The measure and analysis of tire deflection is of significant importance to the dynamic performance of the vehicle and dynamic pavement loads. It provides insight on the possible wheel lift-off, which could have crucial implications on the vehicle performance in terms of stability, handling, traction, braking, etc. Furthermore, in this case the linear model will no longer be valid.

Various vibration performance measures discussed under the quarter-car model and represented by eqns [26]–[32] are plotted for a typical city bus in Figure 9 and Figure 10 to illustrate the expected trends.

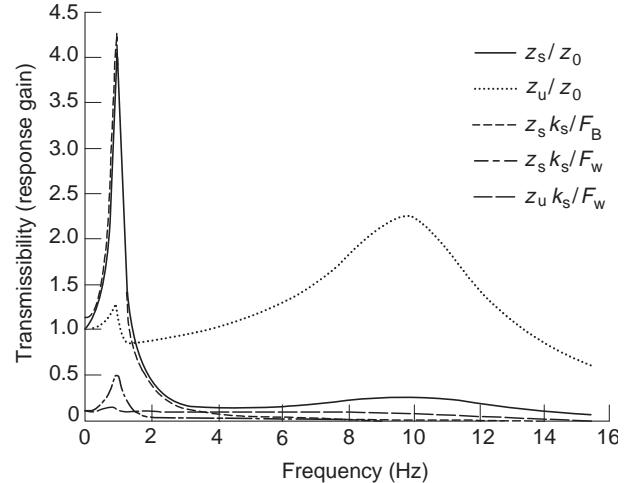

Figure 9 Sprung and unsprung mass transmissibility for various inputs (z_o, F_B, F_w)

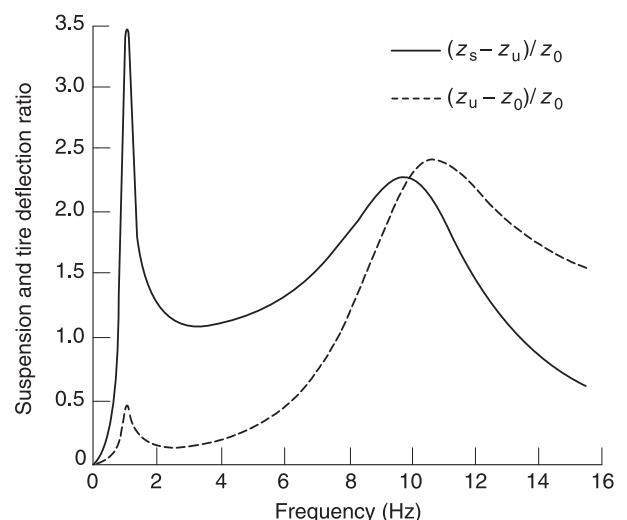

Figure 10 Suspension and tire deflection ratio.

Estimation of Ride Natural Frequencies

The quarter-car model can be simplified to estimate the natural frequencies and damping ratios associated with the vertical ride vibration. Based on the fact that sprung mass and unsprung mass natural frequencies are far apart, and the sprung mass is significantly larger than the unsprung mass, each mass can be treated as a separate independent system. Neglecting tire damping, these can be modeled as shown in Figure 11. Based on this sprung mass model, ride stiffness, k_{ride} , and effective unsprung stiffness, k_u , are defined as:

$$k_{\text{ride}} = \frac{k_t k_s}{k_t + k_s}, \quad k_u = k_t + k_s \quad [33]$$

The natural frequencies can therefore be estimated from:

$$\omega_{n_s} = \sqrt{\left(\frac{k_{\text{ride}}}{m_s}\right)}, \quad \text{and} \quad \omega_{n_u} = \sqrt{\left(\frac{k_u}{m_u}\right)} \quad [34]$$

The suspension-damping ratio, ξ , can be estimated from:

$$\xi = \frac{c_s}{2m_s\omega_n} = \frac{c_s}{2\sqrt{(k_{\text{ride}}m_s)}} \quad [35]$$

These equations provide useful tools for preliminary selection of suspension parameters for given m_s and m_u .

Guidelines and Rules of Thumb

In view of the ride quality as determined from vibration environment of vehicles, a number of guidelines

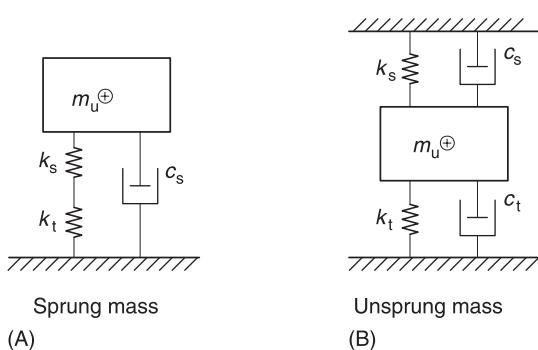

Figure 11 (A, B) Simplified quarter car model for estimation of natural frequencies.

and rules of thumb have been developed for the design of suspension systems on the basis of experimental and analytical results. These are summarized below:

- In view of the human comfort, the suspension systems should be designed to achieve low vertical mode natural frequency of the sprung mass. A limiting value for this natural frequency is approximately 1 Hz to ensure adequate rattle space and it should not be greater than 1.5 Hz for passenger vehicles.
- Forces due to wheel motions and unbalance are transmitted to the sprung mass through the suspension. The unsprung mass (wheel hop) natural frequency therefore should lie outside the frequency range of vibration to which the human body is most sensitive. This implies that the vertical mode frequency of the unsprung mass should not be less than 8 Hz. On the other hand, larger frequencies will demand stiff tire affecting ride quality. A practical value for unsprung mass natural frequency is around 10 Hz.
- Pitch and bounce frequencies should be close together. The pitch motion of the sprung mass enhances the bounce motion of the body at a location away from the c.g., such as the driver location in a long wheelbase truck or bus. The bounce natural frequency less than 1.2 times the pitch frequency gives good results.
- When a vehicle goes over a bump, the front axle is subjected to the impact occurring at $\tau_d(L/V)$ seconds before the rear axle. This will excite the pitch resonance, which is more annoying than the vertical motion. Designing rear suspension with slightly larger ride rate than the front will introduce higher frequency of oscillation for the rear than the front. This will convert the pitch motion to a bounce motion within half a cycle after the bump is passed. Based on common operating speeds, V , and wheelbase, L , the rear suspension may be assigned 20–30 percent larger ride rate, or the c.g. should be closer to the rear axle than the front.

Determination of Vehicle Model Parameters

The accuracy of vibration simulation results that can be predicted from the mathematical models are only as good as the accuracy of the system parameters. Characteristics of many elements associated with vibration analysis are strongly nonlinear. A model with linearized parameters, however, can provide good qualitative trends and comparative results. This section presents the relevant components and

their characteristics, and outlines the methodology that can be used to establish the parameters of a given ground transportation system.

Weights and Dimensions

Weights and dimensions can be established through measurement of front and rear wheel loads (W_f , W_r) as shown in **Figure 12**, and using the following relationships:

$$m_s + 2m_{uf} + 2m_{ur} = (W_f + W_r)/g = W/g \quad [36]$$

and

$$c = \frac{W_f L}{W}, \quad b = \frac{W_r L}{W}, \quad L = b + c$$

The sprung and unsprung mass components of the total weight is difficult to determine as the mass of the suspension contributes to both masses depending on the type of suspension. As a general guideline, **Table 1** may be used to estimate the total unsprung mass as a fraction of the total vehicle mass. The total unsprung mass can then be distributed to the front and back based on the suspension system installed on the vehicle. For example, for a vehicle with Wishbones in the front and solid axle in the back, the mass distribution should be assigned as: $m_{uf} = m_u(0.13/(0.13 + 0.26))$ and $m_{ur} = (m_u - m_{uf})$

Pitch mass moment of inertia, I_s , of a vehicle is a difficult parameter to estimate. Knowing the location

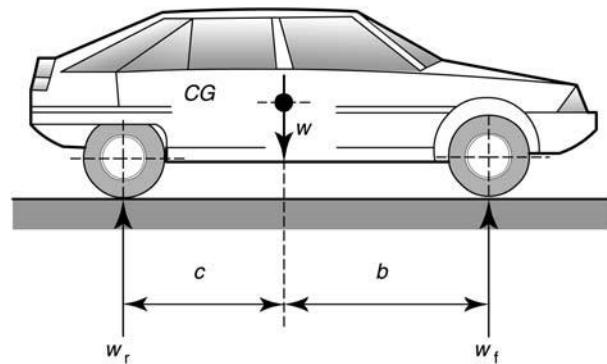

Figure 12 Location of center of gravity, c.g.

of c.g., the moment of inertia of each section of the structure and components may be established about the c.g. of the vehicle using parallel axis theorem. There are also swing tests that can be carried out to establish I_s experimentally. In the absence of the reliable data, the following empirical relationship may be used to establish I_s within 5–20 percent accuracy for most vehicles:

$$I_s = [(W_f + 0.4W_r)b^2 + 0.6W_r c^2]/g \quad [37]$$

Suspension System

Suspension system components, namely spring and damper, may be highly nonlinear in character and require nonlinear analysis of vibration. For nonlinear simulation, the equations of motions presented in this chapter may be used with spring and damper forces defined by nonlinear relationships and solving the equations by numerical methods in time domain. For comparative and qualitative studies, the component characteristics may also be linearized to employ the convenience linear analytical tools.

