frequency, velocity, and shape and which can travel indefinitely in an elastic structure. Indeed, it is reverberation of these guided-wave modes back and forth between the ends of the finite plate which sets up what is referred to as the vibration modes. From a theoretical point of view, both kinds of properties are the unforced steady-state solutions to the elastodynamic equations of motion, the difference coming simply from the different boundary conditions (see **Mode of vibration**).

An important feature of guided waves is that they may propagate over very long distances because the structure, or waveguide, retains the energy by its boundaries, so that it does not spread out as it would in an unbounded volume of material. For example, the waves which are guided along a tensioned wire propagate in only a single dimension, the direction along the wire. In contrast, the waves which propagate from a point source in an unbounded volume of material spread out in all three dimensions, so that the amplitude then diminishes with the distance of propagation. This is why the surface wave in an earthquake can be more damaging than the compression waves which reflect from deep strata; the surface wave is guided by the surface and so spreads in only two dimensions rather than three. The property of long-distance propagation is one reason why guided ultrasonic waves have become popular for nondestructive testing.

Another key characteristic of guided waves is that they exhibit dispersion. The velocity of a guided wave, in general, varies with its frequency. Consequently, the shape of the signal of a wave packet (a short-time wave train) may vary with the distance and time of propagation. The short time signal contains a finite band of frequencies; if the low-frequency components of the signal travel at different speeds from the high-frequency components, then the signal shape must change with time. In fact, what happens is that the wave packet spreads out and its amplitude

diminishes. It is important to appreciate that this dispersion is not a function of the material properties (at least for linear elastic materials) but is caused by the properties of the guided wave. It is therefore essentially a result of the boundary conditions which are imposed by the waveguide structure.

Theoretical Basis

The primary property of a guided wave which needs to be calculated is the velocity–frequency relationship, that is, the variation of the velocity of the mode with the frequency. This relationship is known as a dispersion curve. There can be many different modes which may propagate in a given structure; each has its own dispersion curve, so that at any chosen frequency the velocity can be read off the curve. The curves are continuous and they represent two-dimensional eigenvalues of the modal equations. Thus, whereas a natural vibration mode of a finite plate has its value of natural frequency, a guided-wave mode in a plate has its frequency–velocity curve.

The guided-wave modes also have their eigenvectors, that is, their mode shapes. The mode shapes of a guided wave which are of interest are the distributions of the displacements and stresses in the directions normal to the direction of propagation; in the example of a plate, the mode shapes are the profiles of these quantities through the thickness. In the direction of propagation the mode shapes are simply harmonic functions: thus a displacement or stress quantity at any location in the thickness of the structure additionally varies sinusoidally in time and in the direction of propagation. The mode shapes of a mode vary, in general, from one location to another along the dispersion curve. Another interesting feature is that the wave crests of a guided wave are straight and aligned exactly at right angles to the direction of propagation for all modes in which there is no attenuation (modes with attenuation will be discussed later in this entry).

There are various ways to approach the problem of calculation of the dispersion curves. One approach, which has the benefit of being rather physical, is to compose the field in the waveguide from a superposition of bulk waves (waves which could propagate in an unbounded medium), the sum of the bulk waves being such that the boundary conditions are satisfied. Such an approach is illustrated for the example of a plate in Figure 1. The plate is assumed to be infinite in extent, both in the direction of propagation of the wave and in the direction normal to the plane of the illustration. Four waves are shown in the plate: longitudinal and shear waves traveling in downward directions and a similar pair traveling in upward directions. Each of these partial waves is a continuous plane wave, such as would travel in an unbounded medium. The task then is to find the angles of propagation, the amplitudes and the phases of all of these modes such that when they are superposed the surfaces of the plate are traction-free. This is done by applying Snell's law to relate the stress components of all of the waves at the surfaces of the plate. It turns out that, in order to satisfy the traction-free condition at all positions along the surfaces, the partial waves must all have the same frequency and their directions must be fixed in relation to each other. The angles defining the directions of the partial waves in fact relate to a value of velocity in the direction along the plate, which will be the velocity of the guided mode.

For a given structural geometry and material properties, the mathematical problem then becomes the solution of a characteristic function $f()$ of the form:

$$f(\omega, C) = 0 \quad [1]$$

where ω is the frequency and C is the velocity of the guided wave. The numerical solutions of this function are the frequency–velocity dispersion curves. At any location on a dispersion curve, the distributions of the displacements and stresses through the thickness of

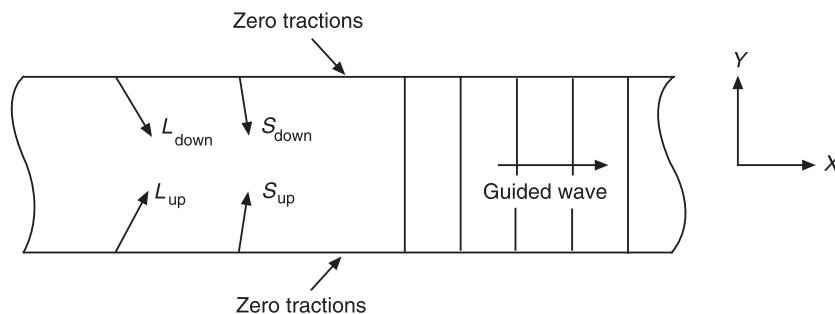

Figure 1 Guided wave in plate composed by superposition of partial waves.

the structure (the wave mode shapes) are simply found by summing the contributions from the four partial waves at that location. To complete the description, the propagation of the wave along the structure is described by a harmonic wave equation in much the same form as that for a wave in an unbounded medium (see **Wave propagation**, Waves in an unbounded medium). Taking, for example, the particle displacement in the Y direction, the space-time equation for the propagation is:

$$u_Y = A e^{i(k_X x - \omega t)} \quad [2]$$

where k_X is the wavenumber in the direction along the structure, which is related to the velocity of the wave by:

$$C = \frac{\omega}{k_X} = \frac{\omega * \text{wavelength}}{2\pi} \quad [3]$$

The dispersion curves and mode shapes of some of the best known guided waves will now be presented in the following several sections.

Waves which are Guided along a Flat Boundary

The surface wave which was mentioned earlier in the earthquake example is in fact the Rayleigh wave which is one of the simplest guided wave modes. The Rayleigh wave exists at the free surface of a semi-infinite half-space of an isotropic solid material. Strictly speaking, the half-space should be bounded by a vacuum in order for the surface to be perfectly traction-free. However, in practice, the tractions at the boundary between typical structural materials and air are virtually zero. Also, a thick plate can act effectively as a semi-infinite half-space provided that the thickness is very much larger than the near-surface region in which the wave propagates; this depends on the wavelength being short enough and thus on the frequency being high enough.

The characteristic function of a Rayleigh wave is a cubic expression:

$$p^3 - 8p^2 + (24 - 16a)p + 16(a - 1) = 0 \quad [4]$$

with:

$$p = \left(\frac{\omega}{k_X C_S} \right)^2 \text{ and } a = \left(\frac{1 - 2v}{2(1 - v)} \right) \quad [5]$$

in which k_X is the wavenumber of the Rayleigh wave, C_S is the bulk velocity of shear waves in an unbounded volume of the material, and v is Poisson's ratio.

The solution of the Rayleigh wave function shows the Rayleigh wave to be nondispersing with a velocity just below the velocity of the bulk shear wave. In steel, for example, the bulk shear wave velocity is about 3.25 km s^{-1} and the Rayleigh wave velocity is about 3.0 km s^{-1} .

The displacement and stress mode shapes of the Rayleigh wave in steel are shown in **Figure 2** for a frequency of 1 MHz, in which case the wavelength is about 3 mm. If the frequency was to be increased then the depth scale of the mode shape plot would be reduced in linear proportion. Thus, it can be seen that the Rayleigh wave exists effectively just in the material within two or three wavelengths of the surface. The shear stress and the stress normal to the surface can both be seen to be zero at the surface, as is the necessary boundary condition for the solution.

If the vacuum is replaced by another solid material, so that the geometry consists of two semi-infinite half-spaces meeting at a flat interface, then another type of guided wave may exist. This is the Stoneley or interface wave. In this case the boundary condition is not traction-free but instead the condition is imposed that the tractions in the two materials must balance at the interface and the displacements must be continuous. Again, the solution, when one exists, yields a velocity which does not vary with frequency. However, a solution only exists within certain ranges of the properties of the two materials. As with the Rayleigh wave, the mode shapes are dominant in the material close to the interface, in this case existing on both sides of the interface.

Waves which are Guided along a Plate

The Lamb waves which are guided along a simple isotropic plate are perhaps the best known guided waves in structures. Strictly speaking, Lamb's theory for these waves requires the surfaces of the plate to be traction-free, that is to say the plate should be in vacuum. In practice however, as with the Rayleigh wave, the Lamb wave solutions are valid for any typical structural material in air.

The solutions of the characteristic functions for Lamb waves can be calculated separately for symmetric and for antisymmetric modes, all modes having shapes which are either perfectly symmetric or perfectly antisymmetric with regard to the midplane of the plate. The characteristic function for the symmetric Lamb waves is:

$$(B^2 - k_X^2)^2 \tan(Ab) + (4k_X^2 AB) \tan(Bb) = 0 \quad [6]$$

and for antisymmetric waves:

$$(B^2 - k_X^2)^2 \cot(Ah) + (4k_X^2 AB) \cot(Bh) = 0 \quad [7]$$

in which:

$$A = \sqrt{\left[\left(\frac{\omega}{C_L}\right)^2 - k_X^2\right]} \text{ and } B = \sqrt{\left[\left(\frac{\omega}{C_S}\right)^2 - k_X^2\right]} \quad [8]$$

C_S and C_L are the velocities of bulk shear and longitudinal waves respectively, and the thickness of the plate is $2h$.

Figure 3 shows the Lamb wave dispersion curves for a steel plate. The horizontal axis shows the frequency-thickness product because the results can be scaled linearly in this way. Thus, for example, these curves could represent the modes in a 1-mm-thick plate for the frequency range up to 10 MHz or, equally, for a 2-mm-thick plate up to 5 MHz. The vertical axis shows the phase velocity, that is, the velocity of the wave crests. The modes are labeled in the conventional way for Lamb waves: the 's' modes are the symmetric modes and the 'a' modes are the antisymmetric modes. The subscripts, 0,1,2 ..., indicate the series of these two types, the complexity of the mode shapes increasing with the increasing mode number. The fundamental modes, s_0 and a_0 , are very easily understood as extensional and bending modes when the frequency is low, as illustrated in the

exaggerated displaced shape sketches in the figure. As the frequency is increased, the velocities of both modes change, until ultimately, at the high-frequency end of the plot, they converge to the same value. This is the velocity of the Rayleigh wave and, indeed, the solution is asymptotic to the Rayleigh wave solution at high frequency. Looking at the mode shapes at high frequency, it can be seen that the motion is concentrated more and more at the surfaces of the plate so that in the limit a Rayleigh wave propagates simultaneously on both surfaces. In the case of the s_0 mode, these two Rayleigh waves have the same phase, and in the case of the a_0 mode, they are in opposite phase. The particle motion of all Lamb modes is in the plane defined by the direction of the guided-wave propagation and the normal to the surface of the plate.

Another way in which the Lamb wave dispersion curves are often presented is by wavenumber instead of phase velocity. The relationship between wavenumber and phase velocity is the simple expression in eqn [3]. The wavenumber curves are shown in Figure 4.

The phase velocity curves present the velocity of the wave crests but this is not in fact the velocity at which a pulse or other short-time wave signal (wave packet) travels. A wave packet travels at the group velocity which is obtained by taking the derivative of the frequency with respect to the wavenumber:

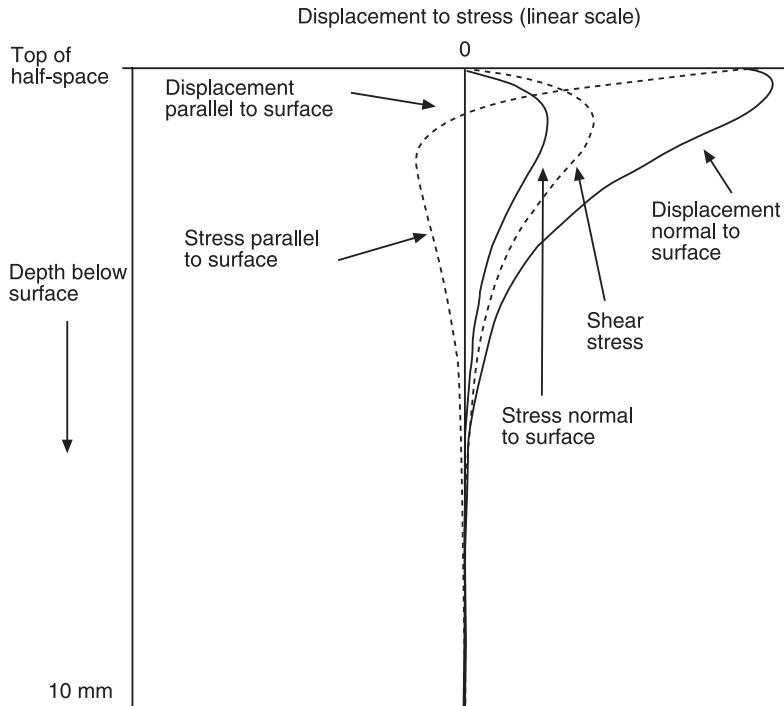

Figure 2 Mode shapes of 1 MHz Rayleigh wave in steel.

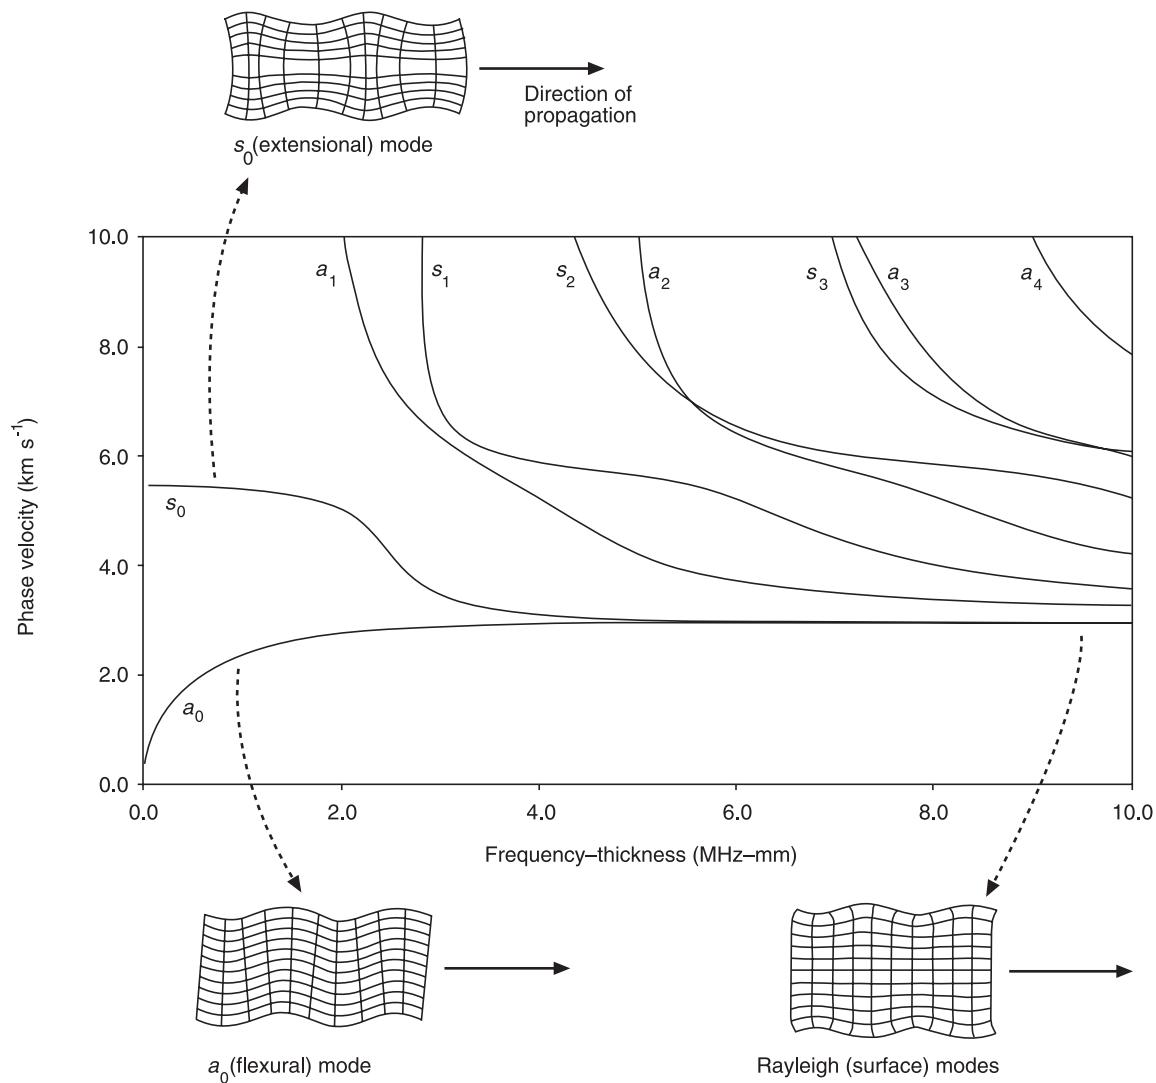

Figure 3 Phase velocity dispersion curves for Lamb waves in steel plate, showing shapes of fundamental modes.

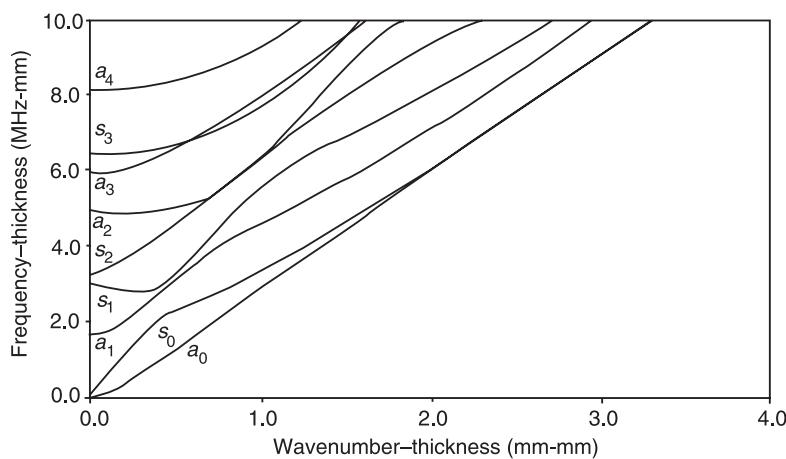

Figure 4 Wavenumber dispersion curves for Lamb waves in steel plate.

$$\text{Group velocity} = \frac{d\omega}{dk_x} \quad [9]$$

Therefore if, for example, a wave packet signal consists of a sinusoidal tone windowed by an envelope function, then the envelope travels at the group velocity whereas the crests of the sinusoidal signal within the envelope travel at the phase velocity for that particular frequency. The value of calculating the group velocity is that this gives the important information for long-range propagation about the arrival times of the wave packets. **Figure 5** shows the group velocity dispersion curves for the steel plate.

Finally, there is one more family of modes which can propagate in a plate which are quite different from the Lamb modes. These are the Love modes, or shear horizontal (SH) modes and they differ from the Lamb modes in the direction of their particle motion. In this case the particle motion is entirely in the direction which is normal to the direction of propagation and parallel to the surface of the plate. **Figure 6** shows the Love mode dispersion curves for the steel plate. The displacement mode shapes are illustrated on the figure in an exaggerated scale for the first two modes. The fundamental mode has a very simple mode shape, with no variation of the displacement through the thickness of the plate; therefore, the only variation is the distance-time harmonic variation along the axis of propagation. Consequently it travels at exactly the velocity of shear bulk waves. The next mode, SH₁, has a variation of the displacement through the thickness which follows the shape of half a sine wave; the displacement profile is antisymmetric with a positive value at one surface and negative at the other. Higher-numbered modes have

profiles with increasing numbers of half-waves through the thickness. Interestingly, the mode shapes for each SH mode remain identical for all locations on the curve; this is very much the exception since the mode shapes vary considerably along the curves for most types of guided waves.

Waves in a Bar or Hollow Cylinder

All kinds of beams, rods, and cylinders make excellent waveguides, and of course they occur frequently in engineering structures. Guided waves in these objects can propagate for extremely long distances. The dispersion curves for a cylindrical object are calculated in the same way as for the flat geometries discussed above, except that the partial waves must be expressed in the form for propagation in a cylindrical coordinate system; specifically, the harmonic exponential functions are replaced here by Bessel functions. The resulting dispersion curves differ conceptually from the flat-geometry case in that there now exist multiple families of modes, each family corresponding to a different circumferential order of the Bessel functions.

An example, using a solid steel bar, is given in **Figure 7**. The horizontal axis shows the frequency-radius product; thus, the upper limit could be, for example, 5 MHz for a 1-mm-radius bar or 10 MHz for a 0.5-mm-radius bar. The dispersion curves show the conventional labels for cylindrical geometry: 'L' denotes the axially symmetric modes, 'T' denotes torsional, and 'F' denotes flexural. The first index of each label denotes the circumferential order and the second index is simply a sequence identifier. The order 0 modes have mode shapes which are constant

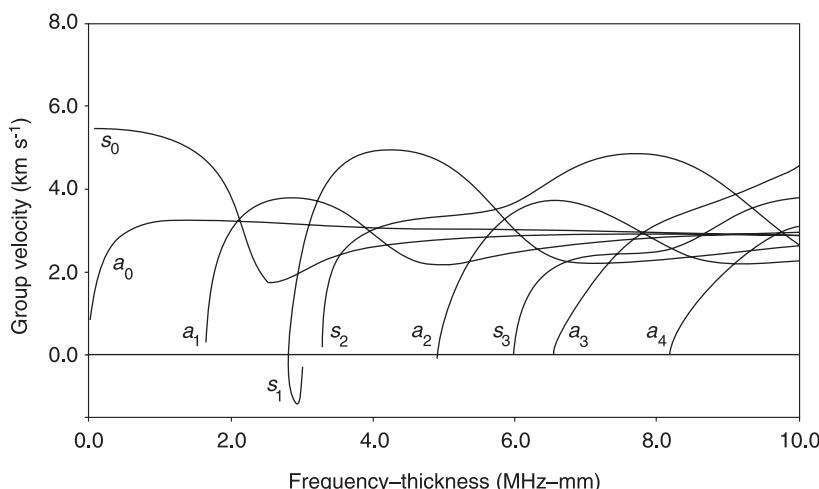

Figure 5 Group velocity dispersion curves for Lamb waves in steel plate.

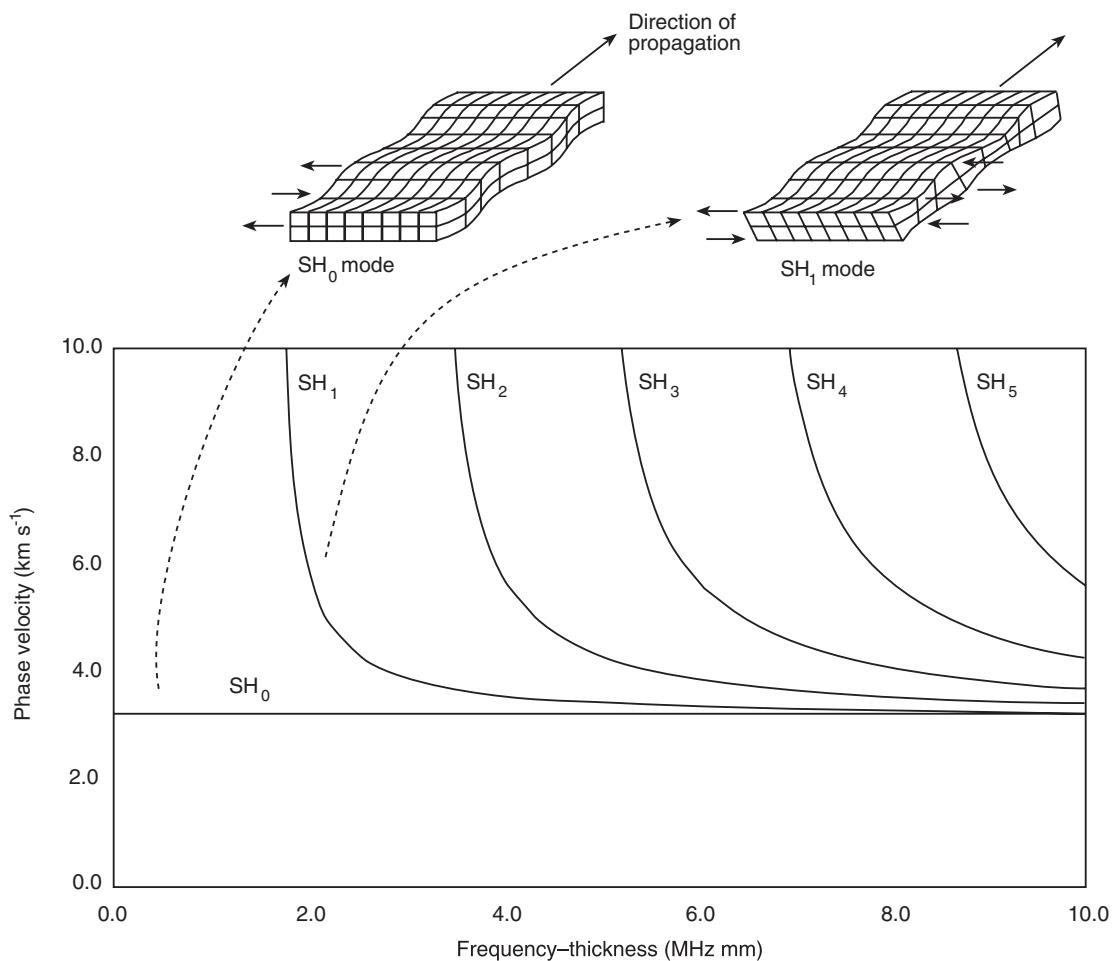

Figure 6 Phase velocity dispersion curves for Love waves in steel plate.

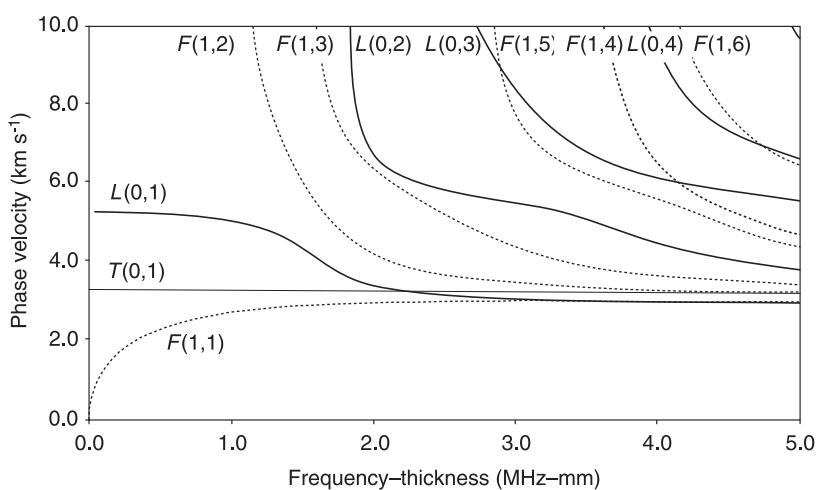

Figure 7 Phase velocity dispersion curves for waves which propagate along a solid steel cylinder (bar).

around the circumference of the cylinder. The $L(0, \dots)$ modes are therefore essentially axial extensional modes, although with various different mode shape profiles across the radius. The $T(0, 1)$ mode is pure torsion of the cylinder, with displacements only in the tangential direction, and accordingly it travels at exactly the bulk shear velocity. The $F(1, \dots)$ modes have mode shapes which vary sinusoidally in the circumferential direction, the circumferential order of 1 indicating that in these cases there is exactly one sinusoid around the circumference. Higher orders ($2, 3, 4, \dots$) may also exist but are not shown here. The fundamental flexural mode, $F(1, 1)$, is thus a bending mode as, for example its axial stress would be positive at one circumferential location and negative at 180° around the circumference. It is therefore analogous to the a_0 mode in the plate, and, indeed, its dispersion curve is rather similar.