Suspension springs Common springs used in ground transportation suspension systems include coil, leaf and air springs. Coil springs exhibit linear relationships and its stiffness can either be measured or estimated based on its design configuration or static deflection. The leaf springs exhibit hardening characteristics and hysteresis due to interleaf and bushing friction. The hardening characteristics are introduced through change of leaf length with deflection as well as auxiliary springs. Such a characteristic is useful for vehicles that may have large variation in load. A typical leaf spring characteristic is shown in **Figure 13**. The ride motions of such suspension are often small in amplitude as shown by the small inner loop. The loop for a given motion represents the damping energy dissipated by the suspension. The most important aspect of such suspension is the fact that the effective ride stiffness of the suspension may be significantly larger than the nominal stiffness under small deflections as illustrated in the figure. Air springs are gaining popularity for commercial vehicles as they exhibit hardening characteristics and provide adaptive ride height control. For commercial

Table 1 The unsprung and sprung masses as a fraction of the total vehicle weight

Suspension type	Wishbones with coil springs	De Dion with coil springs	Swing axle with coil springs	Solid axle with coil springs	Solid axle with leaf spring
m_{ug}/W	0.13	0.15	0.18	0.22	0.26
m_{sg}/W	0.87	0.85	0.82	0.78	0.74

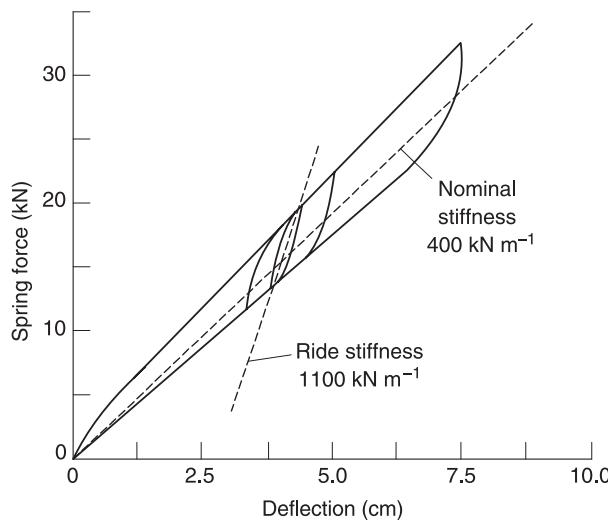

Figure 13 Loading–unloading characteristics of a leaf spring.

applications, air springs are considered most desirable to achieve improved ride quality and pavement load performance. Such a system can provide wide design parameters through variations in piston geometry. The dynamic forces developed by the air springs are related to the instantaneous relative displacements across the spring. The dynamic restoring forces are dependent on the instantaneous air pressure and effective piston area, which are related to instantaneous height of the airbag. Experimental force–deflection and effective piston area characteristics of an air spring used in urban buses for two different preloads are shown in **Figure 14** and **Figure 15**. An analytical model of the air spring can be developed based on the experimental data for given preloads.

Suspension damping Vehicle suspensions employ hydraulic dampers with blow-off and bleed-control valves to provide variable damping as a function of velocity, as well as asymmetric characteristics in

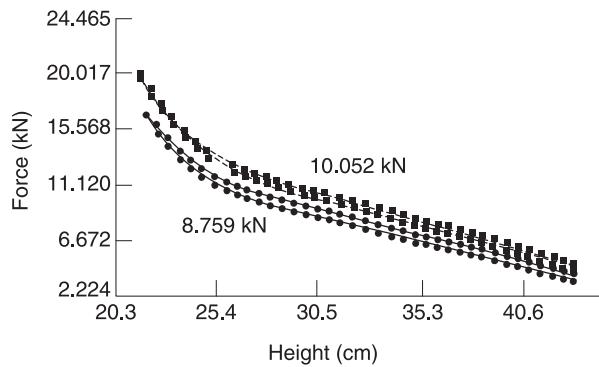

Figure 14 Force–displacement characteristics of an air spring (design height = 31.49 cm).

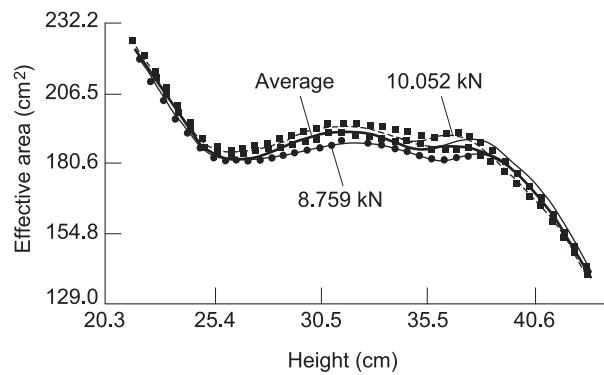

Figure 15 Effective area–displacement characteristics of an air spring (design height = 31.49 cm).

compression and rebound. Typical force–displacement and force–velocity characteristics of automotive dampers are shown in **Figure 16**. As shown, depending on the characteristics, the nonlinear force velocity relationship can be expressed by an exponent n , such that:

$$F_d = c_s z^n \quad [38]$$

The area enclosed within the force–deflection curve represents the energy dissipated by the damper over a cycle. An equivalent viscous damping coefficient may be determined from the experimentally derived area within the curves. The estimated damping coefficient, however, could be considered valid in the vicinity of the selected test frequency, ω , and magnitude, z , and is often referred to as local equivalent damping coefficient:

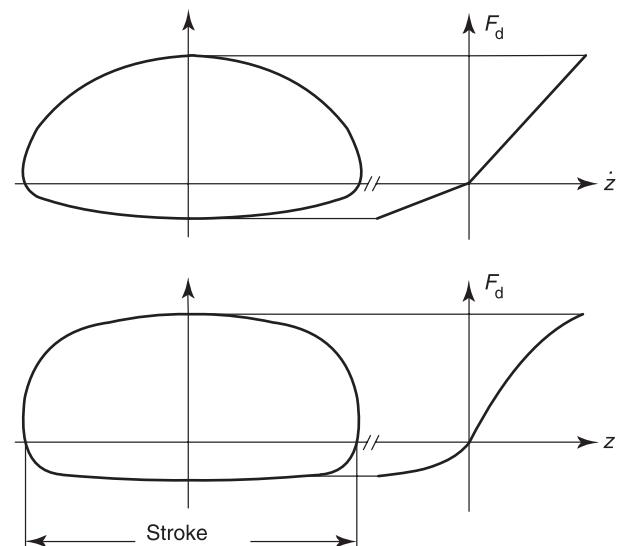

Figure 16 Typical damper force–displacement characteristics.

$$C_{eq}(\omega, z) = \frac{\text{Area}}{\pi \omega z^2} \quad [39]$$

Since such coefficients are functions of frequency and peak displacements, an iterative process can be utilized in a linear frequency domain analysis to obtain the frequency response for given amplitude of harmonic excitations. A nonlinear damper for ground vehicle with two-stage damping characteristics can be considered to exhibit piecewise linear relations with asymmetric characteristics in compression and extension, as shown in **Figure 17**. The high value of damping at low velocities is required to control resonant oscillations, whereas low value is desirable at high velocities to achieve improved vibration isolation. The piecewise linear component may be modeled using the following relationships in a time domain analysis.

$$F_d = \begin{cases} c_1 \dot{z} & 0 \leq \dot{z}_1 \leq \alpha_1 \\ c_3 \dot{z} & \alpha_2 \leq \dot{z}_1 \leq 0 \\ c_1 \alpha_1 + c_2 (\dot{z} - \alpha_1) & \dot{z} \geq \alpha_1 \\ c_3 \alpha_2 + c_4 [\dot{z}_1 - \alpha_2 \text{sgn}(\dot{z}_1)] & \dot{z} \leq \alpha_2 \end{cases}$$

where the ‘sgn’ function assumes a value of either 1 or –1 for positive and negative values of \dot{z} , respectively. Based on the principle of energy similarity, equivalent linear viscous damping coefficients for the three regions can be found as:

$$C_{eq}(\omega_i, z_i) = \begin{cases} 0.5(c_1 + c_3) & \omega_i z_i \leq \alpha_1 \\ \frac{1}{2\pi} [\pi(c_1 + c_3) + \{\sin 2\omega_i t_1 - 2\omega_i t_1\}(c_1 - c_2)] & \alpha_1 \leq \omega_i z_i \leq |\alpha_2| \\ \frac{1}{2\pi} [\pi(c_1 - c_3) + \{\sin 2\omega_i t_1 - 2\omega_i t_1\}(c_1 - c_2) \\ + 2\pi c_4 + \{\sin 2\omega_i t_2 - 2\omega_i t_2\}(c_3 - c_4)] & \omega_i z_i \geq |\alpha_2| \end{cases} \quad [40]$$

where:

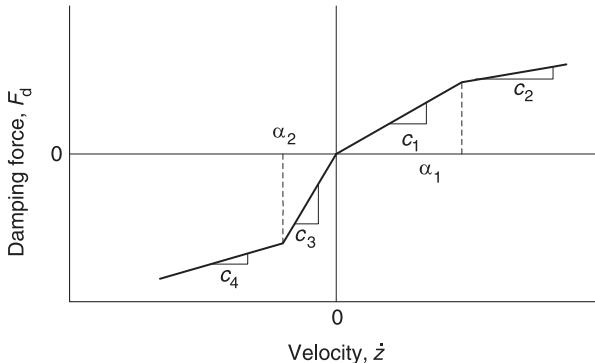

Figure 17 Characteristics of a typical nonlinear damper.

$$\omega_1 z_i = |\dot{Z}| \quad t_1 = \frac{1}{\omega} \cos^{-1} \left[\frac{\alpha_1}{\omega z} \right]$$

and:

$$t_2 = \frac{1}{\omega} \cos^{-1} \left[\frac{|\alpha_2|}{\omega z} \right], \quad t_2 > t_1$$

Similar to eqn [38], an iterative process can be utilized in a linear frequency domain analysis to obtain the frequency response for given amplitude of harmonic excitations.

Tire Properties

For a given inflation pressure, the vertical force developed by a pneumatic tire can be considered as a linear function of the tire deflection. The stiffness coefficient of the tire, however, is a function of the inflation pressure. A simple test, known as the ‘drop test’ can be carried out to establish its stiffness and damping properties using the ‘logarithmic decrement method’. The tire with a certain load (total mass, m) is allowed to fall freely ensuring that the tire remains in contact with the ground at all times. The decaying response signature, shown in **Figure 18**, can then be used to establish dynamic stiffness of the nonrolling tire:

$$k_t = \frac{m \omega_d^2}{1 - [\delta^2 / (\delta^2 + 4\pi^2)]} \quad [41]$$

$$c_t = \sqrt{\left[\frac{(4m^2 \omega_d^2) / (\delta^2 + 4\pi^2)}{(1 - \delta^2) / (\delta^2 + 4\pi^2)} \right]}$$

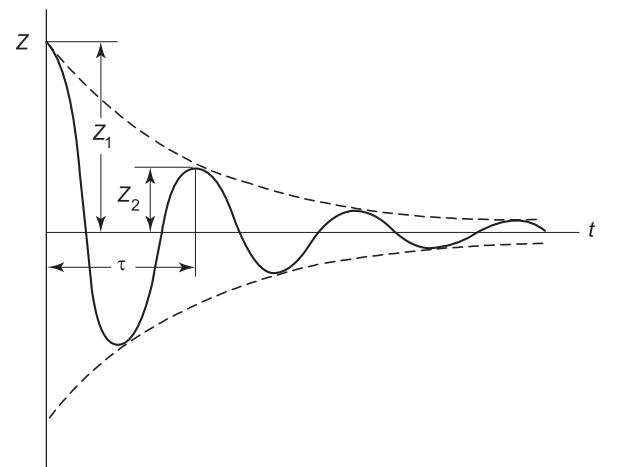

Figure 18 Response of the tire drop test.

where:

$$\omega_d = 2\pi/\tau \quad \text{and} \quad \delta = \ln(z_1/z_2)$$

The dynamic stiffness of a rolling tire may be 10–15% less than the static stiffness for typical car tires whereas for truck tires it is only about 5% less. The tire damping on the other hand reduces significantly with speed. Typical car radial tire static stiffness range between 80 and 200 kN m⁻¹ for inflation pressure in the range 100–250 kPa. Truck tires at rated pressure exhibit vertical stiffness in the range 700–1000 kN m⁻¹.

A set of linearized parameters for a range of ground vehicles relevant to the vibration analyses presented in this chapter is summarized in **Table 2**. These data are collected from various sources and estimated for multiaxle vehicles by lumping axles such that the equations derived in this chapter can be used to evaluate the ride vibrations.

Road Excitations

Roughness of a road surface is described by its elevation profile along the path over which the wheels travel. For in-plane vehicle vibration models, it is assumed that the same input is applied to the left and right wheels. For harmonic motion, the road profile is assumed to be of the sinusoidal form:

$$z_{of} = z_o \sin\left(\frac{V}{\lambda}\right)t \quad [42]$$

where V is the forward velocity and λ is the wavelength. For pitch plane, the rear wheel is subjected to the same input after a time delay of $\tau_d = L/V$:

$$z_{or} = z_o \sin\left(\frac{V}{\lambda}\right)(t - \tau_d) \quad [43]$$

While an assumption of sinusoidal input provides highly useful results for qualitative performance and comparison of designs, they could not serve as a valid basis for studying the actual vibration behavior of the vehicle. Road profiles are highly random in nature and may include abrupt motions arising from occasional potholes or discontinuities. The road surface profiles have been characterized by their statistical properties, mostly in terms of power spectral density (PSD) of the roughness. These studies have established that the road roughness follows a nearly Gaussian distribution. A parameter, referred to as roughness index (RI) and defined as the sum of road elevations measured at specified intervals over length of 1 km, is used as a serviceability index for the roads,

given by:

$$RI = \frac{1}{n\Delta x} \sum_i^n |\Delta z_i| \quad [44]$$

where n is the number of equidistant measurement points, Δz_i , is the elevation at the i th measurement location, and Δx is the measurement spacing. Based on the urban road measurements, the typical values of RI for smooth, medium, and rough roads may vary from 1.2 to 1.3, 3.2 to 3.4, and 6.4 to 6.8 respectively. The PSD of roughness properties of roads are available as a function of spatial frequency $\Omega(m^{-1})$ and the trend for a range of roads are shown in **Figure 19**. The random road profiles of various highways, secondary roads and dirt roads have been measured in many studies (for more information please see Further reading).

Temporal PSD of roughness $S(\omega)$ in terms of temporal angular frequency ω for different road surfaces may be expressed as a function of vehicle speed:

$$S(\omega) = \frac{\sigma_1^2}{\pi} \left[\frac{\lambda_1 V}{\omega^2 + \lambda_1^2 V^2} \right] \quad [45]$$

where ω denotes the angular frequency, V is vehicle speed, and λ_1 , σ_1 are coefficients to fit road type. The

Table 3 Roughness parameters for typical roads

Type of road	$\lambda_1(\text{m}^{-1})$	$\sigma_1(\text{m})$
Asphalt (smooth)	0.30	0.0033
Concrete (medium rough)	0.40	0.0056
Concrete (rough)	0.80	0.0120

spatial PSDs $S_s(\Omega)$ in terms spatial frequency $\Omega(\text{m}^{-1})$ are related to the temporal PSD and temporal frequency $\omega(\text{rad s}^{-1})$ in the following manner:

$$S(\omega) = \frac{S_s(\Omega)}{V} \quad \text{and} \quad \omega = \Omega V \quad [46]$$

Figure 19 also presents the approximations generated by eqn [45] to demonstrate the effectiveness in representation of the PSD for different roads. The roughness parameters λ_1 , σ_1 used in the computation are presented in Table 3. For linear analysis of response to random input, the transfer functions derived in the chapter may be applied directly as:

$$\text{Response}(\omega) = |T(\omega)|^2 S(\omega) \quad [47]$$

where $T(\omega)$ is the transfer function or response gain derived as a function of ω . For nonlinear analysis, a synthesized or measured time history of the road input may be used with the equations of motions and solved numerically in time domain.

HAND-TRANSMITTED VIBRATION

M J Griffin, Institute of Sound and Vibration Research,
University of Southampton, Southampton, UK

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0083

Introduction

Hand-transmitted vibration occurs where the hands or fingers grasp or push vibrating tools or workpieces. The vibration may be produced by machines in industry, agriculture, mining, construction, and transport.