Attenuation of Guided Waves

Guided waves are attenuated by the mechanisms of scattering, absorption, and leakage.

Scattering and absorption of guided waves are no different conceptually with guided waves than with bulk waves: scattering losses occur when some of the energy of the waves is lost because of partial reflections from features such as inhomogeneities or inclusions in the material, or roughness of the surface; absorption occurs when the material has damping

properties, this is the case for example with plastic materials.

Leakage is quite a different phenomenon which is peculiar to guided waves. Leakage occurs when a waveguide structure is in contact with another medium so that some of the energy is able to leak from the waveguide into the surrounding material. An example of this is ‘leaky Lamb waves’ the Lamb waves which propagate in a plate that is immersed in a fluid. The dispersion curves for leaky Lamb waves in a steel plate immersed in water are almost the same as those for the strict Lamb waves (in fact, this is to be expected because the acoustic impedance of the water is very much lower than that of the steel). However, there is an additional attenuation associated with each location on each dispersion curve. The attenuation is very much a part of the modal properties of the plate–water system and the attenuation curves can be calculated along with the dispersion curves. Figure 8 shows the attenuation curves for this example. The attenuation is exponential with distance so it may be expressed by multiplying the wave propagation eqn [2] by an exponential with a real negative argument. Another consistent form of expression is to add an imaginary part to the wave-number of the guided wave. The attenuation in the figure is expressed in the converted units of dB mm^{-1} , using also the attenuation–thickness scaling relationship; thus, the attenuation at the top of the scale could be, for example, 2 dB mm^{-1} traveled in a 1-mm-thick plate or 1 dB mm^{-1} traveled in a 2-mm-thick plate.

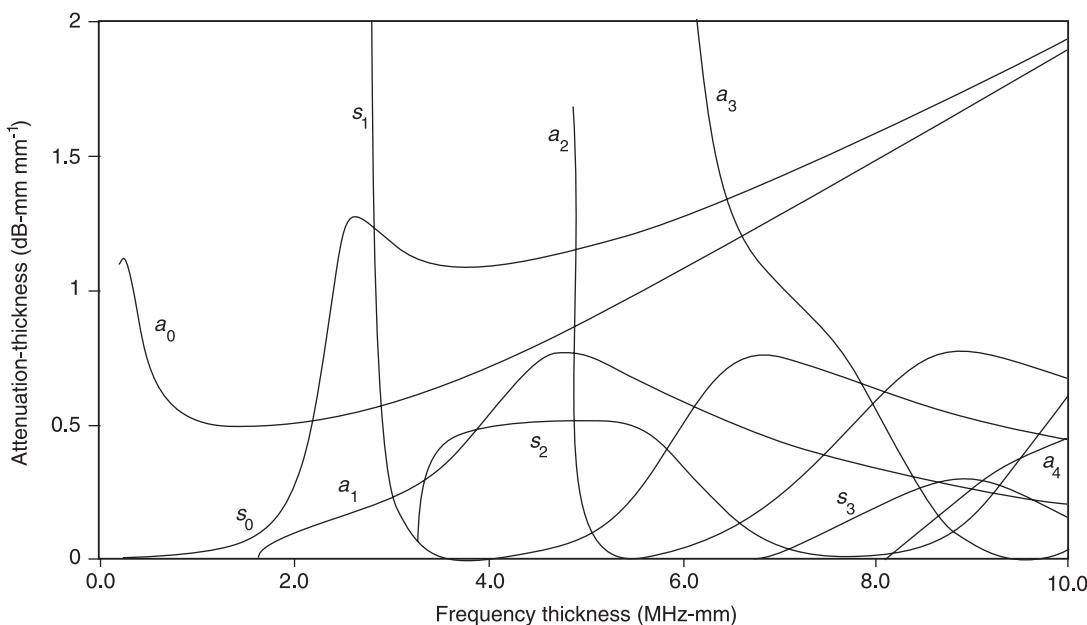

Figure 8 Attenuation curves for leaky Lamb waves in a steel plate immersed in water.

The curves show significant variations of attenuation, and this can be understood by examining the mode shapes. For example, the s_0 mode at low frequency has very little displacement in the direction normal to the surface of the plate, and therefore it leaks very little; on the other hand, the a_0 mode has significant lateral motion and so it has high attenuation. The attenuations of the s_0 and a_0 modes can be seen to be converging towards a straight line. In the high-frequency limit these modes both become the Rayleigh mode, for which the attenuation per unit distance increases linearly with frequency, or this can alternatively be expressed as a constant attenuation per wavelength. In the case of a steel half-space in contact with water, the attenuation is 0.58 dB per wavelength.

Guided Waves in Engineering

Guided waves occur in several diverse instances in engineering. Already briefly mentioned are the examples of earthquakes and the field of acoustics, but there are others. At the very low-frequency end of the scale, seismic exploration has for many years used guided waves to survey, particularly for oil reserves. A point source (for example, an explosion) is used to generate waves, then multiple receivers are used to detect the arrivals of waves; these include waves which are guided by the rock strata. Accordingly, much of the research literature for guided waves is focused on modeling such phenomena. At higher frequencies, typically between about 50 kHz and 10 MHz, guided waves are used for nondestructive testing. For example, surface waves may be used to detect microcracking of the surface of a material, or to measure the properties of thin electroplated or painted layers deposited on a much thicker object. Waves which are guided in plates, bars, and pipes may be used to detect regions where there is material thinning, cracking or corrosion. At very high frequency, in the GHz range, surface-guided waves are used in many electronic surface acoustic wave (SAW) devices, for example, for performing operations in signal processing, such as frequency filtering.

Interaction of Waves with Boundaries

doi:10.1006/rwvb.2001.0172

Introduction

When an elastic wave which is traveling in a fluid or solid medium is incident at a boundary of the material, then it may be partially reflected or transmitted, the characteristics of the interaction depending on the nature of the boundary. Additional waves may also be generated. This entry addresses the physics of this wave interaction. The focus is on the interaction of plane waves with a flat boundary between two materials, although there is some discussion about the interaction of waves with boundaries of arbitrary shapes, which has relevance to the topics of sound scattering and nondestructive testing (NDT).

The understanding of these reflection and transmission phenomena is important in several areas. In the subject of ultrasonic NDT, for example, the interaction of the ultrasound waves with features of the structure is the key to the technique. The ultrasound reflects from boundaries of the body as well as from any defects such as cracks, and the measurement of these reflections reveals the desired informa-

tion. In another example, the understanding of structure-guided elastic waves relies very much on the interaction characteristics at the waveguide boundaries as these determine the properties of the guided waves. In considering shock and vibration problems, it can be useful to examine the internal reflections of waves within a body. Or, in acoustics studies, it is useful to determine the extent to which sound is reflected and transmitted at structural boundaries such as partitions.

Reflection and Transmission of a Plane Wave Normally Incident at a Boundary

Consider a flat interface between two half-spaces, as illustrated in **Figure 1**. The two half-spaces are composed of materials M_1 and M_2 – they may be either fluid or solid materials, both of which have the same solution for the normal incidence case. A continuous elastic compression wave is incident from material M_1 at the boundary; its direction of propagation, X , is normal to the interface.

The particle displacement, u_X , and the stress in the direction normal to the interface, σ_{XX} , of the incident wave are given by the expressions:

$$u_X = I e^{i(kx - \omega t)} \quad [1]$$

$$\sigma_{XX} = i\omega C_{M1} \rho_{M1} u_X \quad [2]$$

where I is the amplitude of the particle displacement (I for incident wave), k is the wavenumber, x is the distance from the interface along the path of propagation, C_{M1} is the wave speed, ρ_{M1} is the density of material M_1 , and i is $\sqrt{(-1)}$ (see **Wave propagation, Waves in an unbounded medium**).

At the interface it is now assumed that some of the energy of this wave is transmitted into medium M_2 and some is reflected. The transmitted and reflected waves are both of the same type as the incident wave (in this case, compression) and have amplitudes, not yet known, of T and R respectively. The particle displacement and stress equations for T and R are the same as eqns [1] and [2] except for these different amplitudes and the fact that the harmonic exponent of the R wave is in negative X (opposite direction of travel).

The amplitudes of T and R are found by satisfying the boundary conditions at the interface. These conditions are the continuity of the particle displacement and the equilibrium of the stress across the boundary. Specifically, at $x = 0$, $u_{X(M1)} = u_{X(M2)}$ and $\sigma_{XX(M1)} = \sigma_{XX(M2)}$. These lead to the two equations:

$$I + R = T \quad [3]$$

$$Z_{M1}(I - R) = Z_{M2}T \quad [4]$$

in which Z is the product of the density and the wave speed, $Z = \rho C$; this is a property of the material and is known as the acoustic impedance (SI units rayls). The

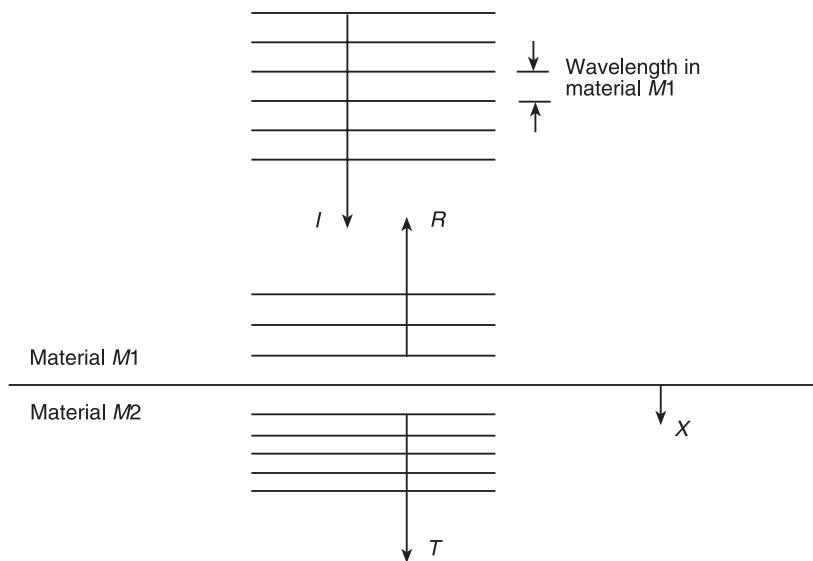

Figure 1 Interface between two media, showing incident (I), reflected (R), and transmitted (T) waves.

reflection and transmission coefficients for particle displacements are then:

$$\frac{u_{X(R)}}{u_{X(I)}} = \frac{R}{I} = \frac{Z_{M1} - Z_{M2}}{Z_{M1} + Z_{M2}} \quad [5]$$

$$\frac{u_{X(T)}}{u_{X(I)}} = \frac{T}{I} = \frac{2Z_{M1}}{Z_{M1} + Z_{M2}} \quad [6]$$

The reflection and transmission coefficients for the stresses are not the same as those for the displacements, essentially because of the phase difference between displacement and stress, but are:

$$\frac{\sigma_{XX(R)}}{\sigma_{XX(I)}} = \frac{Z_{M2} - Z_{M1}}{Z_{M1} + Z_{M2}} \quad [7]$$

$$\frac{\sigma_{XX(T)}}{\sigma_{XX(I)}} = \frac{-2Z_{M2}}{Z_{M1} + Z_{M2}} \quad [8]$$

Finally, the reflection and transmission can be expressed in terms of the energy in the waves, which is proportional to the product of the displacement and the stress, by:

$$\frac{\text{Energy}_{(R)}}{\text{Energy}_{(I)}} = \left(\frac{Z_{M2} - Z_{M1}}{Z_{M1} + Z_{M2}} \right)^2 \quad [9]$$

$$\frac{\text{Energy}_{(T)}}{\text{Energy}_{(I)}} = \frac{4Z_{M1}Z_{M2}}{(Z_{M1} + Z_{M2})^2} \quad [10]$$

These equations apply equally to the compression waves used in this derivation or to shear waves, provided that the materials are solids so that they can support shear waves.

In the special case of reflection from a free surface, when the second material is absent, the acoustic impedance Z_{M2} is zero. Then it can be seen from these equations that there is total reflection; that is to say, the amplitude of the reflection coefficient is unity and this is true whether one looks at displacement, stress, or energy. Also, the particle displacement at the boundary is twice the displacement of the incident wave; this is the sum of the displacements of the incident and reflected waves, which are in the same phase. However, the stress at the boundary is zero; this is again the sum of the stresses of the incident and reflected waves but now the phase differences lead to cancellation rather than addition. One other point worth mentioning in regard to this case is standing waves. In the steady state, when there is perfect reflection from the boundary and the reflected wave

is equal to the incident wave, there is no net transport of energy, and the resulting field in the material no longer shows the wave propagation characteristic of phase motion. Instead, the field is composed only of standing waves. The displacement field is then of the same form as the displacement mode shapes of a vibrating body; indeed, it is reflections such as this which initiate vibrations.

The acoustic impedance is clearly an important property, since it determines how much reflection and transmission takes place at an interface. Values of acoustic impedance for a few common materials are given in Table 1, and it is worth considering a couple of examples. If a sound wave in air is incident at a concrete wall then, according to eqns [9] and [10], 99.98% of the energy is reflected. If a sound wave in water is incident at an interface with steel, then 12% of the energy is transmitted into the steel (and only 88% is reflected).

Reflection and Transmission of Obliquely Incident Plane Waves

Consider the interface between two media once again, but this time with a wave which is obliquely incident at an angle θ_{IL} , as shown in Figure 2. The materials, M1 and M2, are both solids, and the incident wave is longitudinal. In general, now, the interaction of the incident wave results in two reflected waves, a longitudinal wave (RL) and a shear wave (RS). Similarly there are two transmitted waves, longitudinal (TL) and shear (TS). This would also happen if the incident wave was a shear wave. The angle of reflection of the longitudinal wave is the same as the angle of incidence, but all the other angles

Table 1 Example values of acoustic impedance for some common materials

Material name	Density (kg m^{-3})	Longitudinal velocity (m s^{-1})	Acoustic impedance (rayl)
Air	1.21	343	415
Aluminum	2700	6320	17×10^6
Concrete	2200	3900–4700	$8.6\text{--}10.3 \times 10^6$
Copper	8900	4700	42×10^6
Epoxy resin	1100–1250	2400–2900	$2.6\text{--}3.6 \times 10^6$
Glass	3600	4260	15×10^6
Perspex (acrylic resin)	1180	2730	3.2×10^6
Rubber (soft)	900	1480	1.3×10^6
Steel	7800	5960	46×10^6
Water	998.2	1478	1.48×10^6

depend on the material properties of M_1 and M_2 , according to Snell's law:

$$\frac{C_{L(M2)}}{\sin(\theta_{TL})} = \frac{C_{S(M2)}}{\sin(\theta_{TS})} = \frac{C_{S(M1)}}{\sin(\theta_{RS})} = \frac{C_{L(M1)}}{\sin(\theta_{IL})} \quad [11]$$

where each of the angles θ_{TL} , θ_{TS} , θ_{RS} is the angle which the wave defined by the respective subscript makes with the normal to the interface. Physically, this equation corresponds to the phase matching of the wave crests along the interface, as illustrated for two of the waves on the right-hand side of the figure.

If the bulk velocities of material M_2 are faster than those of material M_1 , then there are limiting angles for the transmission, known as the critical angles. Consider again the incident longitudinal wave and the two transmitted waves in Figure 2. The waves in material M_2 are indeed faster than those in material M_1 in this example because the angles of TL and TS are larger than the angle of IL . If the angle of IL is now increased, then the angle of TL approaches 90° when TL becomes parallel to the interface. At this particular angle, the angle of the incident wave IL is said to be the critical angle for longitudinal waves in medium M_2 . Similarly, there is a second (larger) critical angle for which the transmitted shear wave is parallel to the interface. At all angles larger than the critical angle, the transmitted wave travels parallel to the interface, and has a profile of exponential decay in the direction normal to the interface. This is illustrated in Figure 3 and is known as an inhomogeneous or evanescent wave. The depth of the decay decreases as the angle of the incident wave is increased. If both of the transmitted waves are eva-

nescient then in the steady state there is in fact no transmission of energy into medium M_2 so all of the energy which is incident at the interface is reflected. This is the same phenomenon which is known as total reflection in optics.

The calculation of the amplitudes of the reflected and transmitted waves follows the same approach as that which was taken for the normally incident waves; that is to say, displacement and stress boundary conditions must be satisfied. In this case, there are two displacements which must be continuous: the displacement normal to the interface and the displacement parallel to the interface. Similarly, there are two stress components which must be balanced: the stress normal to the interface and the shear stress in the plane of the figure (these are the two tractions at the interface). These four conditions are sufficient to calculate the four unknown amplitudes.

Two examples of the reflection and transmission coefficients for an obliquely incident wave follow. In the first example, medium M_1 is steel and medium M_2 is vacuum. Thus, the transmitted waves TL and TS are already known to be zero and the task is to find the amplitudes of the reflected waves RL and RS . Figure 4 shows these amplitudes vs the angle of incidence θ_{IL} . The amplitudes are expressed as reflection coefficients, that is, the ratio of the particle displacement in the reflected wave to that in the incident wave.

The second example takes medium M_1 to be water and medium M_2 to be steel. In this case the reflected shear wave is known to be zero (there is no shear wave in the fluid), and the task is to find the amplitude of the reflected longitudinal wave RL . Figure 5 shows this vs the angle of incidence θ_{IL} . Also identified on the plot are the two critical angles. The

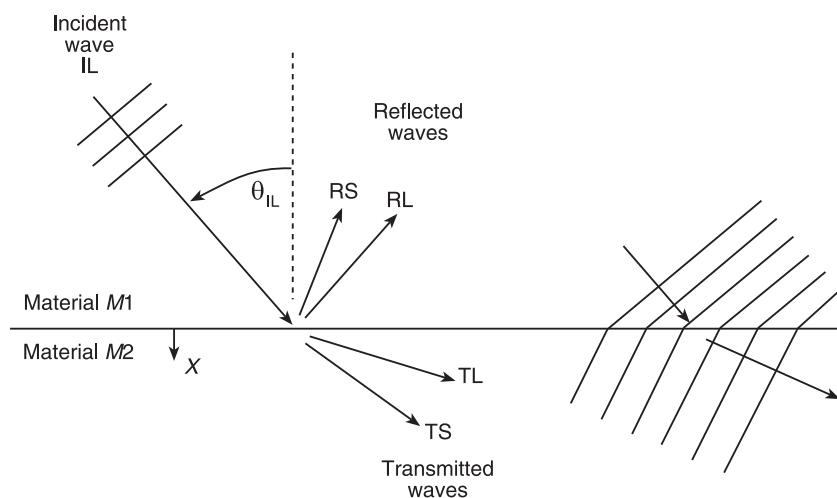

Figure 2 Reflection and transmission at an interface when a wave is incident at an oblique angle.

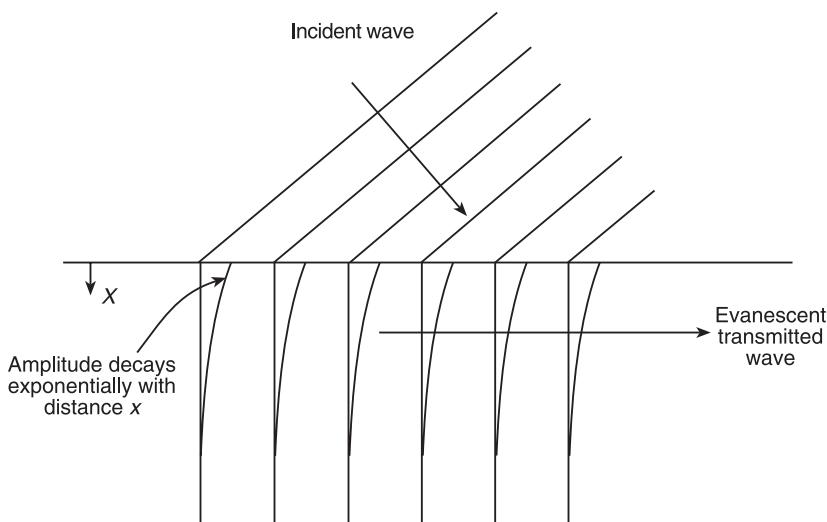

Figure 3 Evanescent waves generated at an interface between two materials when the angle of the incident wave is greater than

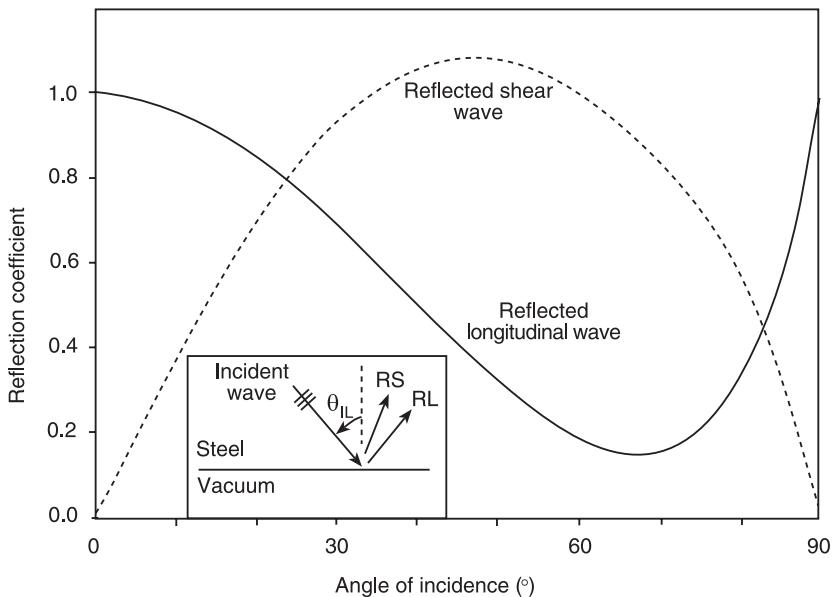

Figure 4 Reflection coefficients of longitudinal and shear waves from a free surface of steel when a longitudinal wave within the steel is incident at the surface at an oblique angle.

reflection coefficient can be seen to be unity at all angles greater than the shear critical angle.

Interaction of Waves with Discrete Structural Features

There are many circumstances where the concepts which have been explained here may be applied directly, such as the example already given of a sound wave incident at a solid wall. In geomechanics, the reflection and transmission of seismic waves

across boundaries between different strata may be studied with these relationships. In ultrasonic NDT, the need to consider reflection and transmission at flat boundaries is commonplace. For example, water is often used as a coupling medium because its impedance is so much higher than that of air, easing the task of getting sound into the structure. Then a transducer which is placed in the water emits ultrasound waves which travel through the water, then arrive at the flat surface of a structure, enter the structure, and finally reflect from any defects or perhaps other surfaces. The full signal which is

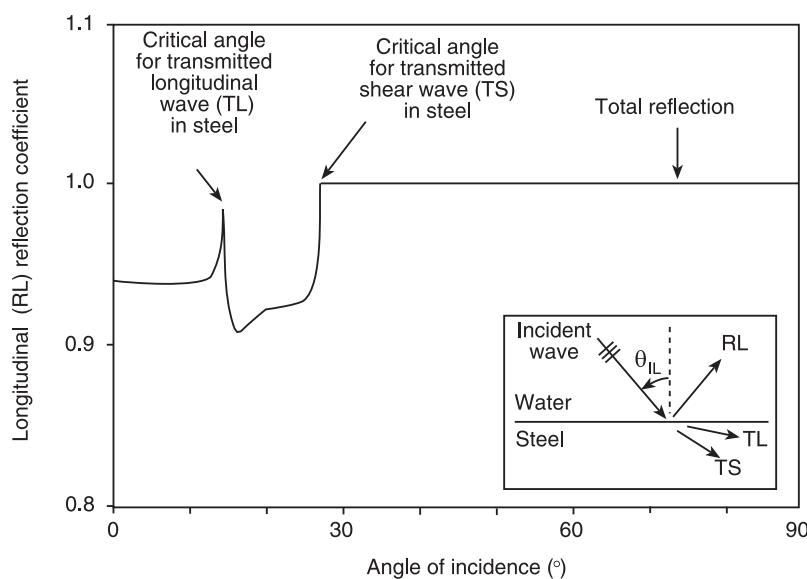

Figure 5 Reflection coefficient when a longitudinal wave in water is incident at an interface with steel.

reflected from the structure thus includes reflections from these various boundaries.

However there are also circumstances where it is necessary to understand the interaction of waves with bodies which are not flat but of arbitrary shapes, for example, the interaction of ultrasonic waves with discrete defects such as cracks, voids, or inclusions. This is a large and complex research topic, particularly the so-called inverse problem of determining the sizes and distributions of such features from the reflected signals. In fact, there are several regimes of scattering, associated with the scale of the interaction; specifically, the ratio of the wavelength of the sound to the characteristic dimension of the scatterer. As a very general rule, if the wavelength is much shorter than the dimension of the scatterer, then it is permissible to take a ray-tracing approach (Kirchoff approximation). In this, the incidence of a beam (or ray) of sound which arrives at the surface of the scatterer is treated using the plane reflection concepts explained above; if it arrives at an angle to the surface, it is reflected and transmitted according to those equations. The total reflection and transmission fields are then calculated as the sum of the actions of all of the rays. This approach is often taken when studying ultrasonic NDT, looking for cracks with high-frequency signals. In the other limit, when the wavelength is much larger than the characteristic size of the scatterer, these techniques are wholly inaccurate. For example, the scattering of a sound wave from a spherical inclusion in a solid, when the inclusion is significantly smaller than the wavelength, is understood much more realistically by studying the displacement

response of the whole inclusion to the presence of the passing stress field than by the ray approach. This is an issue, for example, when studying the scattering of ultrasound from materials containing small-scale porosity.

Nomenclature

C	wave speed
I	incident wave
k	wave number
R	reflected wave
T	transmitted wave
Z	product of density and wave speed
ρ	density

Waves in an Unbounded Medium

M J S Lowe, Imperial College of Science, Technology and Medicine, London, UK

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0140

Background

This entry introduces the propagation of elastic waves in an infinite expanse of a fluid or solid material. The nature and basic equations of elastic waves are explained, together with their relevance to other topics in vibration engineering.

Wave propagation differs from vibration fundamentally according to the structural boundary conditions. A structure which has no boundaries, that is to say, which is infinite in spatial extent, has no natural modes of vibration in the usual sense. It does, however, have the natural properties that waves with particular characteristics may propagate indefinitely in the material in the steady state. These waves in the unbounded space, often known as the bulk waves, depend on the properties of the material and are, indeed, precisely the elastodynamic modal properties of the medium. On the other hand, the natural properties of a body which has boundaries all around it are its modes of vibration; the steady-state solutions to its unforced equations of motion do not include wave propagation. However, as will be illustrated in the following discussion, the modes of wave propagation are closely linked to the natural modes of vibration: it is the creation of standing wave patterns of these wave modes which leads to vibrations.