Exposure of the fingers or the hands to vibration can result in various signs and symptoms of disorder. The interrelation between the signs and symptoms is not fully understood, but five types of disorder may be identified (Table 1). More than one disorder can affect a person at the same time and it is possible that the presence of one disorder facilitates the appearance of another. Confusingly, the terms vibration syndrome, or hand-arm vibration syndrome (HAVS), are sometimes used to refer to an unspecified combination of one or more of the disorders listed in Table 1.

The development of the various disorders is dependent on the vibration characteristics, the dynamic response of the fingers or hand, individual susceptibility to damage, and other aspects of the environment.

Sources of Hand-transmitted Vibration

The vibration on tools depends on tool design and method of tool use, so it is not possible to categorize

individual tool types as safe or dangerous. Table 2 lists tools and processes that are sometimes a cause for concern. Figure 1 shows vibration spectra measured on 24 tools that might sometimes be associated with injury.

Effects of Hand-transmitted Vibration

Vascular Disorders

The first published cases of the condition now most commonly known as vibration-induced white finger (VWF) are generally acknowledged to have been in Italy in 1911. VWF has subsequently been reported in many widely varying occupations in which there is exposure of the fingers to vibration.

VWF is characterized by intermittent whitening (i.e., blanching) of the fingers. The finger tips are usually the first to blanch but the affected area may extend to all of one or more fingers with continued vibration exposure. Attacks of blanching are precipitated by cold and therefore usually occur in cold conditions or when handling cold objects. The blanching lasts until the fingers rewarm and vasodilation allows the return of the blood circulation. Many years of vibration exposure often occur before the first attack of blanching is noticed. Affected persons often have other signs and symptoms, such as numbness and tingling. Cyanosis and, rarely, gangrene, have also been reported. It is not yet clear to what extent these other signs and symptoms are causes of, caused by, or unrelated to, attacks of white finger.

VWF cannot be assumed to be present merely because there are attacks of blanching. It will be necessary to exclude other known causes of similar symptoms (by medical examination) and also necessary to exclude primary Raynaud's disease (also called constitutional white finger). If there is no family history of the symptoms, if the symptoms did not occur before the first significant exposure to vibration, and if the symptoms and signs are confined to areas in contact with the vibration (e.g., the fingers, not the toes, ears, etc.), they will often be assumed to indicate VWF. Diagnostic tests for VWF are not

Table 1 Five types of disorder associated with hand-transmitted vibration exposures (a combination of these disorders is sometimes referred to as the hand-arm vibration syndrome or HAVS).

Type	Disorder
Type A	Circulatory disorders
Type B	Bone and joint disorders
Type C	Neurological disorders
Type D	Muscle disorders
Type E	Other general disorders (e.g., central nervous system)

Table 2 Some tools and processes potentially associated with vibration injuries (standards identifying type tests are indicated in parentheses)

Type of tool	Examples of tool type
Percussive metal-working tools	Riveting tools (ISO 8662-2) Caulking tools (ISO 8662-5) Chipping hammers (ISO 8662-2) Clinching and flanging tools (ISO 8662-10) Impact wrenches (ISO 8662-7) Impact screwdrivers (ISO 8662-7) Nut runners (ISO 8662-7) Scaling hammers Needle guns (ISO 8662-14) Nibbling machines and shears (ISO 8662-10) Swaging
Grinders and other rotary tools	Pedestal grinders Hand-held grinders (ISO 8662-4; ISO 8662-8) Hand-held sanders (ISO 8662-4; ISO 8662-8) Hand-held polishers (ISO 8662-4; ISO 8662-8) Flex-driven grinders/polishers Rotary burring tools Files
Percussive hammers and drills used in mining, demolition, road construction, and stone working	Hammer drill (ISO 8662-3) Rock drills (ISO 8662-3) Tampers and rammers (SO 8662-9) Road breakers (ISO 8662-5) Stone-working tools (ISO 8662-14)
Forest and garden machinery	Chain saws (ISO 7505) Antivibration chain saws (ISO 7505) Brush saws Mowers (ISO 5395) Hedge cutters and trimmers Barking machines Stump grinders
Other processes and tools	Nailing gun (ISO 8662-14) Stapling gun (ISO 8662-11) Pad saws (ISO 8662-12) Circular saws (ISO 8662-12) Scabblers Engraving pens Shoe-pounding-up machines Vibratory rollers Concrete vibrothickeners Concrete leveling vibrotables Motorcycle handle bars Pedestrian-controlled machines

infallible indicators of the disease, but the measurement of finger systolic blood pressure following finger cooling and the measurement of finger rewarming times following cooling can be useful.

The severity of the effects of vibration may be recorded by reference to the stage of the disorder. The staging of VWF is based on verbal statements made by the affected person. In the Stockholm Workshop staging system, the staging is influenced by both the frequency of attacks of blanching and the areas of the digits affected by blanching (Table 3).

A scoring system is used to record the areas of the digits affected by blanching (Figure 2). The scores correspond to areas of blanching on the digits commencing with the thumb. On the fingers a score of 1 is given for blanching on the distal phalanx, a score of 2 for blanching on the middle phalanx, and a score of 3 for blanching on the proximal phalanx. On the thumbs the scores are 4 for the distal phalanx and 5 for the proximal phalanx. The blanching score may be based on statements from the affected person or on the visual observations of a designated observer.

Neurological Disorders

Numbness, tingling, elevated sensory thresholds for touch, vibration, temperature and pain, and reduced nerve conduction velocity are considered to be separate effects of vibration, and not merely symptoms of VWF. A scale for reporting the extent of vibration-induced neurological effects of vibration has been proposed (Table 4). This staging is not currently related to the results of any specific objective test: the sensorineuronal stage is a subjective impression of a physician based on the statements of the affected person or the results of any available clinical or scientific testing. Neurological disorders are sometimes identified by screening tests using measures of sensory function, such as the thresholds for feeling vibration, heat, or cold in the fingers.

Table 3 Stockholm Workshop scale for the classification of vibration-induced white finger.

Stage	Grade	Description
0		No attacks
1	Mild	Occasional attacks affecting only the tips of one or more fingers
2	Moderate	Occasional attacks affecting distal and middle (rarely also proximal) phalanges of one or more fingers
3	Severe	Frequent attacks affecting all phalanges of most fingers
4	Very severe	As in stage 3, with trophic skin changes in the finger tips

If a person has stage 2 in two fingers on the left hand and stage 1 in a finger of the right hand, the condition may be reported as 2L(2)/1R(1). There is no defined means of reporting the condition of digits when this varies between digits on the same hand. The scoring system is more helpful when the extent of blanching is to be recorded.

Table 4 Proposed sensorineural stages of the effects of hand-transmitted vibration

Stage	Symptoms
0 _{sn}	Exposed to vibration but no symptoms
1 _{sn}	Intermittent numbness with or without tingling
2 _{sn}	Intermittent or persistent numbness, reduced sensory perception
3 _{sn}	Intermittent or persistent numbness, reduced tactile discrimination, and/or manipulative dexterity

Muscular Effects

Workers exposed to hand-transmitted vibration sometimes report difficulty with their grip, including reduced dexterity, reduced grip strength, and locked grip. Muscle activity may be of great importance to tool users since a secure grip can be essential to the performance of the job and the safe control of a tool. The presence of vibration on a handle may encourage the adoption of a tighter grip than would otherwise occur and a tight grip may increase the transmission of vibration to the hand. If the chronic effects of vibration result in reduced grip, this may help to

protect operators from further effects of vibration, but interfere with both work and leisure activities.

Articular Disorders

Surveys of the users of some hand-held tools have found evidence of bone and joint problems, most often among workers operating percussive tools such as those used in metal-working jobs and mining and quarrying. It is speculated that some characteristic of such tools, possibly the low-frequency shocks, is responsible. Some of the reported injuries relate to specific bones and suggest the existence of cysts, vacuoles, decalcification, or other osteolysis, degeneration, or deformity of the carpal, metacarpal, or phalangeal bones. Osteoarthritis and olecranon spurs at the elbow, and other problems at the wrist and shoulder are also documented. There is not universal acceptance that vibration is the cause of articular problems and there is currently no dose-effect relation which predicts their occurrence. In the absence of specific information, it seems that adherence to current guidance for the prevention of VWF may provide reasonable protection.