The consideration of waves in an unbounded medium may appear at first to be rather abstract, since real structures always have boundaries. However, there are several good reasons for starting to look at wave theory from this viewpoint.

First, there are in fact very real circumstances in which the theory of waves in an infinite medium is directly useful. A good example is the propagation of sound waves in air. When someone speaks, the sound which travels through the air to the listener can be considered to be traveling through an infinite expanse of air. This is because the waves are not yet influenced by any boundaries, such as the walls of the room, as they travel through the open space; the boundaries

only become important when the waves arrive at them and are reflected or absorbed. A similar example is the propagation of ultrasonic waves in a solid material: after leaving the transducer and before arriving at a boundary of the material or a scattering feature, these waves may be considered to be traveling in an infinite volume of the solid material. Therefore, good use may be made of the theory of the properties of waves in an infinite medium in order to understand the characteristics of a wave while it is in transit between the source and the destination. These characteristics may include its speed, its frequency and wavelength, its intensity, or the rate at which it decays due to material damping or scattering phenomena (see **Nondestructive testing**, **Sonic**; **Nondestructive testing**, **Ultrasonic**; **Ultrasonics**).

A second reason for studying waves in an unbounded medium is that this provides a building block for the consideration of waves in more complicated structures when they reflect and reverberate within the boundaries of the body. Thus, although the wave fields which develop in the structure may be rather complicated, they can be understood by studying the properties of waves which could exist in an unbounded medium and then by examining how these interact with the boundaries. To make this concept more concrete, consider the initiation of vibration in a solid body when it is impacted, for example, by a hammer. The hammer blow sets up waves within the body which reflect internally from the boundaries, reverberate, and ultimately set up standing waves. As stated earlier, once a steady state has been reached, these standing waves define the natural vibration modes of the body. Thus it is possible to study the natural frequencies and mode shapes of the body by considering the characteristics of the unbounded waves together with the patterns of their reverberations which arise (see **Wave propagation**, **Interaction of waves with boundaries**).

Another closely related consideration is the study of more complicated wave propagation phenomena, such as waves which are guided by a structure. Well-known examples of these are the Rayleigh wave which propagates along the surface of a structure, such as the earthquake wave which is guided along the surface of the earth, and the Lamb waves which are guided along a plate. The common feature of these guided waves is that the structure is partially, but not completely, bounded. The plate has two surfaces but is considered to be infinite in the other directions – its length and width. There thus arise wave fields in which there is no propagation through the thickness of the plate but there is propagation along the plate; in other words, the behavior in the

through-thickness direction can be understood in the way in which one thinks about natural vibration, whereas the behavior along the plate is characteristic of the behavior of propagating waves. These wave fields may be considered as a superposition of several unbounded waves in proportions and phases such that the necessary conditions at the boundaries are satisfied (see **Wave propagation**, Guided waves in structures).

Theoretical Basis

Elastic waves are physically no different from seismic, sound, or ultrasound waves, other than in their respective ranges of frequencies. Sound waves conventionally cover the human audible range of frequencies (from about 50 Hz to 20 kHz), ultrasound waves cover frequencies above the audible range (from 20 kHz up to around 1 GHz may be encountered), and seismic waves exist at very low frequencies, significantly lower than the audible range. Therefore, the concepts which are presented here for elastic waves are equally applicable to these specific subject areas, and they differ only by the matter of scale.

The properties of elastic waves depend on the elastic properties of the material in which they propagate. This includes the number of different modes which can propagate and their velocities. Consider, to begin with, as is usually done in this subject, an infinitesimally small cube of the material. This will provide the basis for developing the equation of

motion and the wave equation as its solutions. This rather general starting point could be applied to all sorts of materials; in the following subsections, some specific solutions will be examined.

An infinitesimal cube of a material is shown in **Figure 1**. Its dimensions are δx , δy , δz in the Cartesian coordinate system XYZ with spatial location given by xyz. The material has density, ρ , and the analysis here is additionally limited to consideration of an isotropic material so that only two elastic constants are needed. These are defined by the Lamé constants, λ and μ , which are of course easily expressed as functions of Young's modulus and Poisson's ratio. The stresses acting on the cube are defined by the vector σ , some of which components are shown in the figure, and the displacements of the cube as the vector u .

Consideration of the stresses acting on the faces of the cube, and of the inertia of the cube, leads to the force differential equation of motion in its general form:

$$\rho \frac{\partial^2 \mathbf{u}}{\partial t^2} = (\lambda + \mu) \nabla(\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u} \quad [1]$$

where ∇ is the vector operator ($\partial / \partial X$, $\partial / \partial Y$, $\partial / \partial Z$) and ∇^2 is the scalar operator:

$$\left(\frac{\partial^2}{\partial X^2} + \frac{\partial^2}{\partial Y^2} + \frac{\partial^2}{\partial Z^2} \right)$$

Any permissible nontrivial solutions to this equation

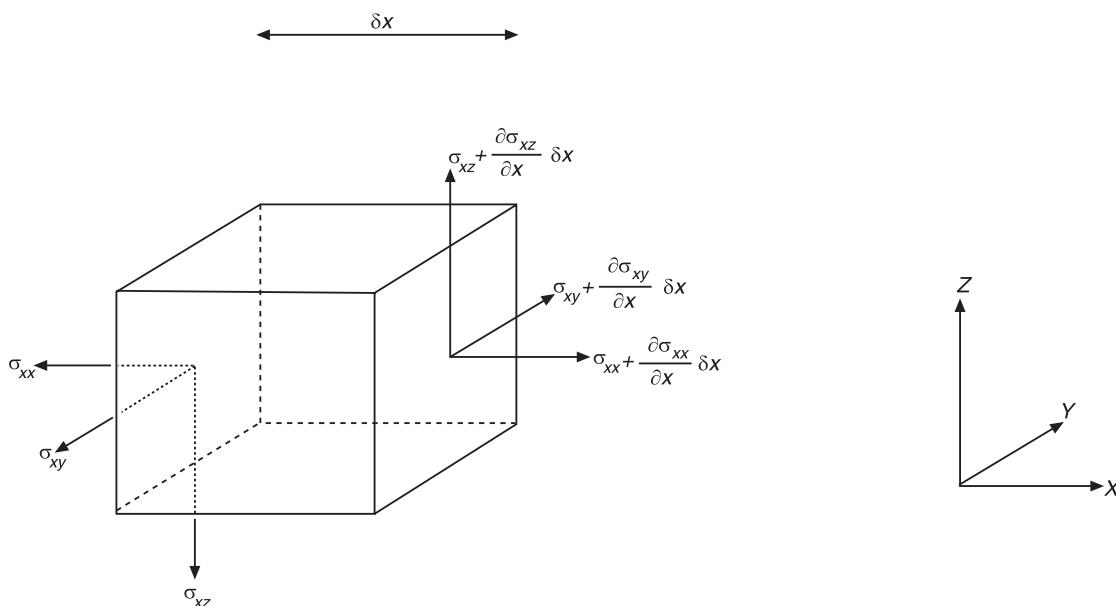

Figure 1 Infinitesimal cube, showing stresses on faces.

will define the motion of the waves in the material. Thus the material properties which affect the properties of the waves are the density, ρ , and the two elastic constants, λ and μ .

Plane Waves in a Perfect Inviscid Fluid or Gas

A perfect inviscid fluid or gas does not support shear stresses and so the Lamé constant μ is zero in this case, thus simplifying eqn [1]. Further simplification is achieved by considering solutions for plane waves in a chosen direction; since the medium is infinite, the direction which is taken for illustration is arbitrary. Taking the direction of travel of the wave to be the X direction, the plane wave assumption imposes the condition that there is no variation of the field in the Y or Z directions. A valid solution to eqn [1] is now given by:

$$u_X = Ae^{i(kx-\omega t)} \quad [2]$$

where A is an arbitrary constant and k is the wave-number, defined in the following expression:

$$C = \text{wavespeed} = \frac{\omega}{k} = \frac{\omega * \text{wavelength}}{2\pi} = \left(\frac{\lambda}{\rho}\right)^{1/2} \quad [3]$$

The pressure of the wave is given by:

$$\sigma_{XX} = i\omega C \rho u_X \quad [4]$$

Eqn [2] shows that the wave motion is defined by a function which is harmonic in both time and space. Thus the variation of the particle displacement u_X takes the form of a sine wave, whether observing the wave passing a particular location over a period of time, or observing a length of the wave train in space at a particular moment in time. Furthermore the wave

propagates without loss of amplitude. The wave speed is the phase speed, that is the speed of a crest of the harmonic function. Figure 2 shows the harmonic waveform which would be seen; in this case the axes are labeled to represent the spatial observation at a moment in time. Also shown on the figure, for illustration, is the same wave train a moment later in time. Eqn [4] shows that the pressure is represented by the same form of function but its phase differs by 90° from that of the particle displacement.

Another feature of the solution is that the particle motion of the wave is parallel to the direction of motion; there is neither strain nor displacement in either direction normal to the direction of motion. Therefore, physically, one can imagine the cube of material being compressed and dilated along the direction of the wave propagation; indeed, the Lamé constant, λ , is the compression stiffness of the fluid or gas when the sample is compressed on one axis and constrained on the other two. The wave thus exists as a propagating cycle of compression and dilation of the material.

Eqn [3] shows that the wave speed in the material is a constant for given values of the material properties and does not vary with frequency. Also, it can be seen that the wave speed is large if the stiffness is large and is small if the density is large. The wavelength is, of course, inversely proportional to the frequency.

Plane Waves in an Elastic Isotropic Solid

An elastic solid does support shear and so both of the Lamé constants must be retained in the solution for this case. Consider again solutions for plane waves which travel in the X direction. The plane wave assumption imposes the condition that there is no variation of the field in the Y or Z directions. However, particle motion in either of those directions

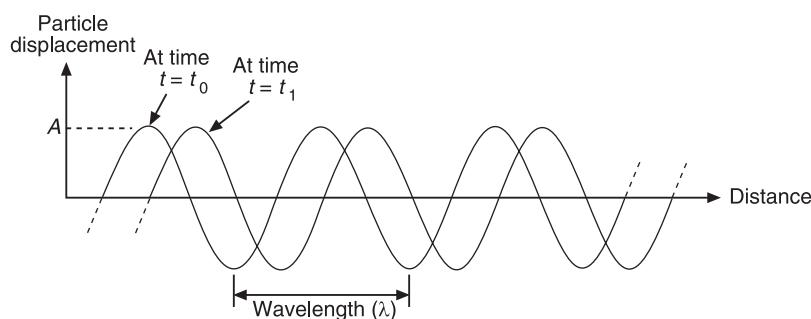

Figure 2 Harmonic motion of elastic wave, showing spatial variation of displacement at two moments in time.

would not violate that condition so long as it does not vary in that direction. Therefore, for this example, the possibility of particle motion in the Y direction will be allowed. There are now two possible solutions to eqn [1]:

$$u_X = Ae^{i(k_L x - \omega t)} \quad [5]$$

$$u_Y = Ae^{i(k_S x - \omega t)} \quad [6]$$

where K_L and K_S are wavenumbers, defined by:

$$\begin{aligned} C_L &= \text{longitudinal wave speed} = \frac{\omega}{k_L} \\ &= \left(\frac{\lambda + 2\mu}{\rho} \right)^{1/2} = \left[\frac{E(1-\nu)}{\rho(1+\nu)(1-2\nu)} \right]^{1/2} \end{aligned} \quad [7]$$

$$\begin{aligned} C_S &= \text{shear wave speed} = \frac{\omega}{k_S} = \left(\frac{\mu}{\rho} \right)^{1/2} \\ &= \left[\frac{E}{2\rho(1+\nu)} \right]^{1/2} \end{aligned} \quad [8]$$

in which for completeness the wave speeds are additionally given in terms of Young's modulus, E , and Poisson's ratio, ν .

Eqns [5] and (7) define the wave motion for the longitudinal wave (subscript L), sometimes known as the compression wave or P wave. As with the fluid wave, it can be seen that the particle motion is parallel to the direction of propagation and the material compresses and dilates as the wave propagates. In fact, the particle motion characteristics of the longitudinal wave are the same as those of the fluid wave; the difference is just in the form of the elastic constants which define the speed.

Eqns [6] and (8) define the shear wave (subscript S), sometimes known as the transverse wave or S wave, and this is somewhat different. In this case the displacement is in the Y direction, and so is normal to the direction of propagation. There is no displacement in the X or Z directions. Thus the material is deformed in a shearing motion as the wave propagates, and there is no change of its volume. Clearly, this introduces the need for another qualification when defining a shear motion because it is now necessary to define the polarization of the wave. In this particular example the shearing motion is defined by the XY plane (or by a polarization vector in the Z direction), but in general it could be in any plane in which the X -axis lies. The speed of the shear wave can be seen, according to the material constants in eqns [7] and

[8], to be lower than that of the longitudinal wave. In typical structural materials, the shear wave speed is a little over half of the longitudinal wave speed.

Waves in Absorbing Isotropic Materials

The discussion up until now has assumed an ideal homogeneous elastic material, in which there is no loss of energy from the propagating waves. In practice, these assumptions are often perfectly workable, for example in many structural materials such as steel, aluminum, or glass. However, there are mechanisms for loss of energy which can be significant and which should be taken into account.

If a material is not homogeneous, then waves propagating through it may lose energy through scattering. When incident at an inhomogeneity the waves may partially reflect, perhaps at an oblique angle, according to the shape of the inhomogeneity. The wave which continues along the original direction must then reduce in amplitude. Strictly speaking, the energy is not lost from the body but is partitioned from one wave into multiple waves. However, from the point of view of following the original wave, the interactions can be considered to be attenuative. Scattering occurs at inclusions of air or other materials within a body, at cracks, or at fibers or grain boundaries. It increases as the frequency is increased, being low when the wavelength is much larger than the scatterers and high when it is of comparable size or shorter. Scattering from fibres is an important consideration when ultrasonic nondestructive (NDT) techniques are applied to carbon fibre composites. Losses from the scattering (and also viscous losses; see next paragraph) typically limit the upper testing frequency to around 10 MHz. The scattering from grain boundaries in metals sets the upper limit for ultrasonic NDT of metal structures. Test frequencies in aluminum and carbon steel are typically limited to around 100 MHz (although this is not a precise figure because it depends on the distance of propagation which is required as well as the particular constitution of the metal), maximum test frequencies in stainless steel can be considerably lower. In practice these limits are rarely a concern; the majority of testing is in any case done at much lower frequencies, typically between 1 and 10 MHz. The ultrasonic testing of concrete illustrates well the problems of scattering: test frequencies are normally limited to around 50–100 kHz to avoid excessive scattering from the aggregate.

The other important mechanism of loss is absorption. This is effectively material damping through

phenomena such as hysteresis and viscoelasticity. In this case the energy is converted to heat in the material. The attenuation again increases with the frequency. All materials exhibit this effect to some extent but often the losses are not significant. The significance depends, of course, on the frequency of the wave and the distance of travel being considered. For practical ultrasonic testing in steel or aluminum at 1–10 MHz the damping is negligible. However, waves in plastic materials such as polyethylene suffer from quite considerable damping.

Attenuation is very often modeled by introducing an extra term, α , in the wave propagation eqn [2]:

$$u_X = Ae^{i(kx-\omega t)}e^{-\alpha x} \quad [9]$$

where the attenuation is included by the real exponential product in which α is the attenuation constant. This equation can also be rearranged to express the attenuation by an imaginary part to the wavenumber. Such a model has the benefit of simplicity, but it limits the attenuation such that the loss is a constant quantity per wavelength traveled. It happens that this is a workable assumption for the absorption losses in many typical structural materials at ultrasonic test frequencies. However, it is not representative of the

more complex loss mechanisms such as are encountered in the earlier scattering examples.

The Effects of Material Anisotropy

The study of elastic waves in anisotropic materials is a complex and specialist subject. However, it is important to mention it here briefly because it is a topic which appears in the literature and in some practical applications. In particular, there is increasing use of ultrasonic techniques to inspect or to measure the elastic properties of fiber composite structures. The anisotropy of granular metals or of crystal structures can also be significant. In brief, when the equation of motion [1] is derived using the anisotropic elastic constants, its solution differs in two principal regards with respect to the solutions for an isotropic material. First, there exists the possibility in general of three bulk waves, rather than two, and second, the velocity of each of these waves varies according to the direction of travel. These velocities, which are properties of the material, are therefore often presented in a graphical way. Figure 3 shows a typical representation of the properties of a unidirectional graphite epoxy. The slowness (inverse of the velocity) is plotted as a function of the angle for each of the three waves.

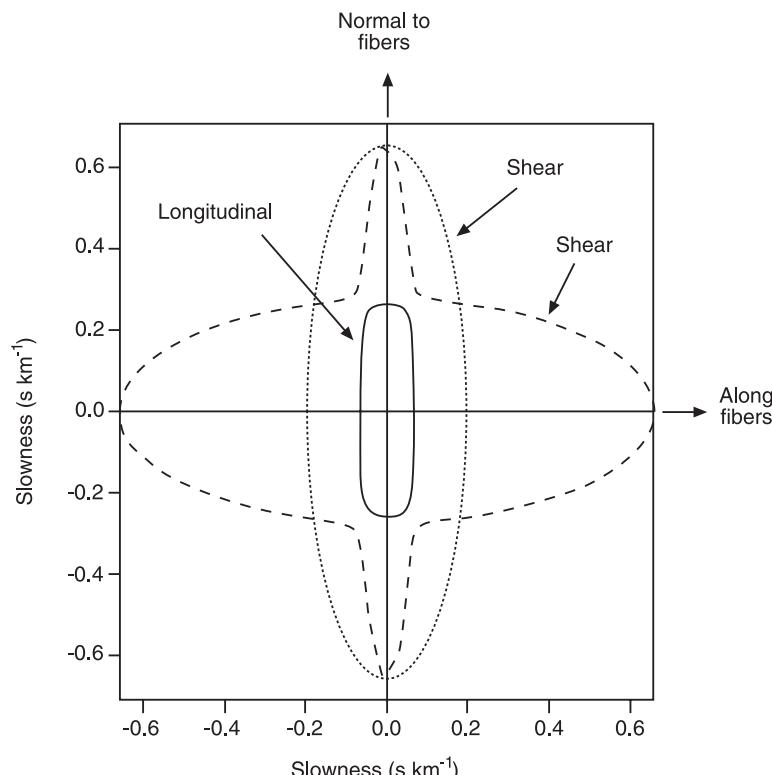

Figure 3 Slowness curves for bulk waves in a unidirectional graphite epoxy composite.

Cylindrical and Spherical Waves

Although it is convenient to consider waves to have plane wave fronts because it reduces any analysis to one dimension in Cartesian space, it should be recognized that this does not represent all practical wave phenomena. Waves which radiate from a point source (spherical waves) or from a line source (cylindrical waves) occur moderately often. Good examples are noise sources in acoustics or seismic sources in geomechanics. In practice, one may make the assumption that the waves are approximately plane when the distance from the source is much greater than the wavelength. However, this is not reasonable in the near field. Strictly, the wave equation must be derived in cylindrical or spherical coordinates, thereby modifying the wave propagation eqn [1]. Practically, this may not be necessary because, apart from in the immediate vicinity of the source, the resulting equation differs significantly from the plane wave equation only in the amplitude of the wave. From simple energy conservation considerations it is straightforward to show that the amplitude of the particle displacement must be inversely proportional to the radius for spherical waves and to the square root of the radius for cylindrical waves (the energy is proportional to the square of the particle displacement).

Nomenclature

A	arbitrary constant
E	Young's modulus

k	wavenumber
λ	Lané constant
μ	elastic constant
v	Poisson's ratio
ρ	density

WHOLE-BODY VIBRATION

M J Griffin, Institute of Sound and Vibration Research, The University of Southampton, Southampton, UK

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0082

Introduction

Whole-body vibration occurs when the human body is supported on a surface that is vibrating (e.g., sitting

on a seat, standing on a floor, or lying on a bed). Whole-body vibration occurs in transport (e.g., road, off-road, rail, air, and marine transport) and when near some machinery. Whole-body vibration affects human comfort, the performance of activities, and health.

The acceptability of vibration in many environments is determined by human responses to vibration. Vibration becomes annoying before it damages a building; the vibration in transport can cause dis-

comfort or interfere with activities when it does not damage the vehicle; the vibration of tools and machines produces injuries and disease without breaking the tool or machinery.

The responses of the body differ according to the direction of the motion (i.e., axes of vibration). The three principal directions of whole-body vibration for seated and standing persons are: fore-and-aft (x -axis), lateral (y -axis) and vertical (z -axis). The vibrations to which the body is exposed are measured at the interfaces between the body and the surfaces supporting the body (e.g., on the seat beneath the ischial tuberosities, at a backrest or at the feet for a seated person; beneath the feet for a standing person). Figure 1 illustrates the relevant translational and rotational axes for a seated person.

Biodynamics

The human body is a complex mechanical system which does not, in general, respond to vibration in the same manner as a rigid mass: there are relative motions between the body parts that vary with the frequency and the direction of the applied vibration. Although there are resonances in the body, it is oversimplistic to summarize the dynamic responses of the body by merely mentioning one or two resonance frequencies. The dynamics of the body affect all human responses to vibration, but the effects of vibration on discomfort, and the interference with activities and health cannot be predicted solely by considering the body as a mechanical system.

Transmissibility of the Human Body

The extent to which the vibration at an input to the body (e.g., the vertical vibration at a seat) is transmitted to a part of the body (e.g., vertical vibration at the head or the hand) is described by the transmissibility. At low frequencies of oscillation (e.g., below about 1 Hz), the vertical oscillations of a seat and the body parts are very similar and so the transmissibility is approximately unity. With increasing frequency of oscillation, the motions on the body increase above those measured at the seat and the transmissibility reaches a peak at one or more frequencies (i.e., resonance frequencies). At high frequencies the motion on the body is less than that at the seat.

The resonance frequencies, and the transmissibilities at resonance, vary according to the direction (i.e., axis) of vibration, vary according to where the vibration is measured on the body, and vary according to the posture of the body. There can be large differences between subjects. For seated persons, there may be resonances in transmissibilities measured to the head and the hand at frequencies in the range 4–12 Hz for

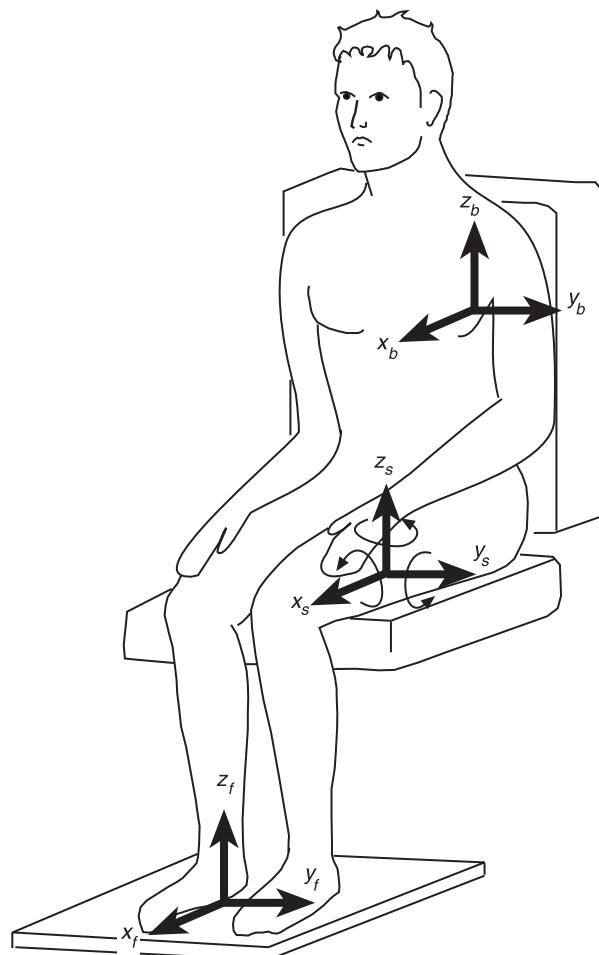

Figure 1 Axes of vibration used to measure exposures to whole-body vibration.

vertical vibration, below 4 Hz with fore-and-aft (i.e., x -axis) vibration and below 2 Hz with lateral (i.e., y -axis) vibration. The backrest of a seat can increase the transmission of x -axis vibration to the upper body and bending of the legs can affect the transmission of vertical vibration to the head of a standing person.

Mechanical Impedance of the Human Body

Mechanical impedance reflects the relation between the driving force at the input to the body and the resultant movement of the body. If the human body were rigid, the ratio of force to acceleration applied to the body would be constant and indicate the mass of the subject. Because the body is not rigid, the ratio of force to acceleration is only close to the body mass at very low frequencies (below about 2 Hz with vertical vibration; below about 1 Hz with horizontal vibration).

Measures of mechanical impedance show a principal resonance for vertical vibration of seated subjects at about 5 Hz, and sometimes a second resonance in

the range 7–12 Hz. The large difference in impedance between that of a rigid mass and that of the human body means that the body cannot usually be represented by a rigid mass when measuring the vibration transmitted through seats (see below). The mechanical impedance of the body is generally nonlinear: the resonance frequency reduces when the vibration magnitude increases.

Biodynamic Models

A simple model with one or two degrees-of-freedom can represent the point mechanical impedance of the body and a dummy can be constructed to represent this impedance for seat testing. The transmissibility of the body is affected by many more variables and requires a more complex model reflecting the posture of the body and the translation and rotation associated with the various modes of vibration.

Vibration Discomfort

The relative discomfort caused by different vibrations can be predicted from suitable measurements and an appropriate evaluation of the vibration. Limits to prevent vibration discomfort vary between environments (e.g., between buildings and transport) and between types of transport (e.g., between cars and trucks) and within types of vehicle (e.g., between sports cars and limousines). The design limit depends on external factors (e.g., cost and speed) and the comfort in alternative environments (e.g., competitive vehicles).

Effects of Vibration Magnitude

As an approximate guide, the threshold for perception of vertical whole-body vibration in the frequency range 1–100 Hz is approximately 0.01 ms^{-2} r.m.s., while 0.1 ms^{-2} is easily noticeable, 1.0 ms^{-2} r.m.s. is uncomfortable and 10 ms^{-2} r.m.s. is potentially dangerous. The precise values depend on vibration frequency and exposure duration and differ for other axes of vibration.

Doubling the vibration magnitude (when expressed in ms^{-2}) produces an approximate doubling of the sensation of discomfort. Halving the vibration magnitude can therefore produce a considerable improvement in comfort. For some types of whole-body vibration, differences in vibration magnitude greater than about 10% may be detectable.

Effects of Vibration Frequency and Direction

The extent to which vibration causes effects on the body at different frequencies is reflected in frequency weightings: frequencies capable of causing the greatest

effect are given the greatest weight and others are attenuated in accord with their decreased importance. Two different frequency weightings (one for vertical and one for horizontal vibration of seated or standing persons) were presented in International Standard 2631 (1974, 1985) and reproduced in other standards. Although International Standard 2631 was revised in 1997 to use different methods, the revision is difficult to comprehend. One reasonable interpretation is that it is broadly similar to British Standard 6841 (1987), and so this standard will be explained here.