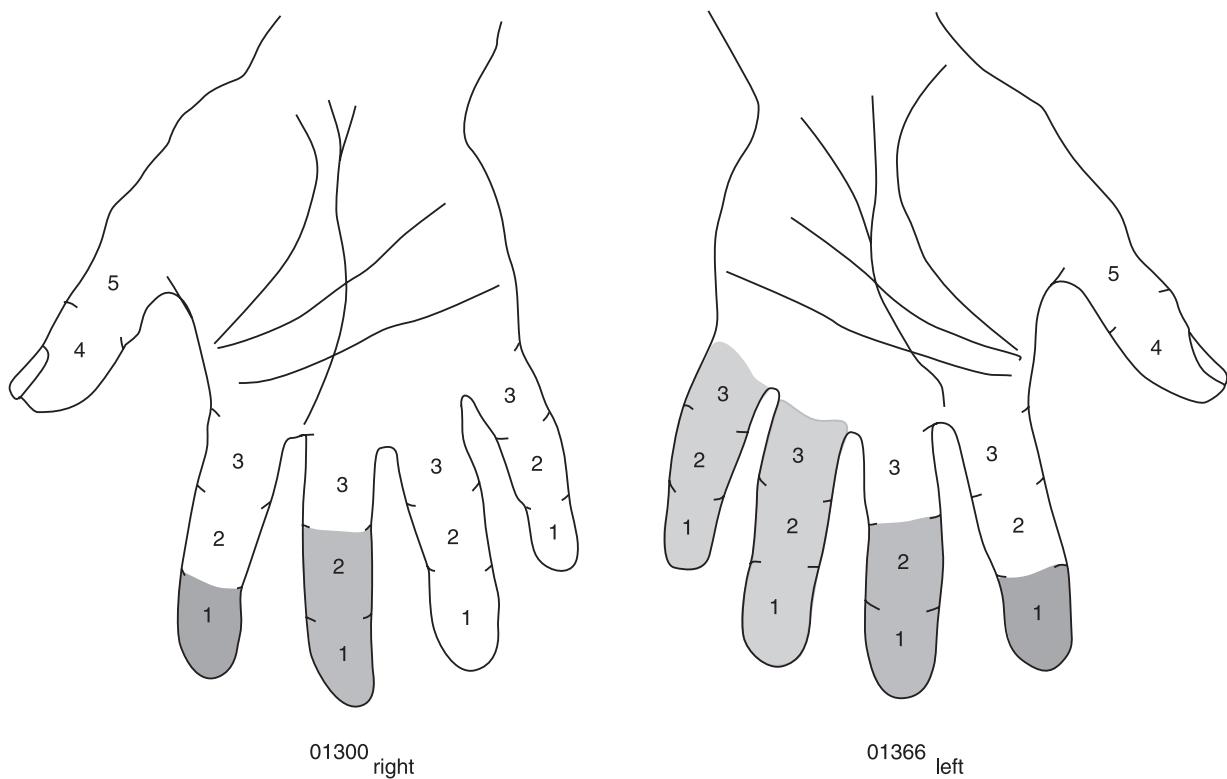

Figure 2 Method of scoring the areas of the digits affected by blanching. The blanching scores for the hands shown are 01300_{right}, 01366_{left}.

Other Effects

Hand-transmitted vibration may not only affect the fingers, hands, and arms: studies have found problems such as headaches and sleeplessness among tool users and have concluded that these symptoms are caused by hand-transmitted vibration. Although these are real problems to those affected, they are subjective effects which are not accepted as real by all researchers. Research is seeking a physiological basis for such symptoms. It currently appears reasonable to assume that the adoption of the modern guidance to prevent VWF will also provide some protection from any other effects of hand-transmitted vibration within, or distant from, the hand.

Preventive measures

Table 5 summarizes preventive measures that may be appropriate for management, tool manufacturers, technicians, physicians, and tool users. When there is reason to suspect that hand-transmitted vibration may cause injury, the vibration at tool-hand interfaces should be measured. It will then be possible to predict whether the tool or process is likely to cause injury and whether any other tool or process could give a lower vibration severity. The duration of exposure to vibration should also be quantified. Reduction of exposure duration may include the provision of breaks in exposure during the day and, if possible, prolonged periods away from vibration exposure. For any tool or process having a vibration magnitude sufficient to cause injury there should be a system to quantify and control the maximum daily duration of exposure of any individual.

Current standards imply that most commonly available gloves do not normally provide effective attenuation of the vibration on most tools. Gloves and cushioned handles may reduce the transmission of high frequencies of vibration but the standards imply that these frequencies are not usually the primary cause of disorders. Gloves may protect the hand from other forms of mechanical injury (e.g., cuts and scratches) and protect the fingers from temperature extremes. Warm hands are less likely to suffer an attack of finger blanching and some consider that maintaining warm hands while exposed to vibration may also lessen the damage caused by the vibration.

Workers who are exposed to vibration magnitudes sufficient to cause injury should be warned of the possibility of vibration injuries and educated on the ways of reducing the severity of their vibration exposures. They should be advised of the symptoms to look out for and told to seek medical attention if the symptoms appear. There should be preemployment

Table 5 Preventive measures to consider when persons are exposed to hand-transmitted vibration

Group	Action
Management	Seek technical advice Seek medical advice Warn exposed persons Train exposed persons Review exposure times Policy on removal from work
Tool manufacturers	Measure tool vibration Design tools to minimize vibration Ergonomic design to reduce grip force Design to keep hands warm Provide guidance on tool maintenance Provide warning of dangerous vibration
Technical at workplace	Measure vibration exposure Provide appropriate tools Maintain tools Inform management
Medical	Preemployment screening Routine medical checks Record all signs and reported symptoms Warn workers with predisposition Advise on consequences of exposure Inform management
Tool user	Use tool properly Avoid unnecessary vibration exposure Minimize grip and push forces Check condition of tool Inform supervisor of tool problems Keep warm Wear gloves when safe to do so Minimize smoking Seek medical advice if symptoms appear Inform employer of relevant disorders

medical screening wherever a subsequent exposure to hand-transmitted vibration may reasonably be expected to cause vibration injury. Medical supervision of each exposed person should continue throughout employment at suitable intervals, possibly annually.

Standards for the Evaluation of Hand-transmitted Vibration

International and National Standards

International Standard 5349 employs a frequency weighting (called W_h in British Standard 6842) to quantify the severity of hand-transmitted vibration over the frequency range 8–1000 Hz (Figure 3). This weighting is applied to measurements of vibration

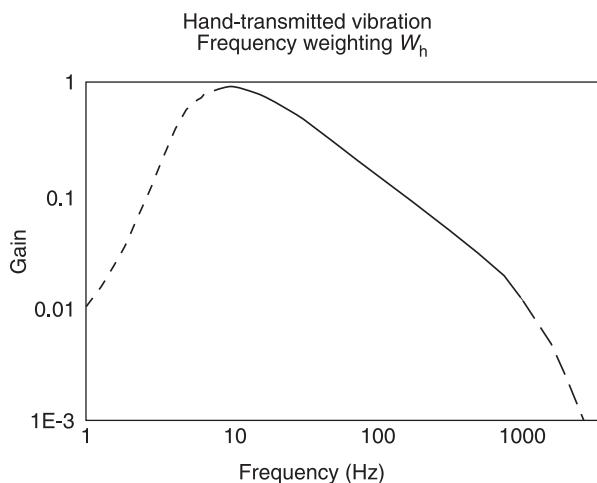

Figure 3 Frequency weighting W_h (shown here as an asymptotic weighting between 8 and 1000 Hz; when evaluating one-third octave band spectra the frequency range is specified as 6.3–1250 Hz).

acceleration in each of the three translational axes at the point of entry of vibration to the hand. Measurements of tool vibration should be obtained with representative operating conditions. The standards imply that if two tools expose the hand to vibration for the same period of time, the tool having the lowest frequency-weighted acceleration will be least likely to cause injury or disease. In Figure 2, the vibration spectra on 24 tools are shown before and after the application of frequency weighting W_h .

Current standards for the evaluation of hand-transmitted vibration use the concept called equal energy so that a complex exposure pattern of any duration during the day can be represented by the equivalent value for an exposure of 8 h (4 h in ISO 5349, 1986). For an exposure of duration, t , to a frequency-weighted r.m.s. acceleration, a_{hw} , the 8-h energy-equivalent acceleration, $a_{hw(eq, 8h)}$, is given by:

$$a_{hw(eq, 8h)} = a_{hw} \sqrt{(t/T_{(8)})} \quad [1]$$

where $T_{(8)}$ is 8 h (in the same units as t). The value of $a_{hw(eq, 8h)}$ is sometimes denoted by $A(8)$.