Frequency weightings W_b to W_f , as defined in British Standard 6841 (1987), are shown in Figure 2 as they may be implemented by analog or digital filters (International Standard 2631 (1997) defines similar weightings and also an additional weighting, W_k , which might be used as an alternative to W_b). Table 1 defines simple asymptotic (i.e. straight-line) approximations to these weightings. Table 2 shows how the weightings should be applied to the 12 axes of vibration illustrated in Figure 1 and multiplying factors for each axis. (The weightings W_g and W_f are not required to predict vibration discomfort: W_g is similar to the weighting for vertical vibration in the old ISO 2631 (1974, 1985); W_f is used to predict motion sickness caused by vertical oscillation.)

The r.m.s. value of the weighted acceleration (i.e., after frequency weighting and after being multiplied by the multiplying factor) is sometimes called a component ride value. Vibration occurring in several axes is more uncomfortable than vibration occurring in a single axis. In order to obtain an overall ride

Table 1 Asymptotic approximations to frequency weightings, $W(f)$, in BS 6841 (1987) for comfort, health, activities, and motion sickness

	Weighting name	Weighting definition
W_b	$0.5 < f < 2.0$	$W(f) = 0.4$
	$2.0 < f < 5.0$	$W(f) = f/5.0$
	$5.0 < f < 16.0$	$W(f) = 1.00$
	$16.0 < f < 80.0$	$W(f) = 16.0/f$
W_c	$0.5 < f < 8.0$	$W(f) = 1.0$
	$8.0 < f < 80.0$	$W(f) = 8.0/f$
W_d	$0.5 < f < 2.0$	$W(f) = 1.00$
	$2.0 < f < 80.0$	$W(f) = 2.0/f$
W_e	$0.5 < f < 1.0$	$W(f) = 1.00$
	$1.0 < f < 20.0$	$W(f) = 1.00/f$
W_f	$0.100 < f < 0.125$	$W(f) = f/0.125$
	$0.125 < f < 0.250$	$W(f) = 1.0$
	$0.250 < f < 0.500$	$W(f) = (0.25/f)^2$
W_g	$1.0 < f < 4.0$	$W(f) = (f/4)^{1/2}$
	$4.0 < f < 8.0$	$W(f) = 1.00$
	$8.0 < f < 80.0$	$W(f) = 8.0/f$

f , frequency in, Hz; $W(f)$, 0 where not defined.

Table 2 Application of frequency weightings for the evaluation of vibration with respect to discomfort

Input position	Axis	Frequency weighting	Axis multiplying factor
Seat	x_s	W_d	1.0
	y_s	W_d	1.0
	z_s	W_b	1.0
	r_x (roll)	W_e	0.63
	r_y (pitch)	W_e	0.40
	r_z (yaw)	W_e	0.20
Seat back	x_b	W_c	0.80
	y_b	W_d	0.50
	z_b	W_d	0.40
Feet	x_f	W_b	0.25
	y_f	W_b	0.25
	z_f	W_b	0.40

value, the root-sums-of-squares of the component ride values is calculated:

$$\text{overall ride value} = (\sum (\text{component ride values})^2)^{1/2}$$

Overall ride values from different environments can be compared; a vehicle having the highest overall ride value would be expected to be the most uncomfortable with respect to vibration.

Effects of Vibration Duration

Vibration discomfort tends to increase with increasing duration of exposure to vibration. The rate of increase may depend on many factors but a simple fourth-power time dependency is used to approximate how discomfort varies with duration of exposure from the shortest possible shock to a full day of

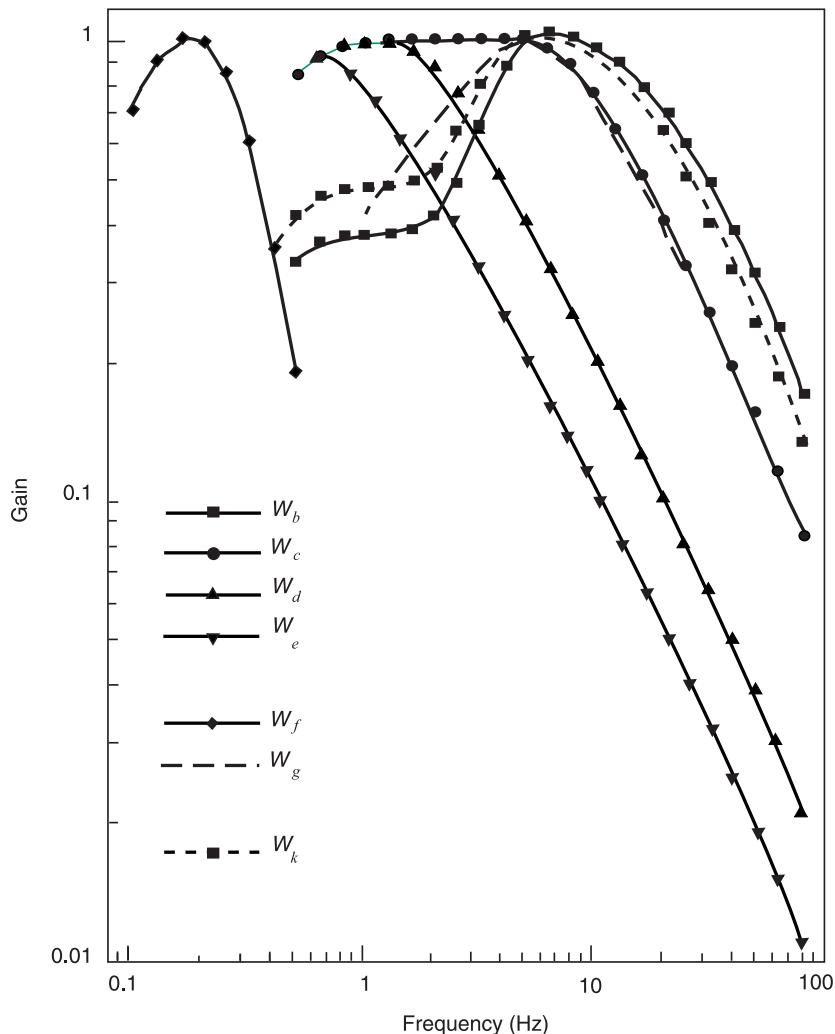

Figure 2 Acceleration frequency weightings for whole-body vibration and motion sickness (as defined in British Standard 6841, 1987 and ISO 2631, 1997).

vibration exposure (i.e., $(\text{acceleration})^4 \times \text{duration} = \text{constant}$; see below).

Interference with Activities

Whole-body vibration can influence input processes (especially vision) and output processes (especially continuous hand control). In both cases there may be a disturbance occurring entirely outside the body (e.g., vibration of a display or vibration of a hand-held control), a disturbance at the input or output (e.g., movement of the eye or hand), and a disturbance within the body affecting the peripheral nervous system (i.e., afferent or efferent system). Central processes (e.g., learning, memory, decision making) may also be affected by vibration but understanding is currently too limited to make confident generalized statements.

Effects of vibration on vision and manual control are most usually caused by the movement of the affected part of the body (i.e., eye or hand). The effects may be decreased by reducing the transmission of vibration to the eye or to the hand, or by making the task less susceptible to disturbance (e.g., increasing the size of a display or reducing the sensitivity of a control). Consequently, the effects of vibration on vision and manual control can often be reduced by redesigning the task. The effects of vibration on task performance are therefore highly task-specific and generalized vibration limits are not useful.

Effects of Vibration on Vision

When an observer sits or stands on a vibrating surface, the effects of vibration on vision depend on the extent to which the vibration is transmitted to the head and eyes. The motions most affecting vision may be the vertical and pitch movements of the head. The pitch motion of the head is compensated by the vestibulocular reflex which serves to stabilize the line of sight of the eyes at frequencies below about 10 Hz. The effects of translational motion of the head depend on viewing distance: the effects are greatest when close to a display. Consequently, the greatest problems with vibration occur with pitch head motion when the display is attached to the head (e.g., a virtual reality display) and with translational head motion when viewing near displays not fixed to the head.

When an observer and a display oscillate together in phase at low frequencies (below about 5 Hz), the retinal image motions (and decrements in visual performance) are less than when either the observer or the display oscillate separately. The advantage is lost as the vibration frequency is increased since there is then an increasing phase difference between the motion of the head and the motion of the display.

The absolute threshold for the visual detection of the vibration of an object by a stationary observer occurs when the peak-to-peak oscillatory motion gives an angular displacement at the eye of approximately 1 min arc. The acceleration required to achieve this threshold can be low at low frequencies but increases in proportion to the square of the frequency to become very high at high frequencies. If the vibration displacement is above the visual detection threshold there may be perceptible blur; the effects of vibration on visual performance (e.g., effects on reading speed and reading accuracy) may then be estimated from the maximum time that the image spends over some small area of the retina (e.g., the period of time spent near the nodes of the motion with sinusoidal vibration). For sinusoidal vibration this time decreases (and so reading errors increase) in linear proportion to the frequency of vibration and in proportion to the square root of the displacement of vibration. With dual-axis vibration (e.g., combined vertical and lateral vibration of a display) this time is greatly reduced and so reading performance is worse than with single-axis vibration. With narrow-band random vibration there is a greater probability of low image velocity than with sinusoidal vibration of the same magnitude and predominant frequency, so reading performance tends to be less affected by random vibration than by sinusoidal vibration.

Manual Control

The mechanical jostling of the hand caused by vibration produces unwanted movement of a control. The gain (i.e., sensitivity) of a control determines the control output. The optimum gain in static conditions (high enough not to cause fatigue but low enough to prevent inadvertent movement) is greater than the optimum gain during exposure to vibration when inadvertent movement is more likely.

Some control errors may increase in linear proportion to vibration magnitude. There is no simple relation between the frequency of vibration and its effects on control performance: the effects of frequency depend on the control order (which varies between tasks) and the biodynamic responses of the body (which vary with posture and between operators). With zero-order tasks and the same magnitude of acceleration at each frequency, the effects of vertical seat vibration may be greatest in the range 3–8 Hz since transmissibility to the shoulders is greatest in this range. In the horizontal axes (i.e., the x- and y-axes of the seated body) the greatest effects appear to occur at lower frequencies: around 2 Hz or below.

The effects of vertical whole-body vibration on spilling liquid from a hand-held cup tend to be great-

est at 4 Hz and the effects of vibration on writing speed and subjective estimates of writing difficulty are most affected by vertical vibration in the range 4–8 Hz. Vibration may affect the performance of tracking tasks by reducing the visual performance of the operator. Collimating a display by means of a lens so that it appears to be at infinity can reduce, or even eliminate, errors with some tasks.

Cognitive Performance

Simple cognitive tasks (e.g., simple reaction time) appear to be unaffected by vibration, other than by changes in arousal or motivation or by direct effects on input and output processes. This may also be true for some complex cognitive tasks. However, the scarcity and diversity of experimental studies allow the possibility of real and significant cognitive effects of vibration.

Health Effects

It is believed that disorders of the back (back pain, displacement of intervertebral discs, degeneration of spinal vertebrae, and osteoarthritis) may be associated with vibration exposure. There may be several alternative causes of an increase in disorders of the back among persons exposed to vibration (e.g., poor sitting posture, heavy lifting). It is not always possible to conclude confidently that a back disorder, or any other complaint, is solely, or primarily, caused by whole-body vibration.

Methods of Vibration Evaluation and Assessment

The manner in which the health effects of oscillatory motions depend upon the frequency, direction, and duration of motion is currently assumed to be similar to that for vibration discomfort (see above). However, it is assumed that the total exposure, rather than the average exposure, is important and so a dose measure is used.

National and international standards British Standard 6841 (1987) defines an action level for vertical vibration based on vibration dose values. The vibration dose value uses a fourth-power time dependency to accumulate vibration severity over the exposure period from the shortest possible shock to a full day of vibration:

$$\text{vibration dose value} = \left[\int_{t=0}^{t=T} a^4(t) dt \right]^{1/4}$$

where $a(t)$ is the frequency-weighted acceleration. If the exposure duration (t , s) and the frequency-

weighted r.m.s. acceleration (a_{rms} , ms^{-2} r.m.s.) are known for conditions in which the vibration characteristics are statistically stationary, it can be useful to calculate the estimated vibration dose value or eVDV:

$$\text{estimated vibration dose value} = 1.4a_{\text{rms}} t^{1/4}$$

The eVDV is not applicable to transients, shocks, and repeated shock motions in which the crest factor (peak value divided by the r.m.s. value) is high.

No precise limit can be offered to prevent disorders caused by whole-body vibration, but standards define useful methods of quantifying vibration severity. British Standard 6841 (1987) offers the following guidance:

High vibration dose values will cause severe discomfort, pain and injury. Vibration dose values also indicate, in a general way, the severity of the vibration exposures which caused them. However there is currently no consensus of opinion on the precise relation between vibration dose values and the risk of injury. It is known that vibration magnitudes and durations which produce vibration dose values in the region of $15 \text{ ms}^{-1.75}$ will usually cause severe discomfort. It is reasonable to assume that increased exposure to vibration will be accompanied by increased risk of injury.

An action level might be set higher or lower than $15 \text{ ms}^{-1.75}$. Figure 3 compares this action level with exposure limits suggested in the old version of ISO 2631 (1974, 1985).

In International Standard 2631 (1997) two different methods of evaluating vibration severity with respect to health effects are defined, and for both methods there are two boundaries. When evaluating vibration using the vibration dose value, it is suggested that below a boundary corresponding to a vibration dose value of $8.5 \text{ ms}^{-1.75}$ ‘health risks have not been objectively observed’ between 8.5 and $17 \text{ ms}^{-1.75}$ ‘caution with respect to health risks is indicated’ and above $17 \text{ ms}^{-1.75}$ ‘health risks are likely’. The two boundaries define a VDV health guidance caution zone. The alternative method of evaluation uses a time dependency in which the acceptable vibration does not vary with duration between 1 and 10 min and then decreases in inverse proportion to the square root of duration from 10 min to 24 h. This method suggests an r.m.s. health guidance caution zone, but the method is not fully defined in the text, it allows very high accelerations at short durations, it conflicts dramatically with the

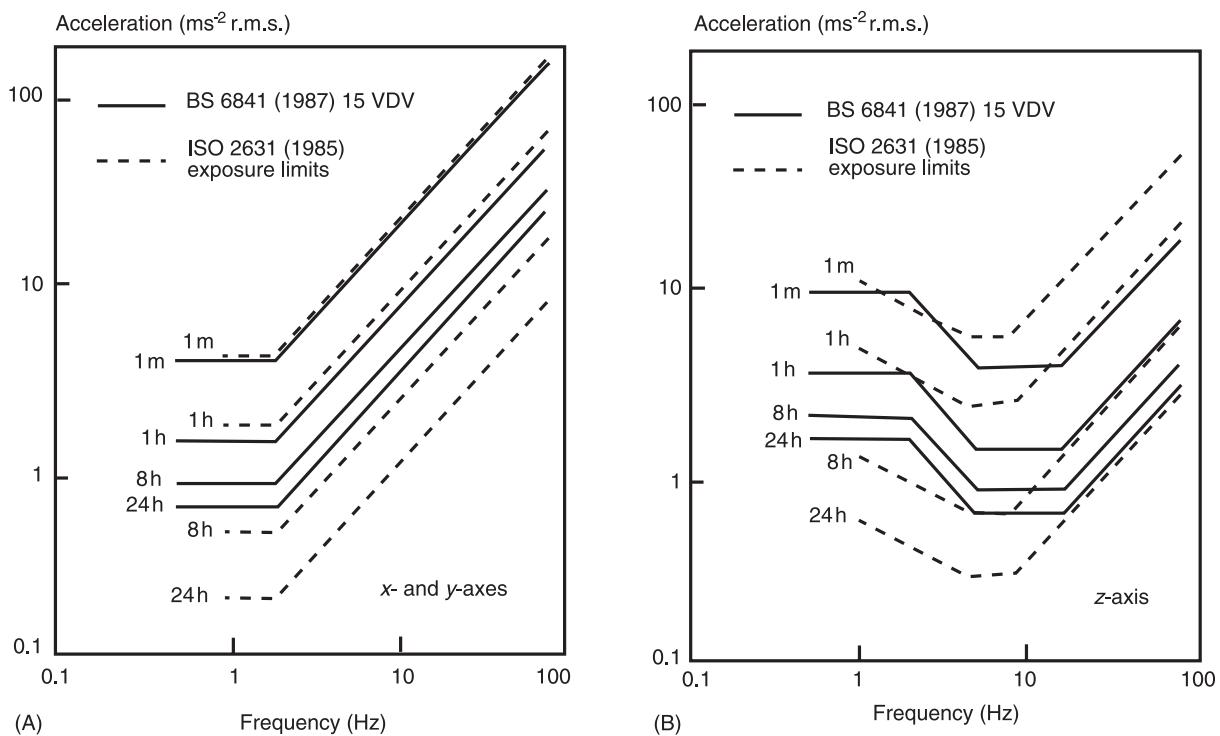

Figure 3 (A, B) Comparison of International Standard 2631 (1985) exposure limits with an action level based on a vibration dose value (VDV) of $15 \text{ ms}^{-1.75}$ from British Standard 6841 (1987). When seated: x-axis = fore-and-aft; y-axis = lateral; z-axis = vertical. (Reproduced with permission from Griffin, 1990).

vibration dose method, and it cannot be extended to durations below 1 min.

With severe vibration exposures, prior consideration of the fitness of the exposed persons and the design of adequate safety precautions may be required. The need for regular checks on the health of routinely exposed persons may also be considered.

Figure 4 illustrates the VDV health guidance caution zone, the root-mean-square health guidance caution zone, and the accelerations corresponding to the $15.0 \text{ ms}^{-1.75}$ action level for exposure durations between 1 s and 24 h. Any exposure to continuous vibration, intermittent vibration, or repeated shock may be compared with either the action level or the VDV health guidance caution zone by calculating the vibration dose value. It would be unwise to exceed the appropriate action level without considering the possible health effects of an exposure to vibration or shock.

EU Machinery Safety Directive The Machinery Safety Directive of the European Community (89/392/EEC) states: 'machinery must be so designed and constructed that risks resulting from vibrations produced by the machinery are reduced to the lowest level, taking account of technical progress and the availability of means of reducing vibration, in parti-

cular at source'. Instruction handbooks for machinery causing whole-body vibration should specify the frequency-weighted acceleration if it exceeds a stated value (currently a frequency-weighted acceleration of 0.5 ms^{-2} r.m.s.). Standardized test procedures are being prepared but the values currently quoted may not always be representative of the operating conditions in the work for which the machinery is used.

Proposed EU Physical Agents Directive The opening principles of a proposed Council Directive on the minimum health and safety requirements regarding hand-transmitted vibration are: 'Taking account of technical progress and of the availability of measures to control the physical agent at source, the risks arising from exposure to the physical agent must be reduced to the lowest achievable level, with the aim of reducing exposure to below the threshold level ...'.

A proposed EU Directive has been drafted based on 8-h energy-equivalent acceleration magnitudes (called A(8) values). The proposed Directive identifies a threshold level ($A(8) = 0.25 \text{ ms}^{-2}$ r.m.s.), an action level ($A(8) = 0.5 \text{ ms}^{-2}$ r.m.s.), and an exposure limit value ($A(8) = 0.7 \text{ ms}^{-2}$ r.m.s.). When exposures exceed the threshold level it is proposed that workers must receive information concerning the potential

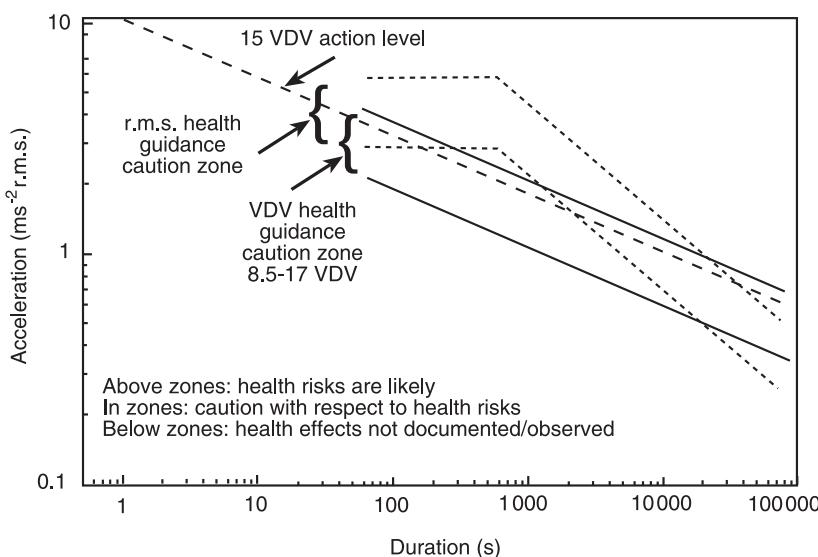

Figure 4 Action level corresponding to a vibration dose value (VDV) of $15\text{ ms}^{-1.75}$ (see British Standard 6841, 1987) compared with r.m.s. and VDV health guidance caution zones suggested in ISO 2631 (1997).

risk of exposure to whole-body vibration. The action level is intended to identify the conditions in which training in precautionary measures is required, an assessment of the vibration is to be made, and a program of preventive measures is to be instituted. The proposed Directive also indicates that when the action level is exceeded workers shall have the right to regular health surveillance, including routine examinations designed for the early detection of disorders caused by whole-body vibration. If the exposure limit value is exceeded, health surveillance must be carried out and member states of the Community will be expected to control the harmful effects. This draft is not consistent with current standards and may be expected to be modified prior to finalization.

Seating Dynamics

Seating dynamics influence the vibration responsible for discomfort, interference with activities, and injury. Most seats exhibit a resonance at low frequencies which results in higher magnitudes of vertical vibration occurring on the seat than on the floor. At high frequencies there is usually attenuation of vibration.

Seat transmissibility may be measured on laboratory simulators with volunteer subjects, but precautions are required to protect subjects from injury. Measurements may also be performed with drivers or passengers in vehicles. Anthropodynamic dummies are being developed to represent the average mechanical impedance of the human body so that laboratory and field studies can be performed without exposing people to vibration. Seat transmissibility may also be predicted using measurements of the impedance of a

seat and the known mechanical impedance of the human body.

The suitability of a seat for a specific vibration environment depends on: (1) the vibration spectra present in the environment, (2) the transmissibility of the seat; and (3) the sensitivity of the human body to the different frequencies of vibration. These three functions of frequency are contained within a simple numerical indication of the isolation efficiency of a seat called the seat effective amplitude transmissibility or SEAT. In concept, the SEAT value compares the vibration severity on a seat with the vibration severity on the floor beneath the seat:

$$\text{SEAT (\%)} = \frac{\text{ride comfort on seat}}{\text{ride comfort on floor}} \times 100$$

A SEAT value greater than 100% indicates that, overall, the vibration on the seat is worse than the vibration on the floor beneath the seat; SEAT values below 100% indicate that the seat has provided some useful attenuation. The optimization of seating dynamics may be both the cheapest and the most effective method of improving vehicle ride and reducing any associated hazard.

The SEAT value may be calculated from either the frequency-weighted r.m.s. values (if the vibration does not contain transients) or the vibration dose values of the frequency-weighted acceleration on the seat and the floor:

$$\text{SEAT (\%)} = \frac{\text{vibration dose value on seat}}{\text{vibration dose value on floor}} \times 100$$

Conventional seating (comprising some combination of foam, rubber, or metal springing) usually has a resonance at about 4 Hz and therefore provides no attenuation at frequencies below about 6 Hz. Attenuation can be provided at frequencies above about 2 or 3 Hz using a separate suspension mechanism beneath the seat pan (i.e., sometimes called a suspension seat).

Disturbance in buildings

Acceptable magnitudes of vibration in some buildings are close to vibration perception thresholds. The acceptability of vibration in buildings depends on the use of the building in addition to the vibration frequency, direction, and duration. Using the guidance contained in ISO 2631 part 2 (1989) it is possible to summarize the acceptability of vibration in different types of building in a single table of vibration dose values (**Table 3**). The vibration dose values in **Table 3** are applicable irrespective of whether the vibration occurs as a continuous vibration, intermittent vibration, or repeated shocks.

doi:10.1006/rwvb.2001.0155

Introduction

As modern structures move toward taller and more flexible designs, the problems of wind effects on structures – those compromising structural integrity

and those inducing human discomfort – have become increasingly apparent. To fully address this problem, a diverse collection of contributions must be considered, as illustrated in **Figure 1**. It is the complexity and uncertainty of the wind field and its interaction with structures that necessitates such an interdisciplinary approach, involving scientific fields such as meteorology, fluid dynamics, statistical theory of turbulence, structural dynamics, and probabilistic methods. The following sections will describe the contributions from each of these areas, beginning with a description of the wind field characteristics and the resulting wind loads on structures. Subsequent sections will then address procedures for determining wind-induced response, including traditional random vibration theory and code-based approximations, with an example to illustrate the application of both approaches. The treatment of wind effects on structures will conclude with a discussion of aeroelastic effects, wind tunnel testing, and the evolving numerical approaches.

Wind Characteristics

Civil engineering structures are immersed in the earth's atmospheric boundary layer, which is characterized by the earth's topographic features, e.g., surface roughness. The most common description of the wind velocity within this boundary layer superimposes a mean wind component, described by a mean velocity profile, with a fluctuating velocity component. The vertical variation of the mean wind

velocity, \bar{U} , can be represented by a logarithmic relationship, or by a power law given as:

$$\bar{U}(z) = \bar{U}_{\text{ref}} \left(\frac{z}{z_{\text{ref}}} \right)^{\alpha} \quad [1]$$

where z_{ref} is the reference height, \bar{U}_{ref} is the mean reference velocity, and α is a constant that varies with the roughness of the terrain, with specific values defined in fundamental texts.

The fluctuating wind field is characterized by temporal averages, variances of velocity components, probabilities of exceedance, energy spectra, associated length scales, and space-time correlations. One important measure is the total energy of the wind fluctuations, expressed as the standard deviation of the velocity fluctuations normalized by the mean wind velocity, and referred to as turbulence intensity. The energy spectra describe the distribution of energy at each frequency, whereas the space-time correlation describes the degree to which velocity fluctuations are correlated in space and/or time. A measure of the average size of turbulent eddies, the length scale, can be then estimated by integrating velocity cross-correlation functions.