A relation between years of vibration exposure, E , the 4-h energy-equivalent frequency-weighted acceleration, $a_{hw(eq, 4h)}$, and the predicted prevalence of finger blanching, C , was proposed in an Annex to International Standard 5349 (1986) (Table 6 and Figure 4):

$$C = 100 \cdot \left[\frac{a_{hw(eq, 4h)} \cdot E}{95} \right]^2 \quad [2]$$

The values in Table 6 and Figure 4 refer to frequency-weighted acceleration (i.e., referenced to the frequency range 8–16 Hz after passing through the filter shown in Figure 3). British Standard 6842 (1987) offers similar guidance, but is restricted to a 10% prevalence of VWF. Figure 5 shows how the magnitudes required for a predicted prevalence of 10% VWF after 8 years are assumed to depend on vibration frequency from 8 to 1000 Hz for exposure durations from 1 min to 8 h per day.

The frequency weighting, the time dependency and the dose–effect information used in ISO 5349 (1986) are based on less than complete information, and such information as exists has been interpolated, extrapolated, and simplified for practical convenience. Consequently, the percentage of affected persons in any group of exposed persons will not always closely match the values shown in Table 6 or Figures 4 and 5. Additionally, the number of persons affected by vibration will depend on the rate at which persons enter and leave a group exposed to vibration.

EU Machinery Safety Directive

The Machinery Safety Directive of the European Community (89/392/EEC) states: machinery must be so designed and constructed that risks resulting from vibrations produced by the machinery are reduced to the lowest level, taking account of technical progress and the availability of means of reducing vibration, in particular at source. Instruction handbooks for hand-held and hand-guided machinery should specify the equivalent acceleration to which the hands or arms are subjected where this exceeds a stated value (currently a frequency-weighted acceleration of 2.5 ms^{-2} r.m.s.). The relevance of any such value will depend on the test conditions to be specified in type-testing standards (see International Standard 8662 Part 1 (1988); Table 2 provides a guide to other parts of ISO 8662). In use, many hand-held vibrating tools exceed 2.5 ms^{-2} r.m.s.

Table 6 Number of years before blanching develops in 10–50% of vibration-exposed persons according to International Standard 5349 (1986)

Weighted acceleration, $a_{hw(eq, 4h)}$	Percentage of population affected by finger blanching					
	(ms $^{-2}$ r.m.s.)	10%	20%	30%	40%	50%
2		15	23	>25	>25	>25
5		6	9	11	12	14
10		3	4	5	6	7
20		1	2	2	3	3
50		<1	<1	<1	1	1

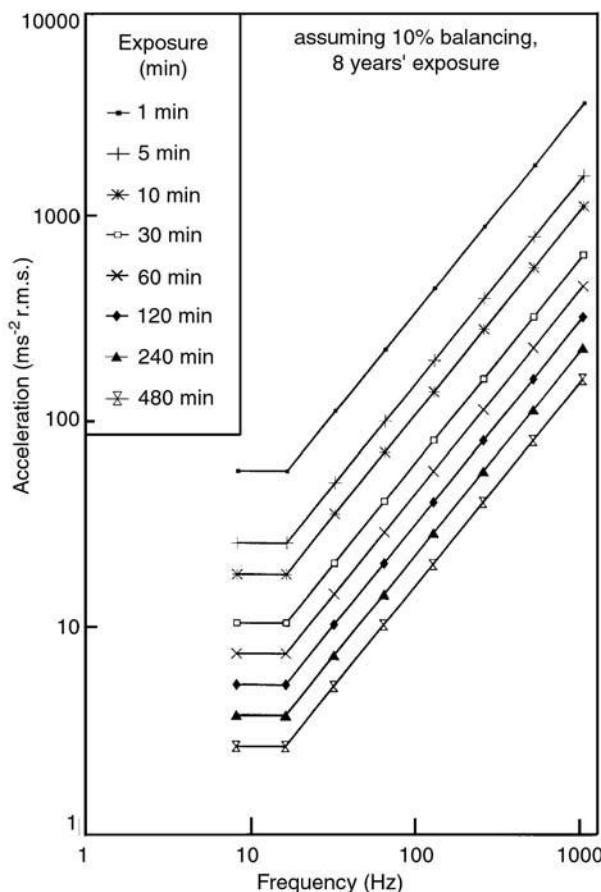

Figure 5 Acceleration magnitudes predicted to give 10% prevalence of vibration-induced white finger after 8 years for daily exposure durations from 1 min to 8 h (according to International Standard 5349, 1986).

Proposed EU Physical Agents Directive The opening principles of a proposed Council Directive on the minimum health and safety requirements regarding hand-transmitted vibration are: Taking account of technical progress and of the availability of measures to control the physical agent at source, the risks arising from exposure to the physical agent must be reduced to the lowest achievable level, with the aim of reducing exposure to below the threshold level

For hand-transmitted vibration, the proposed EU Directive currently identifies a threshold level ($a_{hw(eq, 8h)} = 1.0 \text{ ms}^{-2} \text{ r.m.s.}$), an action level ($a_{hw(eq, 8h)} = 2.5 \text{ ms}^{-2} \text{ r.m.s.}$), and an exposure limit value ($a_{hw(eq, 8h)} = 5.0 \text{ ms}^{-2} \text{ r.m.s.}$). The manner in which these 8-h equivalent magnitudes correspond to higher magnitudes at shorter durations is shown in Figure 6. When exposures exceed the threshold level it is proposed that workers must receive information concerning the potential risk of exposure to hand-transmitted vibration. The action level is intended to identify the conditions in which training in precautionary measures is required, an assessment of the vibration is to be made, and a program of preventive measures is to be instituted. The proposed Directive also indicates that when the action level is exceeded workers shall have the right to regular health surveillance, including routine examinations designed for the early detection of disorders caused by hand-transmitted vibration. If the exposure limit value is exceeded, health surveillance must be carried out and member states of the Community will be expected to control the harmful effects.

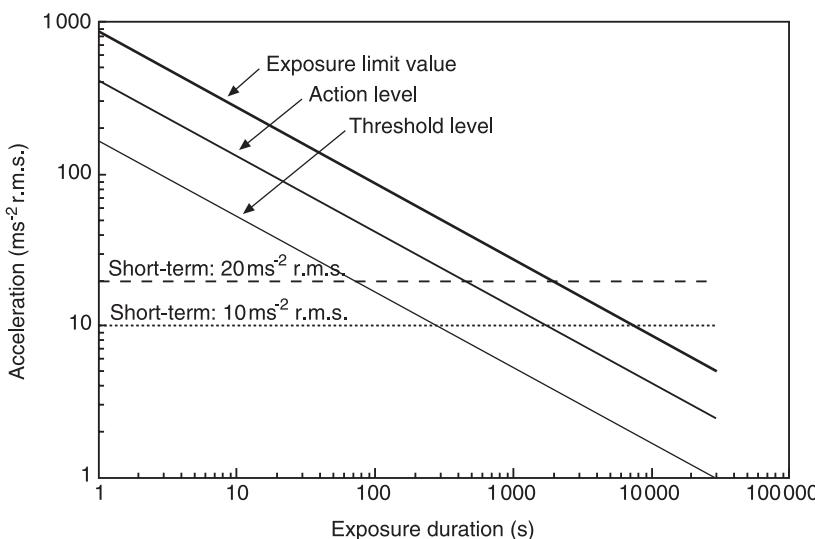

Figure 6 Threshold level, action level, and exposure limit proposed in a draft EC Directive on Physical Agents (Commission of the European Communities, 1994). In addition to these three criteria, effort shall be made to reduce the hazard when a short-term (a few minutes) equivalent acceleration exceeds 10 ms^{-2} r.m.s. Exposure to a short-term (a few minutes) equivalent acceleration equal to or greater than 20 ms^{-2} r.m.s. is considered a hazardous activity.

The extremely high magnitudes for short durations shown in Figure 6 should not be considered to be representative of their safety: these high magnitudes are a consequence of the equal energy concept described above. The proposed Directive identifies exposures ‘for a short-term (a few minutes) equivalent acceleration equal to or greater than 20 ms^{-2} ’ as ‘activities with increased risk’ which must be declared to the authority responsible. Member states would be required to ensure that appropriate measures are taken in order to control the risks associated with these activities. Equipment which transmits to the hand-arm system a short-term (a few minutes) equivalent acceleration equal to or greater than 20 ms^{-2} r.m.s. must be marked. For lower magnitudes of vibration, the proposed Directive states: Where the activity involves the use of work equipment which transmits to the hand-arm system a short-term (a few minutes) equivalent acceleration exceeding 10 ms^{-2} , increased efforts shall be made to reduce the hazard, with priority to the use of low-vibration equipment and processes, including the revision of product design and work practice. Pending the effective implementation the duration of continuous exposure shall be reduced.

The proposed Directive is based on the root-sums-of-squares (r.s.s.) of the frequency-weighted accelerations in three axes, although an axis can be omitted if the values are less than 50% of the value in another axis at the same location. This differs from International Standard 5349 (1986) which is based on the axis having the highest weighted acceleration; how-

ever, a forthcoming revision of ISO 5349 is expected to change the evaluation method to the use of r.s.s. This proposed EU directive may be expected to be modified prior to finalization.