Wind Loads on Structures

Just as the most elementary description of the velocity of the oncoming wind field superimposes a mean component, $\bar{U}(z)$, increasing with height according

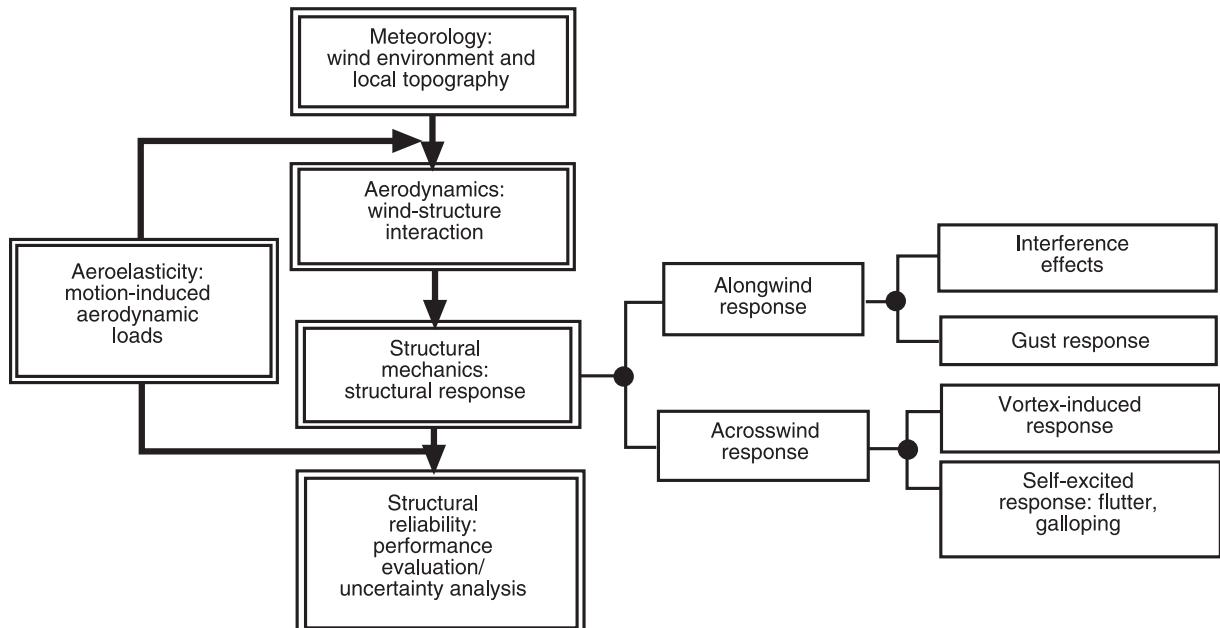

Figure 1 Overview of scheme to determine wind effects on structures.

to the power law given in eqn [1], with a randomly fluctuating component, $u(z, t)$, the oncoming wind will impose loads on the structure that vary both spatially and temporally. The fluctuating wind velocity translates directly into fluctuating positive pressures ($p_w(z, t)$) distributed across the building's windward face, as shown in Figure 2. Corresponding negative pressures, $p_l(z, t)$, result on the leeward face of the structure.

Upon impacting the windward face, the wind is then deflected around the structure and accelerated such that it cannot negotiate the sharp corners and thus separates from the building, leaving a region of high negative pressure, also shown in Figure 2. This separated flow forms a shear layer on each side, and subsequent interaction between the layers results in the formation of discrete vortices, which are shed alternately. This region is generally known as the wake region.

The three-dimensional simultaneous loading of the structure due to its interaction with the wind results in three structural response components, illustrated in Figure 2. The first, termed the alongwind component, primarily results from pressure fluctuations in the approach flow, leading to a swaying of the structure in the direction of the wind. The acrosswind component constitutes a swaying motion perpendicular to the direction of the wind and is introduced by side-face pressure fluctuations primarily induced by the fluctuations in the separated shear layers, vortex shedding and wake flow fields. The final torsional component results from imbalances in the instantaneous pressure distribution on the building surfaces. These wind load effects are further amplified on asymmetric buildings as a consequence of inertial coupling in the building's structural system.

As the wind pressures vary spatially over the face of the structure, there is the potential for regions of high localized pressures, of particular concern for the design of cladding systems; however, it is their collective effect that results in the integral loads used for the design of the structural system, which will be of primary interest in this discussion.

Since the alongwind motion primarily results from the fluctuations in the approach flow, its load effects have been successfully estimated using quasi-steady and strip theories, which imply that the fluctuating pressure field is linearly related to the fluctuating velocity field at any level on the building. Although the alongwind response may also include interference effects due to the buffeting of the structure by the wake of upstream obstacles, it is the gust response due to the oncoming wind that is primarily considered. Thus, the aerodynamic loads, $F(t)$, considering only this component, are expressed in terms of velocity fluctuations as:

$$F(t) = \frac{1}{2} \rho A C_D (\bar{U} + u(t))^2 \approx \frac{1}{2} \rho A C_D \bar{U}^2 + \rho A C_D \bar{U} u(t) \quad [2]$$

in which ρ = air density, A = projected area of the structure loaded by the wind, and C_D = drag coefficient. This expression is approximated by ignoring the generally small term containing the square of the fluctuating velocity.

The preceding expression implicitly assumes that the velocity fluctuations approaching a structure are fully correlated over the entirety of the structure and these are transformed linearly to force fluctuations. This assumption may be valid for very small structures, but fails to hold for structures with larger spatial dimensions and leads to overestimation of

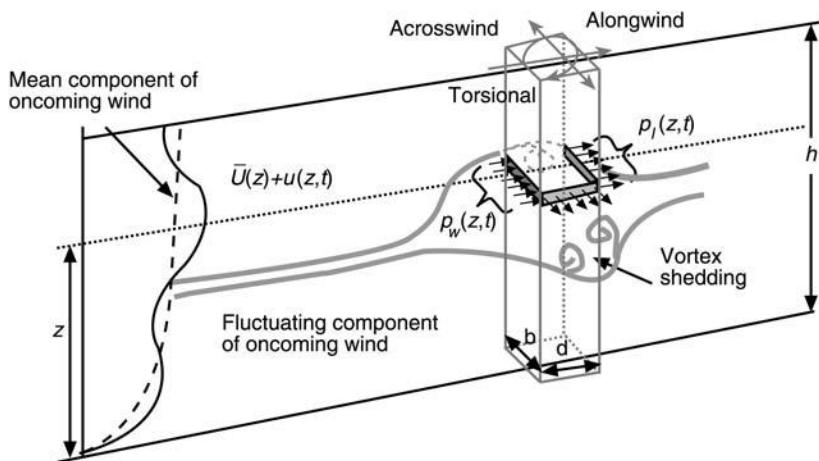

Figure 2 Description of oncoming wind field and resulting wind-induced effects on structure.

loads. In this case, the effect of imperfect correlation of wind fluctuations is conveniently introduced through an aerodynamic admittance function. As this loading scenario is described relatively easily in the frequency domain, eqn [2] is accordingly transformed and the aerodynamic admittance, $\chi^2(f)$, is introduced:

$$S_F(f) = (\rho C_D)^2 \chi^2(f) S_u(f) \quad [3]$$

where $S_F(f)$, $S_u(f)$ = power spectral density (PSD) of wind loads and wind fluctuations, respectively. Ideally, $\chi^2(f)$ not only represents the lack of correlation in the approach flow, but it also captures any departure from quasi-steady theory that may result from complex nonlinear interactions between the fluctuating wind and the structure. The transformation of wind velocity fluctuations to wind force fluctuations is illustrated in the frequency domain in Figure 3. For simple rectangular plates and prisms, both experimental and theoretical information concerning $\chi^2(f)$ is available. For typical buildings that are aerodynamically bluff, one needs to resort to wind tunnel tests to directly obtain the PSD of the aerodynamic force. Alternatively, one can invoke the strip and quasi-steady theories with an appropriate correlation structure of the approaching flow field to estimate $\chi^2(f)$ and hence $S_F(f)$; however, this may introduce some uncertainty in the estimates, as this approach may not fully capture all the features of the wind-structure interactions.

The approach described above has served as a building block for the 'gust loading factor' used in most building codes. However, the acrosswind and torsional responses cannot be treated in terms of these gust factors inasmuch as they are induced by the unsteady wake fluctuations, which cannot be conveniently expressed in terms of the incident turbulence. As a result, experimentally derived loading functions have been introduced. Accordingly, the acrosswind and torsional load spectra obtained by synthesizing

the surface pressure fields on scale models of typical building shapes are available in the literature. In a recent study, scale models of a variety of basic building configurations, with a range of aspect ratios, were exposed to simulated urban and suburban wind fields to obtain mode-generalized loads.

Wind-induced Response: Theory

In order to derive the structural response from aerodynamic loads, basic random vibration theory is utilized. The equations of motion of a structure represented by a discretized lumped-mass system are given by:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{F}(t) \quad [4]$$

in which \mathbf{M} , \mathbf{C} , and \mathbf{K} are the assembled mass, damping and stiffness matrices of the discretized system, respectively, \mathbf{x} is the displacement, and $\dot{\mathbf{x}}$ and $\ddot{\mathbf{x}}$ are the first two time derivatives of \mathbf{x} , representing velocity and acceleration, respectively. In general, these equations are derived to provide two translations and one rotation per story level; however, for the sake of illustration, it is assumed here that the structure is uncoupled in each direction. By employing the standard transformation of coordinates, the following modal representation is obtained for one of the translation directions:

$$\ddot{q}_j + 2\zeta_j(\omega_n)_j \dot{q}_j + (\omega_n)_j^2 q_j = P_j(t) \quad [5]$$

in which $P_j(t) = [\phi_j]^T \mathbf{F}(t)$ where $[\cdot]^T$ denotes transpose, ϕ_j , ζ_j and $(\omega_n)_j = 2\pi(f_n)_j$ are the j th mode shape, modal critical damping ratio and natural frequency, respectively, and q and its derivatives now represent modal response quantities related to x and its derivatives, respectively, by $x(t) = [\phi_j]q_j(t)$. The PSD of response, $S_{q_j}^{(r)}$ is given by:

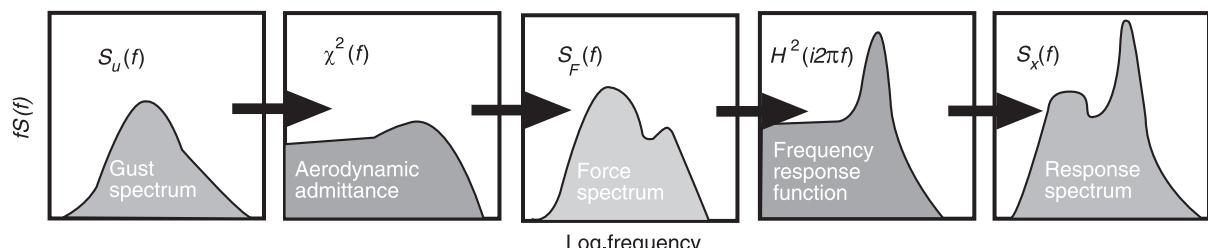

Figure 3 Procedure for determination of response spectrum.

$$Sg_j^{(r)}(f) = \left| H_{j(r)}^2(i2\pi f) \right| S_{P_j}(f)$$

[6] The peak factor $g^{(r)}$ varies between 3.5 and 4 and is given by:

$$S_{P_j}(f) = [\phi_j]^T S_F(f) \phi_j \quad [7]$$

in which $|H_{j(r)}^2(i2\pi f)|$ is the j th-mode frequency response function (FRF). The superscript r indicates the derivative of response, i.e., $r = 0, 1, 2, 3$ denotes displacement, velocity, acceleration and jerk. Determination of wind-induced response by this approach is summarized in Figure 3.

The root mean square (RMS) value of response in physical coordinates, $\sigma_{x^{(r)}}^2$, is then given by the weighted superposition of all N modal contributions:

$$\begin{aligned} \sigma_{x^{(r)}}^2 &= \sum_{j=1}^N \frac{\phi_j^2 \pi(f_n)_j S_{P_j}(f_n)_j (2\pi(f_n)_j)^{2r}}{4(2\pi(f_n)_j)^4 \zeta_j m_j^2} \\ &\quad + \sum_{j=1}^N \frac{\phi_j^2 \int_0^{(f_n)_j} S_{P_j}(f) df (2\pi(f_n)_j)^{2r}}{(2\pi(f_n)_j)^4 m_j^2} \end{aligned} \quad [8]$$

where m_j is the j th modal mass, $m_j = [\phi_j]^T \mathbf{M}$, and the first term of eqn [8] represents the resonant component, and the second term, the background component. The preceding equation is an approximation of the area under the response PSD, which is very close to exact for most lightly damped structures.

Wind-induced Response: Codes and Standards

International codes and standards have simplified the random vibration-based response analysis described in the previous section through the use of simplified algebraic expressions and the statistically derived gust effect factor, which accounts for the gustiness of the wind by providing equivalent static loads. Both time and spatial averaging play an important role in the development of gust factors, as does the site terrain, structure size, and dynamic characteristics.

Through the use of random vibration theory, the dynamic amplification of loading or response, represented by the gust effect factor, can be readily defined. For example, the expected peak response $y_{\max}^{(r)}$ can be estimated from the RMS value $\sigma_{y^{(r)}}$ and mean value $\bar{y}^{(r)}$ by the following expression, based on the probabilistic description of peak response during an interval T :

$$y_{\max}^{(r)} = \bar{y}^{(r)} + g^{(r)} \sigma_{y^{(r)}} \quad [9]$$

$$g = \frac{\sqrt{(2 \ln((f_n)_1 T)) + 0.5772}}{\sqrt{(2 \ln((f_n)_1 T))}} \quad [10]$$

The gust effect factor (GEF) G is then defined as the ratio of the maximum expected response to the mean response:

$$G = \frac{y_{\max}^{(r)}}{\bar{y}^{(r)}} = 1 + g^{(r)} \frac{\sigma_{y^{(r)}}}{\bar{y}^{(r)}} \quad [11]$$

The RMS response represents the area under the power spectral density of $y^{(r)}$, which can be described in terms of a background component Q , representing the response due to quasi-steady effects, and a resonant contribution R to account for dynamic amplification. To simplify the determination of these terms, international standards provide a series of simplified algebraic expressions. Typically G is defined in terms of the displacement response:

$$G = 1 + 2g_{y^{(0)}} I_H \sqrt{(Q + R)} \quad [12]$$

where I_H = turbulence intensity at the top of the structure. Q and R , respectively, represent the contributions of the background and resonant components approximated in eqn [8].

Most major codes and standards around the world account for the dynamic effects of wind in terms of the equivalent static loads F_{eq} through the use of the GEF:

$$F_{eq}(z) = G C_{fx} \bar{q}(z) A \quad [13]$$

where the mean wind pressure is $\bar{q} = \frac{1}{2} \rho \bar{U}^2$ and C_{fx} = the mean alongwind aerodynamic force coefficient. Each international standard uniquely defines G based on the form in eqn [12]. For example, in the ASCE 7-98 Standard the gust factor is defined as:

$$G = 0.925 \left(\frac{1 + 1.7I_{\bar{z}} \sqrt{(g_Q^2 Q^2 + g_R^2 R^2)}}{1 + 1.7g_v I_{\bar{z}}} \right) \quad [14]$$

where three peak factors are defined: g_Q and g_v are taken as 3.4 for simplicity and g_R is determined from eqn [10] with $T = 3600$ s, and $I_{\bar{z}}$ is the turbulence intensity at the equivalent height of the structure, \bar{z} , is determined by a code-specified expression.

The background and resonant response components are similarly defined by approximate expressions:

$$Q^2 = \frac{1}{1 + 0.63 \left(\frac{b+h}{L_{\bar{z}}} \right)^{0.63}} \quad [15]$$

$$R^2 = \frac{1}{\beta} R_n R_h R_b (0.53 + 0.47 R_L) \quad [16]$$

where b and h are the width and height, respectively, of the structure, shown in Figure 2, and $L_{\bar{z}}$ is the integral length scale of turbulence at the equivalent height. The resonant component involves four factors (R_n , R_h , R_b , R_L) which are dependent upon the first mode natural frequency, defined as n_1 in ASCE 7-98, and the damping ratio, defined in the standard as β , as well as the dimensions of the structure, the mean wind speed at the equivalent height, $\bar{V}_{\bar{z}}$, and the wind field's characteristics. Expressions for these terms may be found in ASCE 7-98.

Following the determination of the gust effect factor, the maximum alongwind displacement X_{\max} and RMS accelerations $\sigma_{\ddot{x}}$ may be calculated directly:

$$X_{\max}(z) = \frac{\phi(z) \rho b h C_{fx} \hat{V}_{\bar{z}}^2}{2m_1 (2\pi n_1)^2} KG \quad [17]$$

$$\sigma_{\ddot{x}}(z) = \frac{0.85 \phi(z) \rho b h C_{fx} \bar{V}_{\bar{z}}^2}{m_1} I_z KR \quad [18]$$

where $\hat{V}_{\bar{z}}$ is the 3-s gust at the equivalent height, $\phi(z)$ is assumed to be the fundamental mode shape, m_1 is the first mode mass and K is a coefficient representative of the terms resulting from the integration of the mode shape and wind profile in the determination of the RMS response. Expressions for these terms are also provided in ASCE 7-98. Note that, in the case of the acceleration response, background effects are not considered, thus the GEF is not directly used as defined in eqn [14]. Instead it is replaced with a collection of terms analogous to using a GEF with only a resonant component.

Example of Wind-induced Response

To illustrate the determination of wind-induced response by both random vibration theory and by the code-based procedure, the following example is provided. Table 1 lists the assumed properties of the structure, which is located in a city center. The basic wind speed, measured as a 3-s gust, at the reference height of 33 ft (10 m) in open terrain, is taken as 90 mph (40.23 ms⁻¹). For the sake of brevity, only

acceleration response will be provided, considering only the first mode with an assumed linear mode shape. To further simplify the analysis, the response will only be calculated at the structure's full height, at which point the mode shape given in Table 1 would equal unity.

The RMS accelerations in the alongwind direction were first determined in accordance with ASCE 7-98, by eqn [18], with all calculated parameters listed in Table 2. Unfortunately, as discussed previously, acrosswind and torsional responses cannot be determined by the same analytical procedure and are thus omitted from the ASCE 7 Standard. However, these response components, as well as the alongwind response, can readily be determined by eqn [8] with the aid of the wind tunnel data provided in Figure 4. Note that it is common practice to plot these load spectra in a nondimensional form, S^* , as defined in Figure 4, where \bar{U}_H is the mean wind velocity at the height of the building, in urban terrain. A power law

^a Spectral values in nondimensional form (see Figure 4).

^b $S_{Mz}^*(n_1)$ should be multiplied by a correlation factor of 0.7042.

relationship (eqn [1]) can be used to translate the reference wind velocity of 90 mph (40.23 m s^{-1}) from open terrain at 33 ft (10 m) to urban terrain at the building height.

In the case of acceleration response, $r = 2$ and $N = 1$ in eqn [8], as only first mode contributions are considered. Note also that in eqn [8], m_j is defined as the modal mass for the alongwind and acrosswind directions, taken as the total mass of the building, divided by three; however, for the torsional response, this modal mass term must be replaced by the first mode mass moment of inertia determined by: $(1/12)m_1(b^2 + d^2)$, where d is the depth of the structure as shown in Figure 2. In addition, the torsional analysis requires the multiplication of the spectral density by a reduction factor to account for the assumption of a constant mode shape inherent in force-balance experimental measurements.

Examining first the properties in Table 2, a comparison of R^2 and Q^2 reveals that this particular structure receives nearly equal contributions from the background and resonant components. For the alongwind response, shown in Table 3, the simplified response estimate given by ASCE 7-98 compares well with the wind tunnel data. Also note that the acrosswind accelerations are twice that of the alongwind response, illustrating that acrosswind response components have a greater role in determining the habitability performance of a structure. On the other hand, the structure's torsional response is slightly less than the alongwind, which should be no surprise considering that the structure has no geometric or structural asymmetries and that the loading data from the wind tunnel was obtained using an isolated building model.

Aeroelastic Effects

The determination of wind-induced loads and response discussed previously did not account for aeroelastic effects, which can sometimes have significant contributions to the structural response. Response deformations can alter the aerodynamic forces, thus setting up an interaction between the elastic response and aerodynamic forces commonly referred to as aeroelasticity. Aeroelastic contributions to the overall aerodynamic loading are distinguished from other unsteady loads by recognizing that aeroelastic loads vanish when there is no structural motion. Different types of aeroelastic effects are commonly distinguished from each other. They include vortex-induced vibration, galloping, flutter, and aerodynamic damping.

As alluded to earlier, aerodynamically bluff cross-sections shed vortices at a frequency governed by the nondimensional Strouhal number, St :

$$St = \frac{f_s b}{U} \quad [19]$$

where f_s is the shedding frequency (in Hz). The shedding of vortices generates a periodic variation in the pressure over the surface of the structure. When the frequency of this variation approaches one of the natural frequencies of a structure, vortex-induced vibration can occur. The magnitudes of these vibrations are governed both by the structure's inherent damping characteristics and by the mass ratio between the structure and the fluid it displaces. These two effects are often combined in the Scruton number defined as:

$$Sc = \frac{4\pi\zeta m}{\rho b^2} \quad [20]$$

where m is the mass per unit length of the structure.

Vortex-induced vibration is more complex than a mere resonant forcing problem. Nonlinear interaction between the body motion and its wake results in the 'locking in' of the wake to the body's oscillation frequency over a larger velocity range than would be predicted using the Strouhal number. Vortex-induced

vibration, therefore, occurs over a range of velocities that increases as the structural damping decreases.

Galloping occurs for structures of certain cross-sections at frequencies below those of vortex-induced vibration. One widely known example of galloping is the large acrosswind amplitudes exhibited by power lines when freezing rain has resulted in a change of their cross-section. Analytically, galloping is considered a ‘quasisteady’ phenomenon because knowledge of the static aerodynamic coefficients of a given structure (i.e., mean lift and drag forces on a stationary model) allows quite reliable prediction of galloping behavior.

Stability of aeroelastic interactions is of crucial importance. The attenuation of structural oscillations by both structural and aerodynamic damping characterizes stable flow-structure interactions. In an unstable scenario, the motion-induced loading is further reinforced by the body motion, possibly leading to catastrophic failure. Such unstable interactions involve extraction of energy from the fluid flow such that aerodynamic effects cancel structural damping. Flutter is the term given to this unstable situation, which is a common design issue for long-span bridges.

Depending on the phase of the force with respect to the motion, self-excited forces can be associated with the displacement, the velocity, or the acceleration of the structure. Because of these associations, these forces can be thought of as ‘aerodynamic contributions’ to stiffness, damping, and mass, respectively. In addition to stiffness and damping, aeroelastic effects can couple modes that are not coupled structurally. Whenever the combined aeroelastic action on various modes results in negative damping for a given mode, flutter occurs. By means of structural dynamics considerations and aerodynamic tailoring, flutter must be avoided for the wind velocity range of interest. Even without resulting in flutter, aeroelastic effects can have a significant effect on response.

Wind Tunnel Testing

Despite the obvious advances of computational capabilities over the years, the complexity of the bluff body fluid-structure interaction problems concerning civil engineering structures has precluded numerical solutions for the flow around structures. Thus, wind tunnels remain, at this juncture, the most effective means of estimating wind effects on structures. However, it should be noted that not all structures require wind tunnel testing. For many conventional structures, for example, low-rise buildings, code-based estimates may well suffice. Wind tunnel testing may be necessary, however, when dealing with a novel design or a design for which dynamic and aeroelastic

effects are difficult to anticipate. Examples of such structures include, but are not limited to, long-span bridges and tall buildings.

Wind tunnel testing of a given structure first involves appropriate modeling of the wind environment, necessitating various scaling considerations. Geometric scaling is based on the boundary layer height, the scale of turbulence, and the scale of the surface roughness all constrained by the size of the wind tunnel itself. Ideally, these lengths should hold to the same scaling ratio – a performance that can be approached when the boundary layer is simulated over a long fetch with scaled floor roughness. Dynamic scaling requires Reynolds number equality between the wind tunnel and the prototype. Without extraordinary measures, this is most often not possible and must be kept in mind when interpreting results. Velocity scaling is most often obtained from elastic forces of the structure and inertial forces of the flow. Kinematic scaling involves appropriate distributions of the mean velocity and turbulence intensity and can be achieved with flow manipulation in the wind tunnel.

Both active and passive means are available to generate turbulent boundary layers. While active devices such as air jets, flapping vanes and airfoils are capable of generating a wide range of turbulence parameters, passive devices are cheaper and more efficient to implement. Passive devices include spires, fences, grids, and floor roughness. Depending on the length and cross-sectional size of the tunnel, surrounding terrain may also be modeled.

Once an appropriate incident flow has been generated, there are several options for obtaining aerodynamic load data for the structure of interest. Pressure measurements can be performed on the surface of a model, forces can be quantified from the base of a lightweight, rigid model, or forces can be obtained from an aeroelastic model of the structure. Pressure measurements are capable of quantifying localized loading on a structure’s surface. Issues such as fatigue loads for cladding panels and panel anchor and glass failure require such localized analysis.

Integrated loads on a structure are often estimated with high-frequency base balances. These devices are generally integrated into a rotating section of the floor of a wind tunnel. A lightweight model of the structure is mounted on the balance for measuring wind loads over a range of incidence angles. The low mass of the model is necessary to ensure that the natural frequency of the model-balance system is well above any expected wind forcing frequency. A primary advantage of this approach is that modal force spectra are obtained directly and can be used in subsequent analytical estimations of building response. As long as the structural geometry does

not change, the forces can be used to analyze the effects of internal structural design changes without the need for further wind tunnel tests.

Aeroelastic models allow interaction between structural motion and aerodynamic forces. Such models can be constructed as continuous or discrete models. Continuous models require specialized materials having structural properties matching those of the prototype. Discrete models are simpler to implement and consist of an internal spine to account for structural dynamic feature, with an external cladding that maintains proper geometric scaling with the prototype. Dynamic response of both buildings and bridges can be estimated utilizing such models.

Numerical Methods

With the evolution of computer capabilities, numerical methods have presented another option for the analysis of fluid-structure interactions. A host of simulation schemes to generate wind fields and the associated response, in a probabilistic framework, are currently available. However, these schemes rely on quasisteady formulations to transform wind fluctuations into load fluctuations. A welcome departure from the limitations of such approaches is offered by the field of computational fluid dynamics (CFD), serving as a promising alternative to wind tunnel testing. One of the more attractive approaches within this area involves the solution of the Navier-Stokes equations in the large eddy simulation (LES) framework to simulate pressure fields around structures that convincingly reproduce the experimentally measured pressure distributions in both the mean and RMS, as well as replicating the aerodynamic forces and flow re-attachment features. Coupled with computer-aided flow visualization, which provides visual animation, this numerical simulation may serve as a useful tool to analyze the evolution of flow fields around structures and estimate the attendant loads. This approach definitely has merit, and as computational capacity increases, these schemes will eventually become the methods of choice.