The helicopter is one of the most severe vibration environments among aerospace vehicles, and vibration damping is of critical importance when enhancing aeromechanical stability and passenger comfort. The model 360 rotor hub (Figure 1) illustrates the typical hub configuration of an articulated rotor. The rotor blade has three degrees of freedom: (1) pitch, or rotation about the blade's longitudinal axis; (2) flap,

or out-of-plane bending; and (3) lag, or in-plane bending. The need to augment damping is critical to mitigate aeromechanical instabilities, including pitch-flap, flag-lag, and ground and air resonance. Pitch-flap flutter is a modal coalescence of blade flap and torsion modes. Flap-lag flutter is an instability of primarily the lag mode, with participation from the flap mode. The flap mode is heavily damped aerodynamically, whereas the lag mode is very lightly damped. Ground resonance is a modal coalescence of the rotor lag mode with the landing gear modes of the helicopter, while the rotor is spinning up to its operational rotational frequency of 1/rev (typically 5–7.5 Hz). Air resonance is a modal coalescence of the lag mode with the rigid body modes of the helicopter while it is in high-speed forward flight. The latter three aeromechanical instabilities can be mitigated via damping augmentation, whereas pitch-flap flutter, as in fixed-wing flutter, must be mitigated in rotor design: the chordwise center of gravity must be kept at or ahead of the quarter-chord point (aerodynamic center) of the blade.

In advanced rotor designs such as bearingless and hingeless rotors, the lag and flap hinges, as well as the pitch bearing, are eliminated, and a flexure or flex-beam is introduced. The Comanche helicopter has such an advanced rotor (Figure 2). In conventional articulated rotors, ground resonance is typically mitigated using hydraulic or elastomeric dampers. Hingeless and bearingless rotors are designed to be soft in-plane rotors, which implies that the lag mode or lag/rev frequency is less than the rotor rotational or 1/rev

frequency. The rotor is soft in-plane due to stress considerations. As a result, elastomeric lag dampers are typically used to mitigate aeromechanical instabilities. Elastomeric dampers have some advantages: first, they have no moving parts, and second, the leakage problems that are present in hydraulic dampers are eliminated. However, a key disadvantage is that elastomeric damper behavior is nonlinear and highly dependent on frequency, temperature, and loading conditions such as preload and excitation amplitudes.

Elastomeric devices are added to the rotor hub to achieve two very different objectives: augmentation of flexibility, and augmentation of lag mode damping. Laminated metal-elastomeric bearings are used to increase the period of vibrations by softening, or introducing flexibility into, the rotor hub structures in order to isolate vibrations. Some examples of these type of bearings are shown in **Figure 3**. However, the primary focus of this article is to describe the behavior and analysis of elastomeric lag dampers used to augment stability of helicopter rotors with respect to air and ground resonance.

Figure 3 (See Plate 39). Laminated metal-elastomeric bearings for isolating transmission gear box vibrations in helicopters. Courtesy of Paulstra-Vibrachoc.

pers were tested in a 1/6th Froude-scale rotor model and it was shown that the limit-cycle instabilities that were observed with elastomeric dampers can be substantially mitigated. A comparison between elastomeric and hybrid fluidic-elastomeric dampers shows that the former has stiffness and damping properties that are nonlinear functions of the displacement amplitude, whereas the latter exhibits relatively constant properties. Several lag dampers are shown in **Figure 4**.

The mechanical properties of lag mode dampers can vary from one damper to the next, so that they are carefully matched sets for a given rotor. Matched sets of dampers are used to minimize the impact of varying damper mechanical properties on rotor tracking conditions. The key to matching the properties of these dampers is to match their linearized damping and stiffness properties as a function of excitation amplitude, temperature, and stiffness. The methods for performing such a characterization will now be presented.

Damping Augmentation

The lag motion in helicopter rotors occurs at two frequencies: the lead-lag regressive frequency and the 1/rev frequency. Under these conditions, the damping in elastomers has been shown to degrade substantially at low amplitudes, thus causing undesirable limit cycle oscillations. In order to circumvent the problems associated with the elastomeric dampers, hybrid fluidic-elastomeric dampers have been used. Hybrid fluidic-elastomeric dampers use elastomers in conjunction with fluids. The fluid adds a viscous component to the energy dissipation mechanism in the dampers. Moreover, the inclusion of the fluid expands the dynamic range of forces generated by the damper. Hybrid fluidic-elastomeric lead-lag dam-

Figure 4 (See Plate 40). Lead-lag dampers are used to augment stability of helicopter rotor blade in-plane bending modes. Courtesy of Paulstra-Vibrachoc.

Example: Filled Elastomer Lag Damper

Rather than cataloging properties of various elastomers used in lag dampers, a primary objective of this article is to introduce how an elastomeric damper would be tested, characterized, and analyzed for use on a helicopter. The primary goal of such a testing program is to characterize the behavior of the damper due to steady-state sinusoidal excitation at the lag/rev frequency, and to assess the effects of the excitation at the rotor or 1/rev frequency on damping performance at the lag/rev frequency. This example is typical of what would be done for elastomeric dampers, as well as for fluidic, hybrid fluidic-elastomeric, and controllable fluid-based dampers.

Elastomeric Damper Testing

For our example, we will present the testing and characterization of double lap shear specimens incorporating Paulstra Industries material E136, which is a silicone-based filled elastomer. These specimens consist of three brass plates and a 10 mm (0.4 in) layer of damping material applied symmetrically across the center plate.

One of the important effects of a filler on viscoelastic material behavior is stress-softening. If a filled sample is stretched for the first time to 100% followed by a release in the strain and then stretched again to 200%, there is a softening in strain up to 100%, after which it continues in a manner following the first cycle. If this stress-strain is repeated in a third cycle, we can again see a softening up to 200% due to the previous strain history. This stress-softening or memory effect was first discovered by Mullins, and is called the Mullins effect. The Mullins effect was taken into account during these single-frequency tests. The material was first subjected to 300 cycles of sinusoidal excitation at 1 Hz at 5 mm (200 mil) of amplitude, which was the maximum amplitude in the chosen test matrix. All subsequent excitations were below this amplitude. During a test run, the material would be periodically excited for an amplitude of 5 mm (200 mil) at 1 Hz frequency to reinforce this memory effect. This was one of the ways in which consistency of results was ensured.

Because a viscoelastic material undergoes relaxation when subjected to loads, it requires a certain amount of time to stabilize and yield a steady value of force when a constant displacement is applied. Moreover, as an elastomeric damper is subjected to dynamic loading, the temperature of the damping material increases. This self-heating phenomenon is the result of energy dissipation via hysteresis. The temperature of the specimen can increase significantly in the first 30–50 s. Eventually, thermal equili-

brium is established between the material, brass plates, and the environment. Based on preliminary tests, we concluded that, for these specimens, the dynamic relaxation, self-heating, and other unsteady effects require about 250 s to reach steady state. Data for characterization purposes were taken after the material properties had reached steady state.

The double lap shear specimens in this example were tested on a 5500 lb MTS servo-hydraulic testing machine. A schematic diagram of the system is shown in Figure 5.

Two types of excitation are typically studied: single-frequency sinusoidal displacement at the lag/rev frequency or a single frequency test, and the sum of two sinusoidal displacements at the lag/rev and 1/rev frequencies or a dual-frequency test.