Nomenclature

<i>A</i>	projected area of building exposed to wind
<i>b</i>	width of structure
<i>C</i>	structural damping matrix
<i>C_{fx}</i>	alongwind aerodynamic force coefficient
<i>C_D</i>	drag coefficient
<i>d</i>	depth of structure
<i>f</i>	frequency
<i>f_n</i>	natural frequency in Hertz

<i>f_s</i>	vortex shedding frequency in Hertz
<i>F</i>	force (or load), in physical coordinates
<i>F_{eq}</i>	equivalent static load
<i>g</i>	peak factor
<i>G</i>	gust effect factor
<i>h</i>	height of structure
<i>H</i>	frequency response function
<i>I_H</i>	turbulence intensity at top of structure
<i>I_{z̄}</i>	turbulence intensity at equivalent height
<i>j</i>	subscript denoting modal index
<i>K</i>	integration constant (ASCE 7-98)
<i>K</i>	structural stiffness matrix
<i>L_{z̄}</i>	integral length scale of turbulence at equivalent height
<i>M</i>	structural mass matrix
<i>m</i>	structural mass per unit height
<i>m_j</i>	<i>j</i> th modal mass
<i>n₁</i>	fundamental natural frequency (ASCE 7-98)
<i>N</i>	total number of modal components
<i>P</i>	force (or load), in modal coordinates
<i>p_l</i>	wind pressure on leeward face of building
<i>p_w</i>	wind pressure on windward face of building
<i>Q</i>	background component
<i>q̄</i>	mean wind pressure
<i>q</i>	modal displacement
<i>q̄</i>	modal velocity
<i>q̄̄</i>	modal acceleration
<i>r</i>	superscript denoting derivative order
<i>R</i>	resonant component
<i>R_{nn}, R_{bb}, R_b, R_L</i>	terms for approximation of resonant component (ASCE 7-98)
<i>Sc</i>	Scruton number
<i>S_F</i>	power spectral density of wind loads, in physical coordinates
<i>S_P</i>	power spectral density of wind loads, in modal coordinates
<i>S_q</i>	power spectral density of response, in modal coordinates
<i>St</i>	Strouhal number
<i>S_u</i>	power spectral density of wind fluctuations
<i>S[*]</i>	nondimensionalized load spectra
<i>t</i>	time
<i>T</i>	time interval
<i>u</i>	longitudinal velocity fluctuations
<i>U</i>	mean wind velocity
<i>U_{ref}</i>	mean wind velocity at reference height
<i>U_H</i>	wind velocity at building height
<i>V̄_{z̄}</i>	mean wind velocity at equivalent height
<i>V̄̄_{z̄}</i>	3-s gust at equivalent height
<i>x̄</i>	structural displacement, in physical coordinates

\dot{x}	structural velocity, in physical coordinates
\ddot{x}	structural acceleration, in physical coordinates
X_{\max}	maximum alongwind displacement (ASCE 7-98)
\bar{y}	mean response
y_{\max}	expected peak response
z	vertical position
\bar{z}	equivalent height
z_{ref}	reference height
$[]^T$	transpose operator
α	power law exponent
β	critical damping ratio (ASCE 7-98)
ρ	air density
ρ_b	building density
σ	root mean square
ϕ	mode shape
χ^2	aerodynamic admittance function
ω_n	natural frequency in rad s ⁻¹
ζ	critical damping ratio

doi:10.1006/rwvb.2001.0052

General

Signal patterns are often investigated in the dual domains of time and frequency. Windows are functions multiplying the signal functions resulting in improved analysis results. While multiplying window functions exist for both the time and frequency domain signal functions, this entry will only deal with the first type. Given a time signal $x(t)$, a window $w(t)$ is applied as follows, resulting in the modified signal $x'(t)$:

$$x'(t) = w(t)x(t) \quad [1a]$$

The window $w(t)$, and hence $x'(t)$, are time limited, even if $x(t)$ is a continuous power signal. An equivalent windowing operation can be performed in the frequency domain, by applying a Fourier transform (FT) to eqn [1a]. This results in the convolution:

$$X'(\omega) = W(\omega) \otimes X(\omega) \quad [1b]$$

The use of these windows usually occurs in one of the following applications:

- Spectral analysis – reduction of leakage
- Spectral analysis – rotating machines, reduction of effect of speed fluctuation
- Spectral analysis – smoothing of spectral estimates
- Spectral analysis – overlapped processing
- Impulse testing – improvement of signal to noise ratio
- Digital filter design – the so-called ‘window’ method

Control of Leakage Error in Spectral Analysis

(see **Spectral analysis, classical methods**)

Leakage

Leakage is an error noticeable in the frequency description of signals: power (or energy) appears in frequency regions outside those where the actual physical phenomena occur. In the analysis, power has ‘leaked’ to neighboring regions. While leakage can occur in general cases of signals, it is the easiest to demonstrate for the specific case of harmonic signals.

Measurements are taken in a finite time. Analyzing via the discrete Fourier transform (DFT) imposes periodicities both in the time as well as in the frequency domain (see **Transform methods**). The respective periods are $N\Delta t$ and $1/\Delta t$, with Δt the sampling interval, and N the number of samples analyzed (**Figure 1**).

Two cases of harmonic signals are shown in **Figure 2A** and **2D**. Only in the first case are an integral number of periods spanned by the observation interval. Noting the effect of the periodicity imposed by the DFT operation, this results in discontinuities only in the second case, where a non-integral number of periods are spanned by the observation interval (**Figures 2B, 2D**). This results in high-

frequency components, hence the leakage occurrence (**Figures 2C, 2F**).

Multiplying windows can be applied, giving gradually less weight to both end regions of the signal. The discontinuities due to the periodic extension of the signal can thus be avoided. To avoid the loss in the total signal power induced by this type of weighing, a correction factor needs to be applied.

A multitude of windows can be used in order to control leakage, but only a handful are used by practitioners of vibration analysis.

The rectangular window

This is defined as:

$$w_R(n) = \begin{cases} 1 & 0 \leq n \leq N - 1 \\ 0 & \text{otherwise} \end{cases} \quad [2]$$

Thus $x'(t) = x(t)$, and the unmodified signal is analyzed. The leakage can be understood by using the convolution of eqn [1b]. **Figure 3** shows the Fourier transformation of the rectangular window $W(\omega)$. This is characterized by a main lobe and decreasing sidelobes, with zeros at multiples of $1/N\Delta t$.

Figure 4 shows the convolution for two cases: denoting the signal’s period by $M\Delta t$ with M the number of points per period, and $p = N/M$ periods spanned in the time interval, the location of the signal on the frequency scale will be $p/N\Delta t$. For the case of

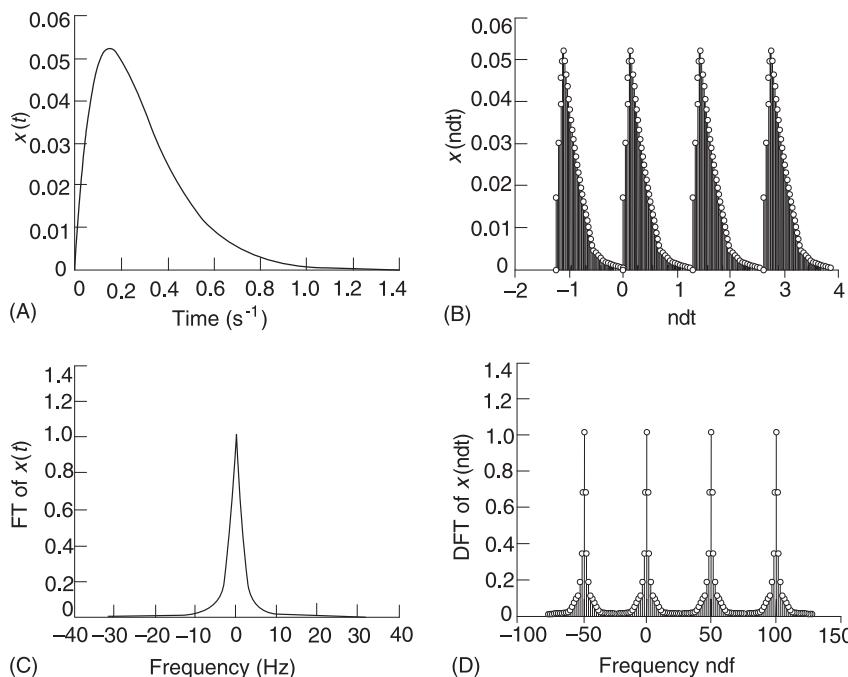

Figure 1 Periodic extension of the discrete Fourier transform. (A) Signal in time domain; (B) extended discrete time domain signal; (C) signal in frequency domain; (D) extended discrete frequency domain signal.

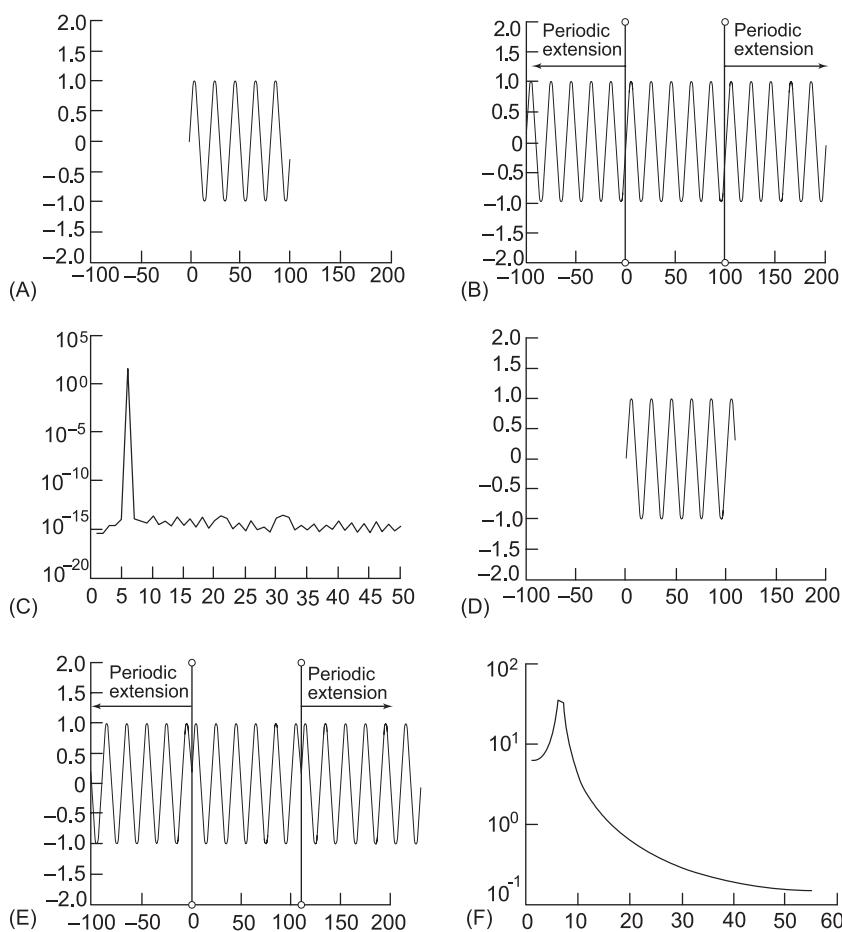

Figure 2 Discrete Fourier transform analysis of a harmonic signal. (A) Signal 1 = integer number of periods; (B) periodic extension of signal 1; (C) signal 1 = magnitude of DFT; (D) signal 2 = odd number of half periods; (E) periodic extension of signal 2; (F) signal 2 = magnitude of DFT.

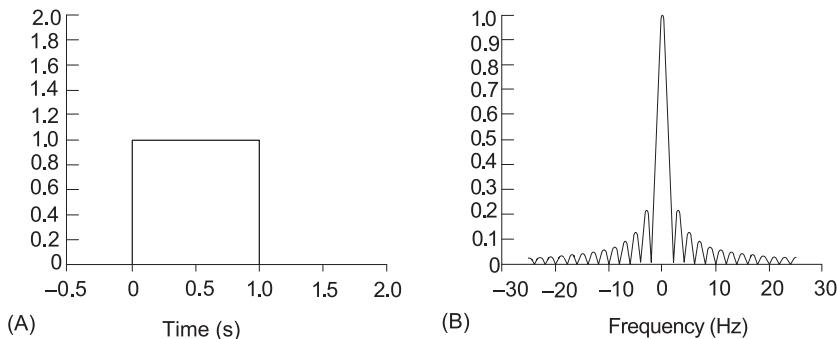

Figure 3 Rectangular window: (A) time domain; (B) magnitude in frequency domain.

Figure 2A, p is an integer, and the convolution, with discrete steps of $1/N\Delta t$, will result in zero, except at the location $p/N\Delta t$. For the case of **Figure 2B**, p is an odd multiple of $\frac{1}{2}$, and the convolution with steps of $1/N\Delta t$ is nonzero for a wide range of frequencies, hence the leakage effect (**Figure 4**). The main characteristics of the window affecting the leakage effect are:

1. Sidelobe characteristics: the maximum sidelobe, and their attenuation as a function of frequency
2. Scalloping loss: the attenuation of signal at frequencies not at the center of the main lobe
3. The correction factor needed in order to preserve the total power.

These are compared later for some popular windows.

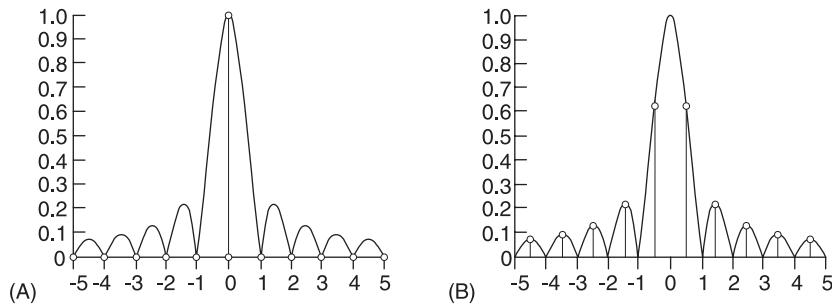

Figure 4 Leakage for the case of harmonic signals, rectangular window: (A) signal spanning an integer number of periods; (B) signal spanning an odd number of half periods.

The Hanning window

This is defined by:

$$w_H(n) = \begin{cases} 0.5 \left[1 - \cos\left(2\pi \frac{n}{N}\right) \right] & 0 \leq n = N - 1 \\ 0 & \text{otherwise} \end{cases} \quad [3]$$

This is probably the most popular window, with very good overall performance. Figure 5 and Table 1 enable a comparison between the Hanning and rectangular (and other) windows. The general shape obviously gradually attenuates both the signals end region. In the frequency domain, the maximum side-lobe is significantly reduced, the side lobe attenuation as a function of frequency has much higher slope and the scallop loss is also lower.

Figure 6 shows a signal composed of three harmonic components of frequencies. For this case, 10, 12.25, and 14.5 periods respectively are spanned by the analysis interval. Also shown is the spectrum using a rectangular as well as a Hanning window (the third window showing the flat top, is addressed in a later paragraph). Note the reduced scallop losses for the Hanning window compared with the rectangular one. The Hanning window is sometimes easier to implement directly in the frequency domain eqn [1b], as the convolution with W_H is one with a

Table 1 Comparisons of some window properties

Window	Highest side lobe level (dB)	Flow of sidelobe maxima (dB/oct)	Scallop loss (dB)
Rectangular	-13	06	3.92
Hanning	-32	-18	1.42
Hamming	-43		1.78
Flat top	-95		0.01

sequence of $[-\frac{1}{4}, \frac{1}{2}, -\frac{1}{4}]$ (which in some computer languages can be implemented via summations and binary shifts).

Additional windows for leakage control

Hamming window:

$$w_{HM}(n) = \begin{cases} 0.54 + 0.46\cos\left(2\pi \frac{n}{N}\right) & 0 \leq n \leq N - 1 \\ 0 & \text{otherwise} \end{cases} \quad [4a]$$

Kaiser window:

$$w_{HK}(n) = \frac{I_0\left[2\beta\sqrt{(N-N^2)}\right]}{I_0(\beta)} \quad [4b]$$

where I_0 is the modified Bessel function of the first

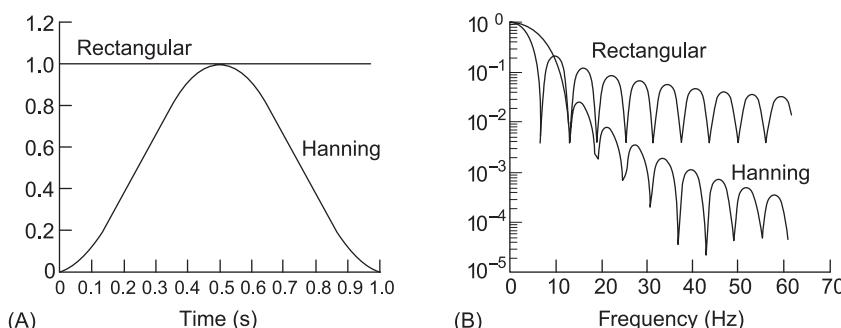

Figure 5 Rectangular and Hanning windows: (A) time domain windows; (B) magnitude in frequency domain.

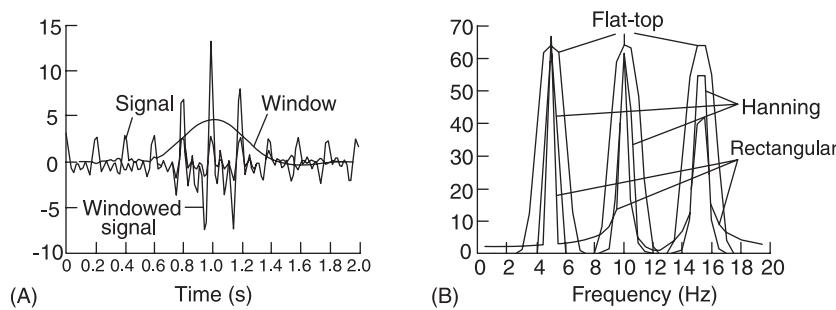

Figure 6 Signal with three components – scallop loss: (A) windowing in the time domain; (B) scallop loss for various windows.

kind, zero order. This window is optimal in the sense that it has a large main lobe together with a sharpest transition beyond it.

Correction Factor

The application of a window decreases the total power of the signal, and a correction scaling factor is thus needed. Unfortunately it is not possible to find an exact correction factor, as this depends on the type of signal, wideband/narrowband, or often random continuous vs harmonic. For a random continuous signal, the correction factor depends on the noise bandwidth of the window. For the Hanning window, the power spectral density (PSD) should thus be multiplied by a factor of 8/3. For a harmonic signal,

the correction factor depends on the exact frequency. For a signal spanning an integral number of periods (i.e., no leakage), the correction of the magnitude of the FT is 2. For a harmonic signal, the correction factor can be in the range, 1.5–2, depending on the exact frequency.

Leakage Reduction Choice of Window

The Hanning window is usually a good choice. The main advantage of controlling the leakage is an increase in the dynamic range of the analysis, as leakage may swamp signal components of close frequencies and much smaller magnitudes. Figure 7 is an example. For signals with closely spaced line spectra (like rotating machinery vibrations), the use of the

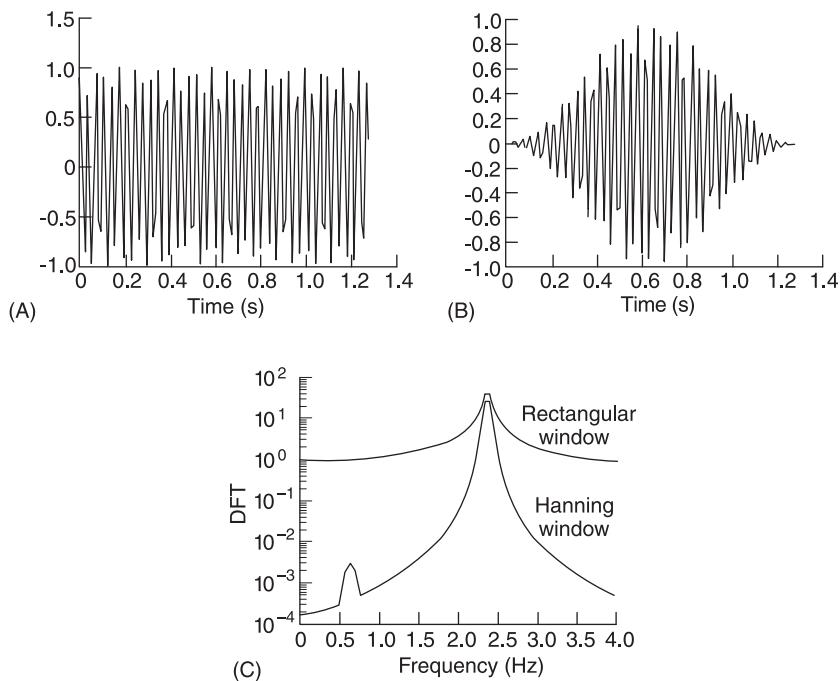

Figure 7 Effect of window on dynamic range: (A) composite signal, rectangular window; (B) composite signal, Hanning window; (C) magnitude of DFT, effect of windows.

Hanning window is almost always recommended. Due to the much smaller secondary lobe, the Hanning window may sometimes be more useful. The Hanning window (and most windows) are not useful however if the frequency spacing between components is less than the window's bandwidth. Unless a longer duration signal can be analyzed, a rectangular window would then perform better. **Table 1** summarizes the main characteristics of some popular windows.

Flat-top Window

Spectral analysis of periodic phenomena results in a discrete spectrum, with spectral ‘lines’ at discrete frequencies. Unless an integral number of periods are spanned by the analysis interval for all existing spectral lines, the leakage error discussed in the prior paragraph results in underestimated magnitudes. The exact underestimation will vary with the line frequency.

In vibration analysis, line spectra are typical of measurements on rotating machinery. The frequencies involved depend on the geometry and kinematics of the rotating elements, but are basically proportional to the machine’s rotating speed. In practice there will always exist some fluctuations in this speed. The location of the line spectra within the main lobe of the analysis window will thus fluctuate, with corresponding varying magnitudes. A window with a ‘flat’ characteristic shape is then of advantage.

Some invariance of the analyzed spectrum to these speed fluctuations can be achieved. **Table 1** summarizes the main characteristics of some popular windows. A typical flat-top window is:

$$\begin{aligned} w_{FT}(n) = & a_0 \\ & + 2 \left[2a_1 \cos\left(2\pi \frac{n}{N}\right) + a_2 \cos\left(4\pi \frac{n}{N}\right) + a_3 \cos\left(6\pi \frac{n}{N}\right) \right] \end{aligned} \quad [5]$$

where:

$$\begin{aligned} a_0 &= 0.9945, & a_1 &= 0.95573, \\ a_2 &= 0.53929, & a_3 &= 0.09158 \end{aligned}$$

and its characteristics are shown in **Figure 8**. The negligible scallop loss is also evident in **Figure 6**. Due to the large width of the main lobe, the window may not be suitable for signals with very close spectral lines.

Another use of the flat-top window is for calibration purposes (obviously in the frequency domain) using harmonic signals.

Control of Variance in Spectral Analysis Random Data

(see **Spectral analysis, classical methods**)

Spectral Estimation via Autocorrelation Functions

While computations of the PSD are now mainly undertaken directly in the frequency domain via the FFT, the classic method of computations via the autocorrelation function appear in the literature. The PSD $S(\omega)$ is computed as the Fourier transform of the autocorrelation function $R(t)$ as (see **Correlation functions**):

$$S(\omega) = \int_{-\infty}^{\infty} R(\tau) \exp(-j\omega\tau) dt \quad [6a]$$

$R(\tau)$ is statistically consistent, i.e., converges to the true value by using an increasing number of signal samples N . The variance of $S(\omega)$ as computed via eqn. [6a] can be controlled by applying a window to $R(\tau)$, resulting in the estimate:

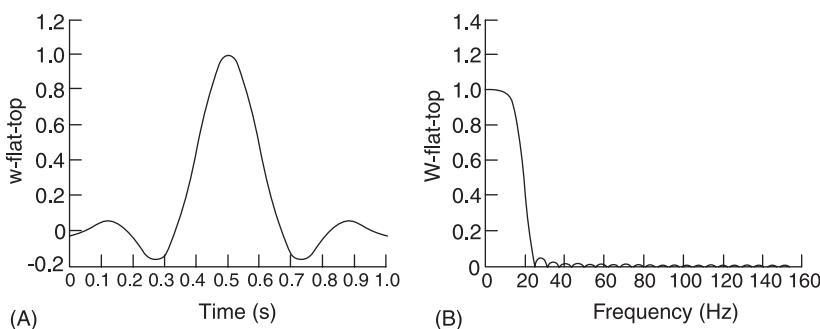

Figure 8 Flat-top window: (A) time domain; (B) magnitude, frequency domain.

$$S'(\omega) = \int_{-\infty}^{\infty} w(\tau)R(\tau) \exp(-j\omega\tau) dt \quad [6b]$$

Possible windows are those already mentioned, i.e., the Hanning window. As the windowing decreases resolution due to their increased main lobe width, it is sometimes claimed that the actual choice of a specific window is not very critical.

Overlap Processing and Windows

In the spectral analysis of random signals, the high variance of the spectral estimates is often controlled by averaging spectral estimates from sections of the signal. For constant signal duration, the number of segments used for this averaging operation can be increased by overlapping these segments. The variance is reduced when such sections are uncorrelated. To avoid the correlation between the signal points of the end of each section and the beginning of the next one due to the overlap, a Hanning window is usually applied to each section before the overlapping operation (Figure 9). This gives less weight to the correlated signal points and results in a higher variance reduction. Comparing for example 50 percent overlap in conjunction with a rectangular and Hanning win-

dow, the variance of the estimator for the first case would be approximately 40 percent higher. The method using a rectangular window is sometimes called the Bartlett method, that with a Hanning window, the Welch method. It is also possible to cast the formulation of the overlapped based PSD estimation as one of windowing like eqn [6b].

Overlapped analysis can be useful for a random continuous signal. There is no advantage in applying it to cases where close harmonic signals (and their spectral lines) are sought, as the increased bandwidth of the window could be detrimental. It is also not recommended for signals having sharp spiky transient components, as the overlapping in conjunction with a Hanning window could suppress some of these transients.

Windowing Used in Impulse Testing/Transient Analysis

Windowing transients can improve the signal to noise ratio. The basic idea is to weight the signal according to the certainty associated with it. Assuming a stationary additive random noise, less weight is given to the signal points of lesser magnitude. The specific weighting is a function of the signal shape.

Force Window

This type of window is applied to transients spanning only a part of the analysis duration. This can occur in multichannel data acquisition tasks, where the duration of the acquisition is equal in all channels, and hence dictated by the channel with the longest transient. One example is that of impulse testing where a short impact excites a structure, with a decaying response of longer duration. The window applied to the force is hence often called a force window. It is a rectangular window, of duration spanning at least the force duration. Its approximate form is hence:

$$w_F(n) = \begin{cases} 1 & 0 \leq n < N_T - 1 \\ 0 & \text{otherwise} \end{cases} \quad [7]$$

where N is the number of samples acquired and N_T is slightly larger than the number of samples spanning the signal. A gradual transition towards zero around N_T is usually preferred, and eqn [7] is thus only approximate.

The noise variance is obviously reduced by the factor N_T/N , and the signal/noise ratio (RMS/RMS) is improved by $(N/N_T)^{1/2}$ (Figure 10).

Exponential Window

Still assuming stationary continuous noise, then an exponentially decreasing weight is indicated for

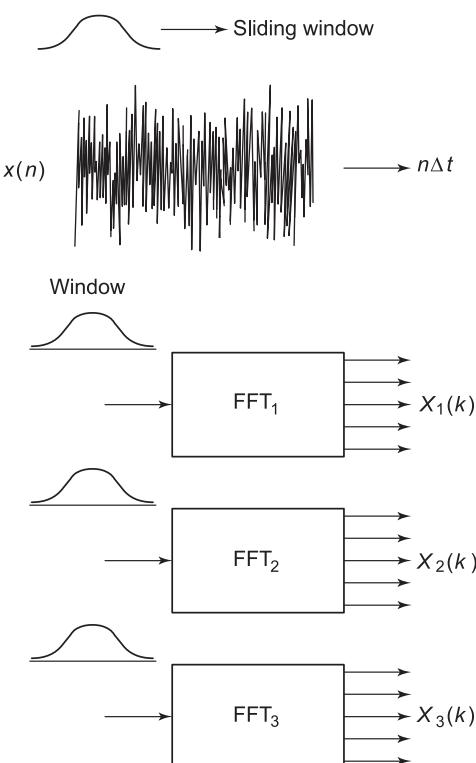

Figure 9 Overlap processing.

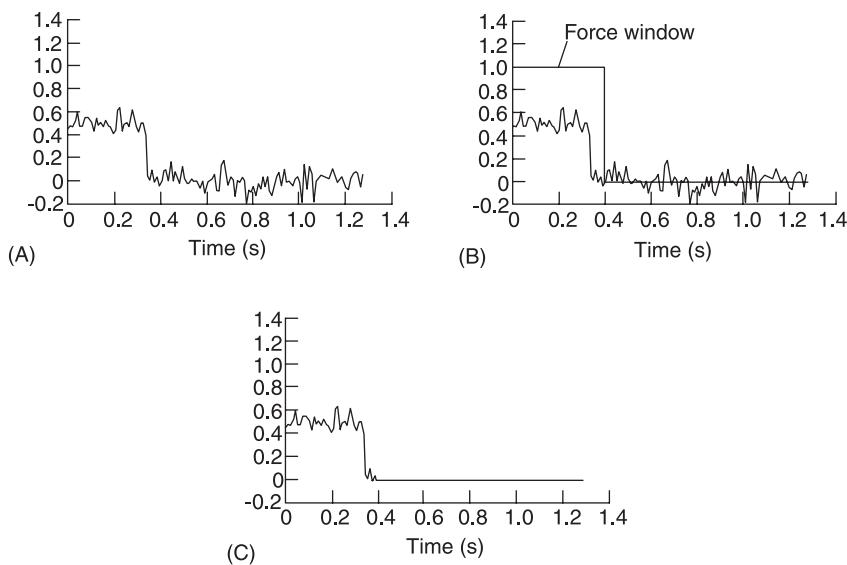

Figure 10 Force window: (A) noisy transient signal; (B) location of window; (C) windowed transient.

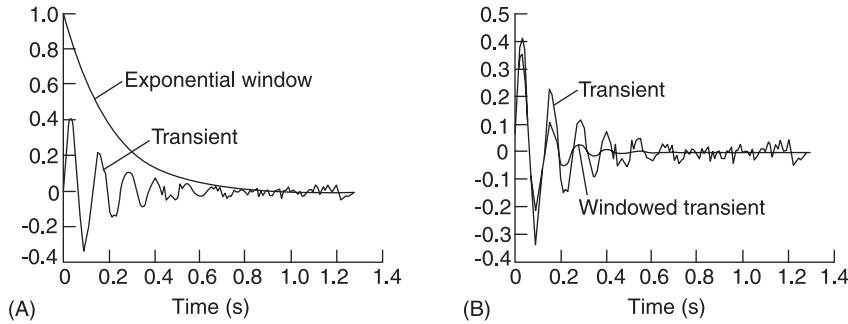

Figure 11 Exponential window: (A) noisy oscillating decaying transient and window; (B) transient original and windowed.

exponentially decaying oscillations. Thus the window is of the form (Figure 11):

$$w_{\text{exp}}(n) = \exp(-an) \quad 0 \leq n < N \quad [8]$$

The parameter a is chosen so as to have a decay to zero for $n = N$. The noise variance is then approximately reduced by a factor of 3, the signal/noise improved by 1.7. The effect of the windowing is to have a faster effective decay than the one due to the physical situation. Any damping factors extracted from the decaying oscillations must be corrected, as its value has been increased artificially. Assuming that the decaying oscillations are a combination of components of the form:

$$x(t) = A_{\text{exp}}(-\zeta\omega_n t) \sin[\omega_n(1 - \zeta^2)^{1/2}t] \quad [9a]$$

where ζ is the physical damping ratio and ω_n the

corresponding natural frequency. Then the computational equivalent damping is:

$$\zeta_{\text{eff}} = \zeta + \frac{a}{\omega_n} \quad [9b]$$

The a/ω_n factor must be used for correction. The exponential window is also used for situations where the signal has not decayed to zero in the analyzing window (a common situation when very light damping exists). The truncation at the end, with the resulting discontinuity and leakage, is avoided by using this window.

Design of Digital FIR Filters

There exists one easily implemented method of designing digital finite impulse response (FIR) filters. The filters are based on a moving average (MA) operation:

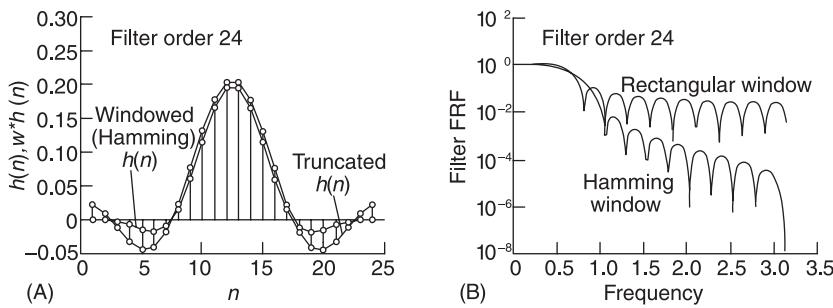

Figure 12 Design of FIR filters: (A) desired impulse response, truncated and windowed; (B) FRF of filter, rectangular (truncated) and windowed.

$$y(n) = \sum_{i=0}^m b_i x(n-i) \quad [10]$$

where the coefficients b_i are actually the impulse response of the digital filter. The desired impulse response is basically computed as the inverse Fourier transform of a desired transfer function of the filter.

The design attempts to approximate the performance of ideal filters. The theoretical impulse response of ideal filters is usually of infinite duration. A practical implementation, necessitating a limited impulse response, should not be based on a simply truncated impulse response. Such a discontinuity in the impulse response, a case causing the Gibbs phenomenon, would result in unfavorable filtering characteristics, far from approximating those of the ideal filters. The solution is to apply a suitable window to the ideal impulse response:

$$b'(n) = w(n)h(n) \quad [11]$$

Some of the windows used for this filter design are the general ones like the Hanning window. The worst one is the rectangular window, i.e., one resulting in the unmodified impulse response. An example of the improvement of the filter's performance is shown in Figure 12. Depending on specific desired filter char-

acteristics, others like the Kaiser, Chebyshev, and Blackman windows can be used. The literature dealing with digital filter describes these in detail (see **Digital filters**).

Nomenclature

I	modified Bessel function
M	number of points per period
N	number of samples
$R(\tau)$	autocorrelation function
$w(t)$	window
w_F	force window
w_{HK}	Kaiser window
w_{HM}	Hanning window
$x(t)$	time signal
Δt	sampling interval

Z

Z TRANSFORMS

See **TRANSFORM METHODS**

GLOSSARY

absorber, vibration:

damped vibration absorber: an added device which introduces damping to a structure at a point by providing an inertial sprung mass against which an added damper can react, thereby introducing damping to a specifically targeted mode of vibration

undamped vibration absorber: an added device which provokes an antiresonance at the point of attachment at a preselected frequency of forced vibration

accelerance: one of the family of different frequency response functions: the harmonic acceleration response in one degree-of-freedom to a single harmonic excitation force applied in the same or another degree-of-freedom. Also known as **inertance** (although this name is not approved by ISO). See also **mobility** and **receptance**

acceleration: see **displacement**

aliasing: the phenomenon in digital signal processing, due to inadequate sampling frequency, whereby a signal with a frequency f_N which is higher than half the digitization sampling frequency, f_S , appears in the resulting spectrum as if it were a signal with a frequency (f_{S-N}), which is lower than its actual value

analysis, modal: a procedure which extracts the normal mode properties of a system, either by analyzing measured response functions (experimental modal analysis — EMA) or by performing an eigensolution on the system's mass and stiffness matrices (analytical modal analysis)

antialiasing filter: signal conditioning or processing device which provides a low-pass filtering effect to reduce in a signal to be analyzed those frequency components which are higher than one-half the sampling frequency (the Nyquist frequency)

antiresonance: a condition in forced vibration whereby a specific point or DOF has zero amplitude at a specific frequency of vibration

Argand diagram: see **diagram**

autocorrelation function: (see **power spectral density**) the signal average of the product of the signal with a delayed version of itself. The inverse Fourier transform of the power spectral density function

balancing: the procedure of adjusting the mass distribution of a rotor so that vibrations or forces reactions during rotation are minimized

bandwidth: strictly, the frequency span encompassed by a resonance curve (Bode diagram of the modulus of a frequency response function) at the level which is 0.707 times the peak value. Alternatively, the frequency range of excitation and measurement during a vibration test

Bode diagram/plot: see **diagram**

burst random: see **signal**

burst sine: see **signal**

coherence: a measure of the degree of correlation between two signals presented in the frequency domain (i.e., a form of spectrum). Has a real value and is normalized between 0 and 1.

coordinate (or co-ordinate): strictly, the location of a point on a structure in space. Often used to mean a degree-of-freedom

principal (or modal) coordinate: a time-varying quantity which describes the extent (amount) of motion in one of the systems modes of vibration. Sometimes referred to as **modal coordinate**

correlation: the systematic quantitative comparison of two sets of like data, such as time histories, or modal properties, resulting in a numerical measure of the degree of similarity or dissimilarity. See **coherence**

critical speed: speed of a rotating rotor that corresponds to a resonance

damping: any of several physical mechanisms whereby mechanical energy (i.e., kinetic or strain) is converted into heat and thereby removed from a vibrating system. In the absence of a steady input of energy, such as is achieved through continuous excitation of the system, the vibration will decay to rest as a direct consequence of the damping mechanisms

hysteretic (also structural): a type of damping for which the mathematical model used to describe it is based on observation of the characteristics of damping due to internal hysteresis of materials

proportional: refers to the distribution (rather than the type) of damping in a structure whereby the damping elements are assumed to be distributed in a way which reflects the distribution of stiffness, and/or mass, of the structure. Has the convenient property that the mode shapes (q.v.) of a proportionally damped structure are identical to the mode shapes of the undamped version of the same

structure, and are therefore real in a mathematical sense

structural: see **damping hysteretic**

viscous: a type of damping in which the damper force is proportional to velocity and whose mathematical description is easily accommodated in the models used to describe a structure's dynamics, especially for time domain analysis

critical: a level of viscous damping above which free oscillatory motion does not take place: it is common practice to define practical levels of damping (usually much lower than critical) as a fraction of critical damping (damping ratio)

dB: the dB (or decibel) is a unit for describing ratio of quantities, based on a logarithmic scale in which x described in dB = $20 \log x$. Thus, 0 dB represents a value of unity (1.0) while 20 dB represents a value of 10.0. Also used to describe ratio of power or energy quantities, in which case a power level P is described as $10 \log P$. Absolute values need to be related to a reference unit

degree-of-freedom: used to define the location and direction of the motion of a specific point of a system or structure. Sometimes called a **coordinate**. Each point on a structure has six degrees of freedom (three translation and three rotation directions)

diagram:

Argand: a plot of a complex function, such as an FRF, in which the x - y axes are the real and imaginary parts of the function, respectively. The corresponding data, plotted as modulus and phase on polar axes, result in an identical plot. Also known as a **Nyquist diagram**

Bode: a form of presentation of a complex function, such as an FRF, in which there are two graphs: the first presenting the log-modulus of the function against log-frequency, and a second plot of the phase (of the complex function) against log-frequency. Used to convey information covering a wide frequency range

Nyquist: see **diagram, Argand**

discrete Fourier transform (DFT): see **transform**

displacement: change of position of element. Often measured in conjunction with rotating rotors and active control tasks. The measurement and use of velocity and acceleration, the first and second derivative of displacement prevail in vibration task. Off-the-shelf acceleration-meas-

suring systems comprise the majority used by practitioners (see **jerk**)

dynamic range: response range of a transducer or data acquisition system between maximum-level noise level: often expressed as a ratio in dB

eigenvalue: mathematical term for a root of the characteristic equation of a dynamic system: generally equal to the square of one of the system's natural frequencies

eigenvector (see **mode shape**): mathematical term for one of the vectors of the characteristic equation of a dynamic system: describes one of the system's normal mode shapes. The matrix product of the eigenvector (transposed) times the mass matrix times the eigenvector is equal to the **modal mass** (q.v.); when the modal mass is unity, the eigenvector is said to be mass-normalized

fast Fourier transform (FFT): see **transform**

forced vibration: see **vibration**

Fourier: see **transform**

free vibration: see **vibration**

frequency:

excitation: the frequency at which a system is made to vibrate under the influence of an external harmonic force

natural (undamped, damped): a frequency at which a structure will vibrate when given an initial disturbance from its equilibrium position and then left to move under free vibration conditions. If the structure is damped, the mathematical description of this frequency will be complex, having an imaginary part which describes the oscillation rate and a real part which defines the decay rate

resonance (sometimes, inaccurately, **resonant**): a frequency at which an FRF or other response curve reaches a local maximum value in the vicinity of a natural frequency. This resonance frequency will often be very close to, but not necessarily equal to, the corresponding natural frequency

sampling: the frequency at which a signal is digitized (sampled, discretized) for the purpose of digital spectral analysis

Nyquist: half the sampling frequency used to discretize a signal prior to digital spectral analysis

frequency response function (FRF): see **function**

forced vibration: see **vibration**

function:

frequency response (FRF): the ratio between the steady-state harmonic response in one degree of freedom of a structure (j , say) to the similarly steady-state harmonic force

applied at another degree of freedom of the structure (such as k)

point: a particular FRF in which the excitation and response degrees of freedom are the same (i.e., $j = k$).

transfer: an FRF in which the excitation and response degrees of freedom are not the same (i.e., $j \neq k$).

impulse response function (IRF): The response time history of a system, measured in one particular degree of freedom to a unit impulse excitation applied at another degree of freedom

harmonic: (*n.*) an integer multiple of a fundamental sinusoidal signal to which it is related
(*adj.*) equivalent to ‘sinusoidal’ in describing signal type

Hilbert transform: see **transform**

impedance, mechanical: one of the family of inverse frequency response functions: the ratio between the single harmonic excitation force applied in one degree of freedom to the harmonic velocity response in the same or another degree of freedom.

impulse response function (IRF): see **function**

inertance: see **accelerance**

isolation, vibration: a feature of forced vibration in which vibration levels in certain regions of a structure are constrained to be much lower than at other regions by suitable distribution of mass and stiffness

jerk: derivative of acceleration, used in conjunction with responses to shock excitations

leakage: a phenomenon which arises during digital spectral analysis of continuous signals as a result of the finite duration of the sampled signal and its relationship with the frequencies present in the original signal. Often, leakage occurs because the signal being analyzed is not periodic with respect to the sample length (duration, period) used for the analysis. The consequence of leakage is that a computed spectrum may indicate the presence of signal components which are not in the original signal and it may not accurately indicate those which are. Windows are used to reduce the effects of leakage

linearity: a characteristic often assumed to be present in structures subjected to vibration analysis or testing techniques: the primary assumption is essentially that the response of the structure to two forces applied simultaneously will be identical to that derived by adding the responses of the structure to each force applied individually. Other definitions can also be applied

line spectrum: see **spectrum**

MAC or modal assurance criterion: a simple parameter used to measure the degree of correlation between two vectors of the same length: usually eigenvectors, or mode shapes. A MAC value of 100% indicates that the two vectors being compared are parallel, or are perfectly correlated. MAC values of greater than 80% generally indicate ‘similar’ mode shapes

mass, modal: a quantity which relates to a given mode shape and which is computed from that mode shape vector and the mass matrix of the system model. The modal mass is automatically unity for mass-normalized mode shapes

mobility: one of the family of frequency response functions: the harmonic velocity response in one degree of freedom to a single harmonic excitation force applied in the same or another degree of freedom

modal coordinate: see **coordinate**

modal mass: see **mass, modal**

modal stiffness: see **stiffness, modal**

mode, mode shape (see eigenvector): strictly, a pattern of vibration exhibited by a structure or system. Generally, described as a vector of values, defining the relative displacement amplitudes and phases of each degree of freedom, which describes the motion of the system

complex: a mode of vibration in which the relative displacements exhibit phase differences between one degree of freedom and the next which are not always 0 or 180° (situation which applies in a real mode). Complex modes do not exhibit modal lines

mass-normalized (see eigenvector)

normal, damped: the vector of relative amplitudes for the vibration of a damped system in one of its natural modes of free vibration. These modes are the modes which the structure assumes in the absence of any external excitation. In this case, the structure is assumed to possess arbitrary damping and, as a result, the normal modes are complex

normal, undamped: the vector of relative amplitudes for the vibration of the undamped system in one of its natural modes of free vibration. These modes are the modes which the structure assumes in the absence of any external excitation. In this case, the structure is assumed to possess no damping and, as a result, the normal modes are real

real: a mode of vibration in which the relative displacements exhibit phase differences between one degree of freedom and the next

which are always 0 or 180°. Real modes exhibit modal lines

mode indicator function: a function which is used to indicate the existence of global system modes (those which are observed throughout the structure) as opposed to local modes (which are only visible in a small region of the structure)

model (mathematical): a mathematical description of a system or structure in a form which can be described by equations of motion which can then be solved analytically or numerically to describe that system's dynamic behavior

continuous: a mathematical model which describes the system or structure as a continuous medium, using partial differential equations with, typically, transcendental expressions for the solutions

discrete, lumped parameter: an alternative type of mathematical model (to the continuous type) in which the mass, stiffness, and damping properties of the structure are discretized so that the behavior can be described by a finite series of ordinary differential equations leading to finite discrete solutions

modal: a model which is defined in terms of eigenvalues and eigenvectors, or natural frequencies and mode shapes. Usually presented as eigenvalue and eigenvector matrices

response: a model which is defined in terms of some characteristic response functions, such as FRFs, or IRFs, or equivalent

spatial: a model which is defined in terms of the system's distribution of mass, stiffness, and damping in space. Usually described as mass, stiffness, and damping matrices

multiple-degrees-of-freedom (MDOF) system (see single-degree-of-freedom (SDOF) system): a system for which two or more coordinates or degrees of freedom are needed to define completely the position of the system at any instant

natural frequency: see frequency

node: 1. a DOF which has zero amplitude of vibration; used when describing a mode shape or an operating deflection shape
2. a specific grid point in a discrete (lumped parameter) model of a structure

nonlinearity: a form of structural behavior which does not conform to the definition of linearity (see linearity)

normal mode: see mode

Nyquist diagram: see diagram

operating deflection shape: see mode shape

pole: mathematical term which is equivalent to

eigenvalue or to (square of) natural frequency. For systems describable by a ratio of rational polynomials in a transform domain, the value of the transform variable for which the denominator polynomial equals zero

power spectral density (PSD): (see autocorrelation function) the distribution of the squared signal (acceleration, velocity, etc.) with frequency (in squared units per Hz, i.e., g²/Hz). The Fourier transform of the autocorrelation function

principal coordinate: see coordinate

receptance: one of the family of frequency response functions: the harmonic displacement response in one degree of freedom to a single harmonic excitation force applied in the same or another degree of freedom. See also mobility and acceleration

resonance (see frequency): a phenomenon associated with forced vibration which relates to a narrow range of frequencies in which the response amplitude of a system attains levels which are much higher than elsewhere

sampling (see frequency)

series, Fourier: a method of representing a periodic signal as the sum of separate sinusoids whose frequencies are integer multiples of the fundamental period of the original signal. See also transform, Fourier

signal (time history): a time-varying quantity which describes the excitation or response of a vibrating system. In vibration testing, a quantity which is used either to drive the excitation of a system into vibration or to represent the measurement of one of the vibration forces or responses which are used to describe the system's movement. Types of signal commonly encountered include:
burst:

random: a signal which consists of two sections, the first being a finite duration of a stationary random signal followed by a second section which is zero

sine: a signal which consists of two sections, the first being a finite duration of a steady sinusoid followed by a second section which is zero

chirp: a signal comprising a single rapidly swept sine wave between a minimum and maximum frequency

harmonic: a sinusoidal signal at a single frequency

periodic: A signal which repeats itself indefinitely after a period, T . In signal analysis or processing, the period of the repeating signal is not necessarily the same as the period over which the signal is measured or analyzed

and in such a situation, analysis of the signal may not yield a true indication of its form (see also **leakage**)

periodic random: a signal which consists of a succession of records (sometimes called ‘samples’), each of finite length, T , which is usually selected to suit the sampling period of a means of analyzing the signal. Each of the first few records is identical to each other and thus represent a periodic signal, even though an individual period appears to be very complex, almost random. Then the next few records consist of several repetitions of another ‘complex’ record. This pattern is repeated for as long as the signal is required

pseudorandom: a periodic signal for which the basis record is very complex, and appears to be random. However, this record is repeated indefinitely and so forms a periodic signal

random: a nondeterministic signal. No analytical expression predicting future values can exist. It is defined only in terms of statistical functions and parameters, for example an amplitude probability function

sine, sinusoid, discrete sine: a signal which consists of a pure, single, sinusoidal or harmonic component; also **stepped sine**

sine sweep: a signal which comprises a sinusoid whose frequency is varied slowly so that a range of frequencies is covered throughout the duration of the signal

stepped sine: a signal which comprise a series of discrete sinusoids, one after the other

transient: a signal which lasts a finite length of time, being zero before and after that period, and which is fully defined within the record length

white noise: a signal with a constant **power spectral density**, independent of frequency. In practice a signal can have white noise characteristics only in a finite frequency range

single-degree-of-freedom (SDOF) system (see also: **multiple-degrees-of-freedom (MDOF) system**): a system for which only one coordinate is needed to define completely the position of the system at any instant

spectrum: description of the essential elements of a signal (or time history) in terms of constituent sinusoidal components

continuous: nonzero in a continuous range of frequencies. Typical for **random signals**

discrete: a spectrum computed only at discrete frequencies. These frequencies are usually equi-spaced, a result of using the **fast Fourier**

transform algorithm. Sometimes synonymous with **line spectrum**

line: a discrete spectrum, with nonzero values only at discrete frequencies. Typical of vibrations generated by rotating machinery

stiffness, modal: a quantity which relates to a given mode shape and which is computed from that mode shape vector and the stiffness matrix of the system model. The modal stiffness is equal to the eigenvalue for a mass-normalized mode shape

time history (see **signal**): description of a time-varying quantity, such as displacement or force, as a direct function of time

transducer: a device which transforms one form of energy into another, practically used synonymously with the term **sensor**

transform

discrete (DFT): a discrete transform which converts a a discrete (usually time domain) sequence into another discrete (usually frequency domain) sequence. With correct sampling, the DFT approximates samples of the (continuous) Fourier transform. In the DFT, the continuous time-varying signal is approximated by a discrete number of sampled values taken from the original data. The resulting spectrum has exactly the same number of components as the number of sampled data points, although not all of these may be displayed

fast Fourier transform (FFT): a computer algorithm for the efficient computation of the DFT of a sampled signal. The algorithm takes advantage of the symmetry of the transform and is very efficient when applied to a data set containing 2^N values

Fourier: a continuous transform between two domains, usually time and frequency. One of the most basic mathematical tools for representing the relevant features of a time history signal in terms of its constituent frequency components, and of reconstructing a time record from a knowledge of the frequency (or spectral) components. For periodic signals, the transform exists only at discrete frequencies (see **line spectrum**), and is more conveniently represented via the **Fourier series**

Hilbert: a type of transform for converting a function from one form to another which, unlike the Fourier transform, derives a transformed function in the same domain as the original (i.e., a time signal transforms to another time signal, a frequency function to another frequency function)

validation: the process of demonstrating the adequacy of the performance of a given prediction capability, usually that of a finite element model constructed to predict the vibration properties of the structure

velocity (see **displacement**)

verification: the process(es) used to demonstrate that an algorithm or other procedure has been correctly implemented in a computer program or test sequence

vibration

forced: the vibration structure which is the direct result of an applied excitation force, or forces. Although there will be an initial transient response which is governed by the free vibration characteristics of the system, this will die away, leaving only the steady response due entirely to the externally applied excitation. This motion can be described completely in terms of the free

vibration normal modes of the system

free: the type of vibration which ensues when a system or structure is set into motion by an initial disturbance and then left to vibrate under the influence only of the internal forces due to its own stiffness, inertia, and damping. This motion can be described completely in terms of the free vibration normal modes of the system

white noise: see **signal**

window: an approach used in signal processing to minimize the approximations introduced when using a discrete Fourier transformation on a continuous signal. Usually applied in the time domain, as a multiplying function applied to the time signal. Various shapes of window functions have been developed to produce optimum frequency information for particular types of signal

3. UNITS AND CONVERSION FACTORS

Common units used in engineering noise and vibration control

Primary units

length metre (m)
mass kilogramme (kg)
quantity of a substance mol

temperature kelvin (K)
time second (s)

Secondary units

energy joule ($J \equiv N\text{m} \equiv \text{Ws}$)
force newton ($N \equiv \text{kg m s}^{-2}$)
frequency hertz (s^{-1})
molecular weight mol^{-1}

power watt ($W \equiv \text{J s}^{-1} \equiv \text{Nm s}^{-1}$)
pressure Pascal ($\text{Pa} \equiv \text{N m}^{-2}$)
radian frequency rad s^{-1}

Derived units

acceleration m s^{-2}
acoustic (radiation) impedance^a (force per unit area/
volume velocity per unit area) Ns m^{-1}
acoustic intensity W m^{-2}
autospectral density (power spectral density)
 $\text{units}^2 \text{ Hz}^{-1}$
energy density J m^{-3}
energy spectral density $\text{units}^2 \text{ s Hz}^{-1}$
entropy $\text{J kg}^{-1} \text{ K}^{-1}$
gas constant $\text{J kg}^{-1} \text{ K}^{-1}$
mechanical impedance (force/velocity) N s m^{-1}
mechanical stiffness Nm^{-1}

mobility $\text{m N}^{-1} \text{ s}^{-1}$
modulus of elasticity, adiabatic bulk modulus N m^{-2}
quefrency s
specific acoustic impedance (pressure/velocity)
 Ns m^{-3}
surface density kg m^{-2}
universal gas constant $\text{J mol}^{-1} \text{ K}^{-1}$
velocity m s^{-1}
viscosity Ns m^{-2}
viscous damping Ns m^{-1}
volume density kg m^{-3}
volume velocity $\text{m}^3 \text{ s}^{-1}$

Conversion factors

Length

1 ft = 0.3048 m
1 in = 25.4 mm
1 mile = 1.609344 km

1 mph = 1.6093 km h^{-1} = 0.44704 m s^{-1}
1 nautical mile = 1.852 km
1 knot = 1 nm h^{-1} = 0.5144 m s^{-1}

Area

1 ft² = 0.09290304 m²
1 in² = 0.00064516 m²

1 acre = 4046.86 m²
1 hectare = 10^4 m²

Volume

1 ft³ = 28.3168 litre
1 litre = 10^{-3} m³
1 UK gal = 4.54609 litre

1 UK pint = 0.568261 litre
1 US gal = 3.7853 litre

Mass

1 lb = 0.45359237 kg
1 oz = 28.3495 g

1 ton = 1.01605 tonne
1 lb ft⁻³ = 16.0185 kg m⁻³

^a Acoustic impedance is sometimes defined as pressure/volume velocity.

Force (N, kg m s⁻²)

$$1 \text{ lbf} = 4.44822 \text{ N}$$

$$1 \text{ kgf} = 1 \text{ kp} = 9.80665 \text{ N}$$

$$\begin{aligned}1 \text{ bar} &= 14.50 \text{ psi} = 10^6 \text{ dyne cm}^{-1} \\&= 10^5 \text{ Pa} = 10^{-5} \text{ N m}^{-2}\end{aligned}$$

$$1 \text{ psi} = 6.89476 \text{ kPa}$$

$$1 \text{ mm H}_2\text{O} = 9.80665 \text{ Pa}$$

$$1 \text{ mm Hg} = 133.322 \text{ Pa}$$

$$1 \text{ atm} = 101.325 \text{ kPa}$$

Energy (J, Nm, Ws)

$$1 \text{ ft-lbf} = 1.355818 \text{ J}$$

$$1 \text{ Btu} = 1055.06 \text{ J}$$

$$1 \text{ kWh} = 3.6 \text{ MJ}$$

$$1 \text{ kcal} = 4.1868 \text{ kJ}$$

Power (W, J s⁻¹, Nm s⁻¹)

$$1 \text{ ft-lbs s}^{-1} = 1.355818 \text{ W}$$

$$1 \text{ hp} = 745.7 \text{ W}$$

$$1 \text{ kcal h}^{-1} = 1.163 \text{ W}$$

Temperature

$$a \text{ } ^\circ\text{C} = b \text{ K} - 273.15$$

$$a \text{ } ^\circ\text{C} = (b \text{ F} - 32)/1.8$$

$$b \text{ } ^\circ\text{F} = (1.8 \times a \text{ } ^\circ\text{C}) + 32$$

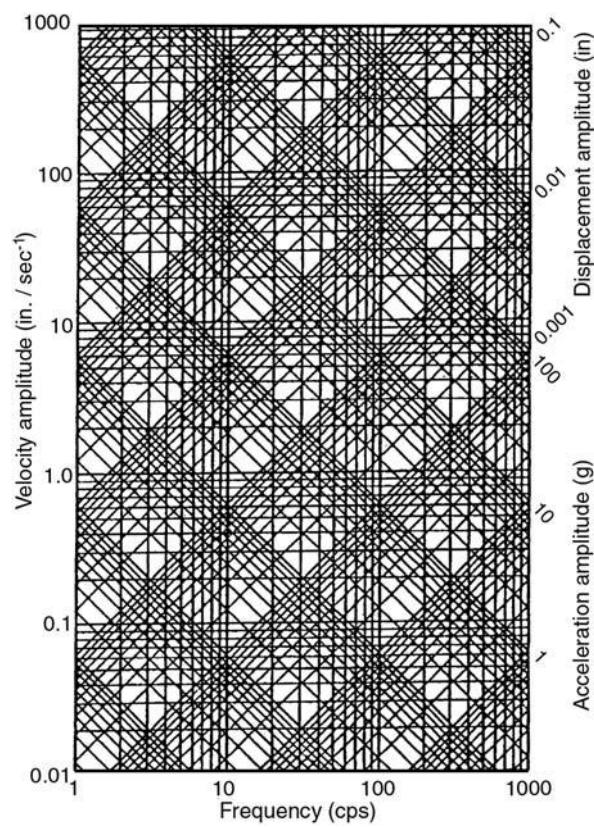

Units and conversion factors (vibration-oriented)

Natural frequencies and nodal lines of square plates with various edge conditions (after D. Young. *J. Appl. Mechanics*, 17:448 (1950))

	1st mode	2nd mode	3rd mode	4th mode	5th mode	6th mode
$\omega_n \sqrt{Da/\gamma ha^4}$	3.494	8.547	21.44	27.46	31.17	
Nodal lines						
$\omega_n \sqrt{Da/\gamma ha^4}$	35.99	73.41	108.27	131.64	132.25	165.15
Nodal lines						
$\omega_n \sqrt{Da/\gamma ha^4}$	6.958	24.08	26.80	48.05	63.14	
Nodal lines						

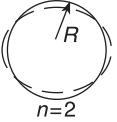

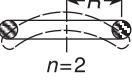

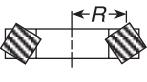

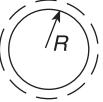

$\omega_n = 2\pi f_n$; $D = Eh^3/12(1-\mu^2)$; γ =weight density; h =plate thickness; a =plate length.

Natural frequencies and nodal lines of cantilevered rectangular and skew rectangular plates ($\mu=0.3$)* (after Barton, M.V. *J. Appl. Mechanics*, 1951; 18:129)

Mode	a/b	1/2	1	2	5
First		3.508	3.494	3.472	3.450
Second		5.372	8.547	14.93	34.73
Third		21.96	21.44	21.61	21.52
Fourth		10.26	27.46	94.49	563.9
Fifth		24.85	31.17	48.71	105.9

Mode	First	Second	First	Second	First	Second
$\omega_n \sqrt{Dg/\gamma ha^4}$	3.601	8.872	3.961	10.190	4.824	13.75
Nodal lines						

Natural frequencies of complete circular rings whose thickness in radial direction is small compared to radius

Type of vibration	Shape of lowest mode	Rectangular cross-section	Circular cross-section
		ω_n	ω_n
Flexural in plane of ring with n complete wavelength in circumference		$\sqrt{\frac{Eg}{\gamma} \frac{l}{AR^4} \frac{n^2(n^2-1)^2}{n^2+1}}$ n any integer > 1	$\sqrt{\frac{E\pi r^4}{4mR^4} \frac{n^2(n^2-1)^2}{n^2+1}}$ n any integer > 1
Flexural normal to plane of ring			$\sqrt{\frac{E\pi r^4}{4mR^4} \frac{n^2(n^2-1)^2}{n^2+1+\mu}}$ n any integer > 1
Torsional		First mode $\sqrt{\frac{Eg}{\gamma R^2} \frac{lx}{lp}}$	$\sqrt{\frac{G\pi r^2}{mR^2} (n^2+1+\mu)}$ $n=0$, or any integer
Extensional		$\sqrt{\frac{Eg}{\gamma R^2}}$	$\sqrt{\frac{E\pi r^2}{mR^2} (1+n^2)}$ $n=0$, or any integer

E =modulus of elasticity; G =modulus of rigidity; γ = weight density; n :defined for each type of vibration; r =radius of ring; μ =Poisson's ratio. Properties of cross-sections: l = moment of inertia with respect to axis of section; l_x =moment of inertia with respect to radial line; l_p =polar moment of inertia; A =area; r =radius; m =mass per unit of length.

6. STANDARDS AND GUIDELINES

- ISO 10055:1996 Mechanical vibration – vibration testing requirements for shipboard equipment and machinery components
- ISO 10068:1998 Mechanical vibration and shock – free, mechanical impedance of the human hand-arm system at the driving point
- ISO 10137:1992 Bases for design of structures; serviceability of buildings against vibration
- ISO 10142:1996 Carbonaceous materials for use in the production of aluminium – calcined coke – determination of grain stability using a laboratory vibration mill
- ISO 10326-1:1992 Mechanical vibration; laboratory method for evaluating vehicle seat vibration; part 1: basic requirements
- ISO/TS 10811-1:2000 Mechanical vibration and shock – vibration and shock in buildings with sensitive equipment – part 1: measurement and evaluation
- ISO/TS 10811-2:2000 Mechanical vibration and shock – vibration and shock in buildings with sensitive equipment – part 2: classification
- ISO 10814:1996 Mechanical vibration – susceptibility and sensitivity of machines to unbalance
- ISO 10815:1996 Mechanical vibration – measurement of vibration generated internally in railway tunnels by the passage of trains
- ISO 10816-1:1995 Mechanical vibration – evaluation of machine vibration by measurements on non-rotating parts – part 1: general guidelines
- ISO 10816-2: 1996 Mechanical vibration – evaluation of machine vibration by measurements on non-rotating parts – part 2: large land-based steam turbine generator sets in excess of 50 MW
- ISO 10816-3: 1998 Mechanical vibration – evaluation of machine vibration by measurements on non-rotating parts – part 3: industrial machines with nominal power above 15 kW and nominal speeds between 120 r/min and 15000 r/min when measured in situ
- ISO 10816-4:1998 Mechanical vibration – evaluation of machine vibration by measurements on non-rotating parts – part 4: gas turbine driven sets excluding aircraft derivatives
- ISO 10816-5:2000 Mechanical vibration – evalua-
tion of machine vibration by measurements on non-rotating parts – part 5: machine sets in hydraulic power generating and pumping plants
- ISO 10816-6:1995 Mechanical vibration – evalua-
tion of machine vibration by measurements on non-rotating parts – part 6: reciprocating machines with power ratings above 100 kW
- ISO 10817-1:1998 Rotating shaft vibration measuring systems – part 1: relative and absolute sensing of radial vibration
- ISO 10819:1996 Mechanical vibration and shock – hand-arm vibration – method for the measurement and evaluation of the vibration transmissibility of gloves at the palm of the hand
- ISO 10846-1:1997 Acoustics and vibration – laboratory measurement of vibro-acoustic transfer properties of resilient elements – part 1: principles and guidelines
- ISO 10846-2:1997 Acoustics and vibration – laboratory measurement of vibro-acoustic transfer properties of resilient elements – part 2: dynamic stiffness of elastic supports for translatory motion – direct method
- ISO 11342:1998 Mechanical vibration – methods and criteria for the mechanical balancing of flexible rotors
- ISO 11342:1998/Cor 1:2000 Mechanical vibration – methods and criteria for the mechanical balancing of flexible rotors
- ISO 13090-1:1998 Mechanical vibration and shock – guidance on safety aspects of tests and experiments with people – part 1: exposure to whole-body mechanical vibration and repeated shock
- ISO 13753:1998 Mechanical vibration and shock – hand-arm vibration – method for measuring the vibration transmissibility of resilient materials when loaded by the hand-arm system
- ISO 14964:2000 Mechanical vibration and shock – vibration of stationary structures – specific requirements for quality management in measurement and evaluation of vibration
- ISO 16063-1: 1998 Methods for the calibration of vibration and shock transducers – part 1: basic concepts

- ISO 16063-11: 1999 Methods for the calibration of vibration and shock transducers – part 11: primary vibration calibration by laser interferometry
- ISO 1925: 2001 Mechanical vibration – balancing – vocabulary
- ISO 1940-1: 1986 Mechanical vibration; balance quality requirements of rigid rotors; part 1: determination of permissible residual unbalance
- ISO 1940-2: 1997 Mechanical vibration – balance quality requirements of rigid rotors – part 2: balance errors
- ISO 2017: 1982 Vibration and shock; isolators; procedure for specifying characteristics
- ISO 2247:2000 Packaging – complete, filled transport packages and unit loads – vibration tests at fixed low frequency
- ISO 2247:1985 Packaging; complete, filled transport packages; vibration test at fixed low frequency
- ISO 2631-1:1997 Mechanical vibration and shock – evaluation of human exposure to whole-body vibration – part 1: general requirements
- ISO 2631-2:1989 Evaluation of human exposure to whole-body vibration; part 2: continuous and shock-induced vibration in buildings (1 to 80 Hz)
- ISO 2631-4:2001 Mechanical vibration and shock – evaluation of human exposure to whole-body vibration – part 4: guidelines for the evaluation of the effects of vibration and rotational motion on passenger and crew comfort in fixed-guideway transport systems
- ISO 2671:1982 Environmental tests for aircraft equipment; part 3.4: acoustic vibration
- ISO 2953:1999 Mechanical vibration – balancing machines – description and evaluation
- ISO 2954:1975 Mechanical vibration of rotating and reciprocating machinery; requirements for instruments for measuring vibration severity
- ISO 3046-5:1978 Reciprocating internal combustion engines – performance – part 5: torsional vibrations
- ISO 4548-7:1990 Methods of test for full-flow lubricating oil filters for internal combustion engines; part 7: vibration fatigue test
- ISO 4866:1990 Mechanical vibration and shock; vibration of buildings; guidelines for the measurement of vibrations and evaluation of their effects on buildings
- ISO 4866:1990/Amd.1:1994 Mechanical vibration and shock – vibration of buildings – guidelines for the measurement of vibrations and evaluation of their effects on buildings; amendment 1
- ISO 4866:1990/Amd.2:1996 Mechanical vibration and shock – vibration of buildings – guidelines for the measurement of vibrations and evaluation of their effects on buildings; amendment 2
- ISO 5007:1990 Agricultural wheeled tractors; operator's seat; laboratory measurement of transmitted vibration
- ISO 5008:1979 Agricultural wheeled tractors and field machinery; measurement of whole-body vibration of the operator
- ISO 5344:1980 Electrodynamic test equipment for generating vibration; Methods of describing equipment characteristics
- ISO 5347-10:1993 Methods for the calibration of vibration and shock pick-ups; part 10: primary calibration by high impact shocks
- ISO 5347-11:1993 Methods for the calibration of vibration and shock pick-ups; part 11: testing of transverse vibration sensitivity
- ISO 5347-12:1993 Methods for the calibration of vibration and shock pick-ups; part 12: testing of transverse shock sensitivity
- ISO 5347-13:1993 Methods for the calibration of vibration and shock pick-ups; part 13: testing of base strain sensitivity
- ISO 5347-14:1993 Methods for the calibration of vibration and shock pick-ups; part 14: resonance frequency testing of undamped accelerometers on a steel block
- ISO 5347-15:1993 Methods for the calibration of vibration and shock pick-ups; part 15: testing of acoustic sensitivity
- ISO 5347-16:1993 Methods for the calibration of vibration and shock pick-ups; part 16: testing of mounting torque sensitivity
- ISO 5347-17:1993 Methods for the calibration of vibration and shock pick-ups; part 17: testing of fixed temperature sensitivity
- ISO 5347-18:1993 Methods for the calibration of vibration and shock pick-ups; part 18: testing of transient temperature sensitivity
- ISO 5347-19:1993 Methods for the calibration of vibration and shock pick-ups; part 19: testing of magnetic field sensitivity
- ISO 5347-20:1997 Methods for the calibration of vibration and shock pick-ups – part 20: primary vibration calibration by the reciprocity method

- ISO 5347-22:1997** Methods for the calibration of vibration and shock pick-ups – part 22: accelerometer resonance testing – general methods
- ISO 5347-3:1993** Methods for the calibration of vibration and shock pick-ups; part 3: secondary vibration calibration
- ISO 5347-4:1993** Methods for the calibration of vibration and shock pick-ups; part 4: secondary shock calibration
- ISO 5347-5:1993** Methods for the calibration of vibration and shock pick-ups; part 5: calibration by earth's gravitation
- ISO 5347-6:1993** Methods for the calibration of vibration and shock pick-ups; part 6: primary vibration calibration at low frequencies
- ISO 5347-7:1993** Methods for the calibration of vibration and shock pick-ups; part 7: primary calibration by centrifuge
- ISO 5347-8:1993** Methods for the calibration of vibration and shock pick-ups; part 8: primary calibration by dual centrifuge
- ISO 5348:1998** Mechanical vibration and shock – mechanical mounting of accelerometers
- ISO 5349:1986** Mechanical vibration; guidelines for the measurement and the assessment of human exposure to hand-transmitted vibration
- ISO 5982:1981** Vibration and shock; mechanical driving point impedance of the human body
- ISO 6070:1981** Auxiliary tables for vibration generators; methods of describing equipment characteristics
- ISO 6267:1980** Alpine skis; measurement of bending vibrations
- ISO 6721-3:1994** Plastics – determination of dynamic mechanical properties – part 3: flexural vibration – resonance-curve method
- ISO 6721-3:1994/Cor 1:1995** Plastics – determination of dynamic mechanical properties – part 3: flexural vibration – resonance-curve method
- ISO 6721-4:1994** Plastics – determination of dynamic mechanical properties – part 4: tensile vibration – non-resonance method
- ISO 6721-5:1996** Plastics – determination of dynamic mechanical properties – part 5: flexural vibration – non-resonance method
- ISO 6721-6:1996** Plastics – determination of dynamic mechanical properties – part 6: shear vibration – non-resonance method
- ISO 6721-7:1996** Plastics – determination of dynamic mechanical properties – part 7: torsional vibration – non-resonance method
- ISO 6721-8:1997** Plastics – determination of dynamic mechanical properties – part 8: longitudinal and shear vibration – wave-propagation method
- ISO 6721-9:1997** Plastics – determination of dynamic mechanical properties – part 9: tensile vibration – sonic-pulse propagation method
- ISO 6954:2000** Mechanical vibration – guidelines for the measurement, reporting and evaluation of vibration with regard to habitability on passenger and merchant ships
- ISO 7096:2000** Earth-moving machinery – laboratory evaluation of operator seat vibration
- ISO 7096:1994** Earth-moving machinery – laboratory evaluation of operator seat vibration
- ISO 7505:1986** Forestry machinery; chain saws; measurement of hand-transmitted vibration
- ISO 7626-1:1986** Vibration and shock; experimental determination of mechanical mobility; part 1: basic definitions and transducers
- ISO 7626-5:1994** Vibration and shock – experimental determination of mechanical mobility – part 5: measurements using impact excitation with an exciter which is not attached to the structure
- ISO/TR 7849:1987** Acoustics; estimation of airborne noise emitted by machinery using vibration measurement
- ISO 7916:1989** Forestry machinery; portable brush-saws; measurement of hand-transmitted vibration
- ISO 7919-1:1996** Mechanical vibration of non-reciprocating machines – measurements on rotating shafts and evaluation criteria – part 1: general guidelines
- ISO 7919-2:1996** Mechanical vibration of non-reciprocating machines – measurements on rotating shafts and evaluation criteria – part 2: large land-based steam turbine generator sets
- ISO 7919-3:1996** Mechanical vibration of non-reciprocating machines – measurements on rotating shafts and evaluation criteria – part 3: coupled industrial machines
- ISO 7919-4:1996** Mechanical vibration of non-reciprocating machines – measurements on rotating shafts and evaluation criteria – part 4: gas turbine sets
- ISO 7919-5:1997** Mechanical vibration of non-reciprocating machines – measurements on rotating shafts and evaluation criteria – part 5: machine sets in hydraulic power generating and pumping plants

- ISO 7962:1987 Mechanical vibration and shock; mechanical transmissibility of the human body in the z direction
- ISO 8002:1986 Mechanical vibrations; land vehicles; method for reporting measured data
- ISO 8041:1990 Human response to vibration; measuring instrumentation
- ISO 8041:1990/Amd 1:1999 Human response to vibration – measuring instrumentation – amendment 1
- ISO 8041:1990/Cor 1:1993 Human response to vibration; measuring instrumentation; technical corrigendum 1
- ISO 8042:1988 Shock and vibration measurements; characteristics to be specified for seismic pick-ups

- ISO 8727:1997 Mechanical vibration and shock – human exposure – biodynamic coordinate systems
- ISO 8821:1989 Mechanical vibration; balancing; shaft and fitment key convention
- ISO 9022-10:1998 Optics and optical instruments – environmental test methods – part 10 combined sinusoidal vibration and dry heat or cold
- ISO 9022-15:1998 Optics and optical instruments – environmental test methods – part 15: combined digitally controlled broad-band random vibration and dry heat or cold
- ISO 9022-19:1994 Optics and optical instruments – environmental test methods – part 19:

temperature cycles combined with sinusoidal or random vibration

ISO 9688:1990 Mechanical vibration and shock; analytical methods of assessing shock resistance of mechanical systems; information

exchange between suppliers and users of analyses

ISO 9996:1996 Mechanical vibration and shock – disturbance to human activity and performance – classification

Vibration severity ranges and examples of their application
(after ISO IS 2372: Mechanical vibration of machines with operating speeds from 10 to 200 rps – basis for specifying evaluation standards)

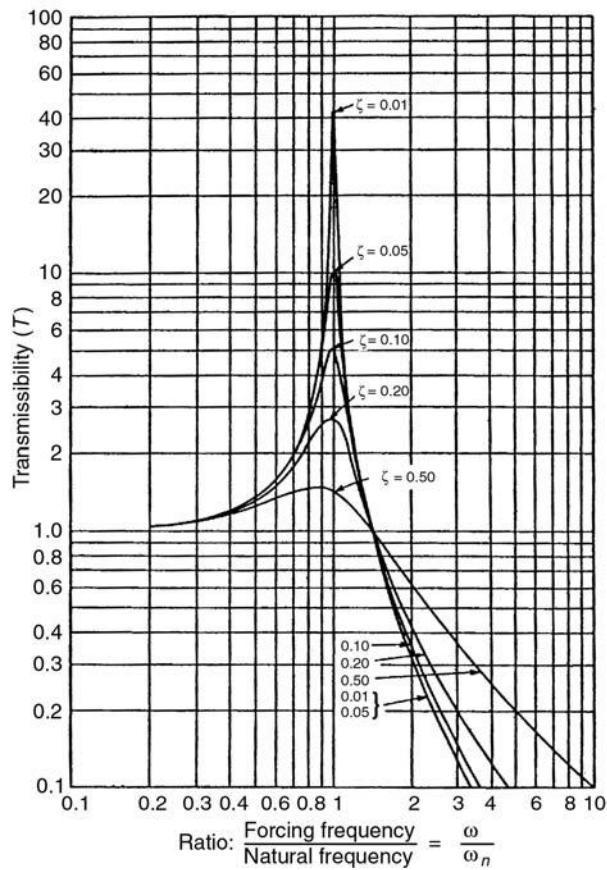

Range of vibration severity	Examples of quality judgement for separate classes of machines			
	Small machines, class I	Medium machines, class II	Large machines, class III	Turbo-machines, class IV
Limits of range, mm /s ⁻¹				
— 0.28 —	A			
— 0.45 —		A		
— 0.71 —			A	
— 1.12 —	B			
— 1.8 —		B		
— 2.8 —	C		B	
— 4.5 —		C		B
— 7.1 —	D		C	
— 11.2 —				C
— 18 —				
— 28 —		D	D	
— 45 —				D

The letters A, B, C and D represent machine vibration quality grades, ranging from good (A) to unacceptable (D).

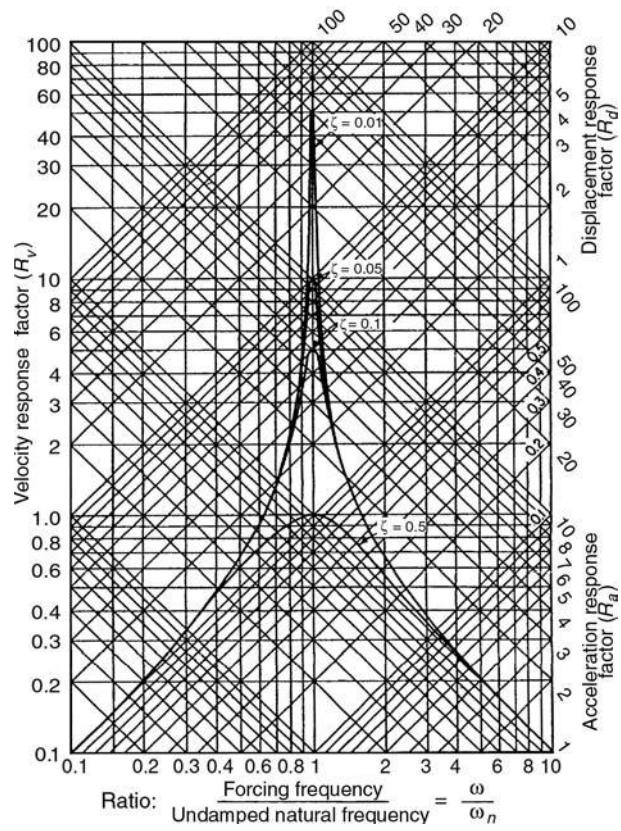

Quality judgement of vibration severity (after ISO IS 3945: The measurement and evaluation of vibration severity of large rotating machines, in situ; operating at speeds from 10 to 200 rps)

Vibration severity		Support classification		
in. /s ⁻¹	mm /s ⁻¹	Hard supports	Soft supports	
— 0.017 —	— 0.45 —	Good	Good	
— 0.028 —	— 0.71 —			
— 0.044 —	— 1.12 —			
— 0.071 —	— 1.8 —	Satisfactory	Satisfactory	
— 0.11 —	— 2.8 —	Unsatisfactory		
— 0.18 —	— 4.5 —			
— 0.28 —	— 7.1 —	Unsatisfactory		
— 0.44 —	— 11.2 —	Impermissible	Impermissible	
— 0.71 —	— 18.0 —			
— 1.10 —	— 28.0 —			
— 2.80 —	— 71.0 —			

7. FREQUENCY RESPONSE FUNCTIONS

Transmissibility of a viscous-damped system. Force transmissibility and motion transmissibility are identical numerically. The fraction of critical damping is denoted by ζ .

Response factors for a viscous-damped single-degree-of-freedom system excited in forced vibration by a force acting on the mass.

INDEX

NOTE

Page numbers in **bold** refer to major discussions. Page numbers suffixed by *T* refer to Tables; page numbers suffixed by *F* refer to Figures. *vs* denotes comparisons

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. Terms in parentheses are excluded from the initial alphabetization.

Cross-reference terms in *italics* are general cross-references, or refer to subentry terms within the same main entry (the main entry is not repeated to save space).

Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

nonlinear systems and 953–956
Poincaré' method and 957–959
Rayleigh quotient 462
Rayleigh-Ritz analysis 462–463,
691
Veldvizen, T 973
velocity
actuator sensitivity and 1140–1141
electromagnetic sensors and 1402
friction and 583–584, 589–597
LDVs and 1403–1404, 1405–1406
optical heterodyning and 1404–
1405
vertical oscillatory motion 857–859,
860F
vestibular system 857
vibrational properties
absorbers 1–9, 9–26
active damping and 351–364
actuators and smart structures 58–
81
adaptive filters 81–87
active isolation 46–48
active suppression of 48–58
aeroelasticity 87–97
averaging and 98–110
balancing and 111–124
basic diagnostics and 376–380
basic principles of 124–137
beams and 137–143
bearings and 143–152, 152–165
belts and 165–174
boundary conditions and 180–191
boundary element methods and
192–202
bounded waves 1559–1564
bridges and 202–207
cables and 209–216
civil structures and 26–36
columns and 236–243
continuous methods 286–294
damping measurement and 332–
335, 342–351, 1548–1551
damping models and 321–327,
335–342
data acquisition 364–376
digital filters and 380–395
discrete elements and 395–404
disks and 404–413
displays and 413–431
dose value (VDV) 1575–1576,
1576F, 1577F
Duhamel's Principle 1304–1308
dynamic systems and 431–438,
433F, 435F, 436F, 437F
earthquakes and 439–461
eigenvalue analysis 461–467
electrostriction 475–490

vibrational properties (*continued*)
energy methods 1308–1324
environmental testing 490–496,
496–504
equations of motion and 1324–
1332
fatigue and 505–512
feedforward control of 513–520
finite difference methods 520–530
finite element methods 530–544
flexural radiation and 1456–1480
fluids and 467–475, 544–553
flutter and 553–565
forced response and 578–582
Fourier-based identification 665–
672
friction 582–589, 589–596
fundamentals of 1290–1299
gear diagnostics 597–603
ground transportation and 603–620
guided waves 1551–1559
hand-transmitted 621–629
helicopter damping 629–642
Hilbert transforms and 642–648
hybrid control and 649–658
hysteretic damping 658–664
identification methods and 673–685
impact and 1531–1548
impulse response function 1335–
1343
intensity and 1480–1487
inverse problems 686–690
isolation theory 1487–1506, 1507–
1521
linear algebra and 710–720
linear damping matrix methods
721–726
liquid sloshing 726–740
localization and 741–751
magnetostriuctive materials 753–
762
magnitude 1572
membranes and 762–770
MEMS 771–779, 779–794
modal analysis 265–272, 805–813,
820–824, 824–829, 829–838
model-based identification and
673–685
model updating/validating and 844–
856
mode of 838–844
motion sickness and 856–861
neural networks and 869–877
noise and 877–887, 887–898
nonlinear normal modes and 918–
924
nonlinear systems and 928–943,
952–966
nonlinear testing and 1285–1289
optimal filters and 977–982
packaging and 983–989
parallel processing and 990–1001
parametric excitation and 1001–
1009
perturbation methods and 1009–
1011