Single-frequency testing To obtain consistent results, a sinusoidal input was applied at a given amplitude and displacement for 300 s and data were collected at the end of this period. These single-frequency tests are typically conducted at the lag/rev frequency, which was nominally $\Omega_{\text{lag}} \approx 5.0 \text{ Hz}$ for this example. Additional single-frequency testing is sometimes performed at the rotor rotational frequency or 1/rev, which in this case was $\Omega_1 = 7.5 \text{ Hz}$. However, only sinusoidal testing at the lag/rev frequency will be

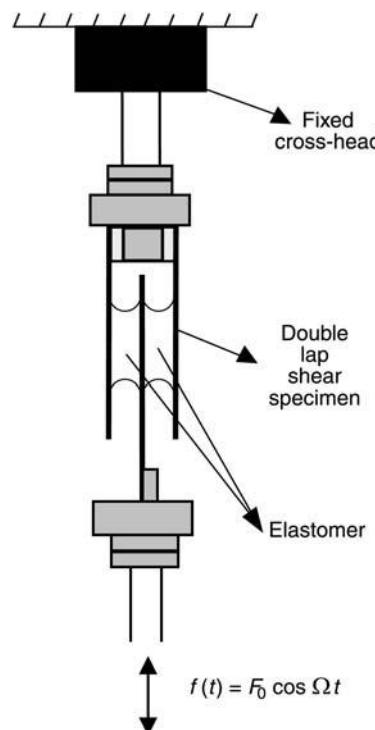

Figure 5 Schematic of MTS servo-hydraulic material testing system showing the double lap shear specimen.

considered. During each test, we measured 20 cycles of force vs displacement data and then calculated the force vs velocity hysteresis cycles for each test condition. The hysteresis cycle force and displacement data collected during each experiment were acquired on a PC-based data acquisition system and were unavoidably noisy. However, the independent displacement variable was sinusoidal, so that a periodic Fourier series was used to eliminate, as much as possible, the effects of this noise in the input displacement signal, and the subsequent differentiations to obtain the input velocity and acceleration signals. The Fourier series expansion of the displacement was taken as:

$$x(t) = \frac{x_0}{2} + \sum_{k=1}^{\infty} (x_{c,k} \cos k\Omega_{\text{lag}}t + x_{s,k} \sin k\Omega_{\text{lag}}t) \quad [1]$$

where:

$$x_{c,k} = \frac{\Omega_{\text{lag}}}{\pi k} \int_0^{2\pi k/\Omega_{\text{lag}}} x(t) \cos k\Omega_{\text{lag}}t dt \quad [2]$$

$$x_{s,k} = \frac{\Omega_{\text{lag}}}{\pi k} \int_0^{2\pi k/\Omega_{\text{lag}}} x(t) \sin k\Omega_{\text{lag}}t dt \quad [3]$$

The bias and higher harmonics were then filtered out, and only the harmonic at the frequency of interest, Ω_{lag} , was retained, so that the displacement signal was reconstructed as:

$$x(t) = X_{c,1} \cos \Omega_{\text{lag}}t + X_{s,1} \sin \Omega_{\text{lag}}t \quad [4]$$

Calculating the velocity signal from the displacement signal using a finite difference method tends to accentuate any noise in the displacement signal. We can exploit the sinusoidal nature of the input displacement signal by differentiating the Fourier series expansion from eqn [4] to obtain:

$$\dot{x}(t) = -\Omega_{\text{lag}} X_{c,1} \sin \Omega_{\text{lag}}t + \Omega_{\text{lag}} X_{s,1} \cos \Omega_{\text{lag}}t \quad [5]$$

However, the force signal is typically not filtered because the damper response is nonlinear and it cannot be determined *a priori* exactly which harmonics contributed to damper response and/or noise. Therefore, it is typical to be conservative, and use the measured (unfiltered) force data in both characterization and model parameter identification studies.

Dual-frequency testing For the dual-frequency testing in this example, the 1/rev frequency was chosen as $\Omega_1 = 7.5$ Hz while the lag/rev was chosen as $\Omega_{\text{lag}} = 5$ Hz. In general, a dual-frequency displacement signal has the form:

$$x(t) = X_{\text{lag}} \sin \Omega_{\text{lag}}t + X_1 \sin \Omega_1 t \quad [6]$$

The resulting signal contains the product of two harmonics $\Omega_1 + \Omega_{\text{lag}}$ and $\Omega_1 - \Omega_{\text{lag}}$. It is periodic with a period equal to the frequency corresponding to the highest common factor of these two harmonics, which in this case is $\Omega = 2.5$ Hz. The displacement signal was filtered by expanding as a Fourier series expansion of many harmonics, N , with a base frequency of $\Omega = 2.5$ Hz, or:

$$x(t) = \frac{X_0}{2} + \sum_{k=1}^n (X_{c,k} \cos k\Omega t + X_{s,k} \sin k\Omega t) \quad [7]$$

and setting the bias term, $X_0 = 0$. In this example, the second harmonic, $2\Omega = \Omega_{\text{lag}} = 5$ Hz, and the third harmonic, $3\Omega = \Omega_1 = 7.5$ Hz, so that only the first three harmonics need to be included in the above Fourier series expansion, or $n = 3$, and noise is eliminated from the displacement. The velocity in the dual-frequency case was determined by differentiating the Fourier series expansion of the displacement signal, so in general:

$$\dot{x}(t) = \sum_{k=1}^n (-k\Omega X_{c,k} \sin k\Omega t + k\Omega X_{s,k} \cos k\Omega t) \quad [8]$$

Again, in this case study, $n = 3$. As in the single-frequency case, the force signal is not filtered because the damper response is nonlinear. The measured (unfiltered) force data are used directly in both the dual-frequency characterization and model parameter identification studies.

Damper Characterization: Single-frequency

Two common approaches are described for a linear characterization of the damper behavior. First, the equivalent spring stiffness and equivalent viscous damping approach is presented. This is based on first characterizing the damping force based on force vs displacement data. The damping force is subtracted from the measured damper force to obtain a residual force signal, that is used to characterize the residual spring behavior. The second approach is the calculation of the complex modulus, K^* , in which a Fourier analysis is used to characterize the in-phase

force or spring force, and the quadrature force or damper force, and hence the complex modulus.

Typical data used for such a characterization study are shown in **Figure 6**, for sinusoidal excitation at $\Omega_{\text{lag}} = 5 \text{ Hz}$, a 10% preload, for a range of amplitudes. The steady-state hysteresis cycle data are taken after stabilization of the material for a duration of 300 cycles at 1 Hz and 5 mm (200 mil) of sinusoidal excitation.

Equivalent spring stiffness and viscous damping The first characterization technique is that of equivalent spring stiffness and equivalent viscous damping. This is a standard linearization technique that can be applied to a nonlinear damper such as this elastomeric damper. Here, the damper restoring force, $f(t)$, is the sum of an equivalent spring or elastic stiffness force proportional to displacement, $f_s(t)$, and an equivalent viscous damping force proportional to velocity, $f_d(t)$:

$$f(t) = f_s(t) + f_d(t) \quad [9]$$

where:

$$\begin{aligned} f_s(t) &= K_{\text{eq}}x(t) \\ f_d(t) &= C_{\text{eq}}\dot{x}(t) \end{aligned} \quad [10]$$

where $x(t)$ and $\dot{x}(t)$ are the damper displacement and velocity, respectively. Here K_{eq} is the equivalent spring stiffness, and C_{eq} is the equivalent viscous damping. The equivalent viscous damping, C_{eq} , is computed by equating the energy dissipated over a cycle, E , at frequency Ω_{lag} using:

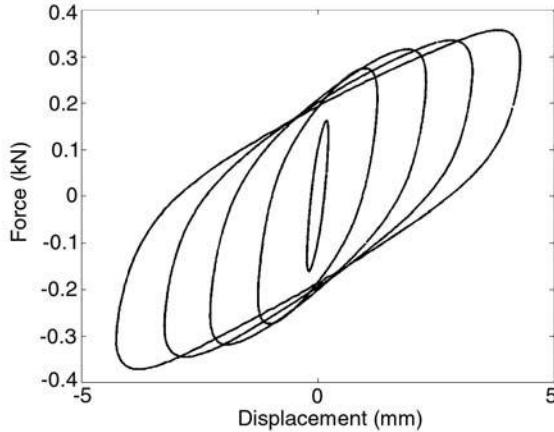

Figure 6 Hysteresis cycles for the double lap shear specimens at the lag/rev ($\Omega_{\text{lag}} = 5 \text{ Hz}$) frequency and 10% preload.

$$E = \oint F(t) dx = \int_0^{2\pi/\Omega_{\text{lag}}} F(t)v(t) dt \quad [11]$$

and equating the dissipated energy of the nonlinear device to that of an equivalent viscous damper:

$$C_{\text{eq}} = \frac{E}{\pi\Omega_{\text{lag}}X_{\text{lag}}^2} \quad [12]$$

where Ω_{lag} is the sinusoidal lag/rev test frequency, and X_{lag} is its amplitude. The energy dissipated over one cycle is computed using a numerical integration technique such as the trapezoidal rule. In **Figure 7**, the hysteresis cycle is shown as the result of a sinusoidal input having nominal amplitude of $X_{\text{lag}} = 5 \text{ mm}$ (200 mil) and frequency of $\Omega_{\text{lag}} = 5 \text{ Hz}$. The damping force, $f_d(t)$, calculated as above, is plotted in **Figure 7** as a flat ellipse. The difference between the total force and the damping force is the elastic stiffness force, or:

$$f_s(t) = f(t) - f_d(t) \quad [13]$$

This residual spring force is shown in **Figure 7**, and is characteristic of a nonlinear stiffening spring, or:

$$f_s(t) = K_1x(t) + K_3x^3(t) \quad [14]$$

The parameters K_1 and K_3 are determined using a least mean squared error parameter optimization technique. The cost function J to be minimized in this procedure is expressed by:

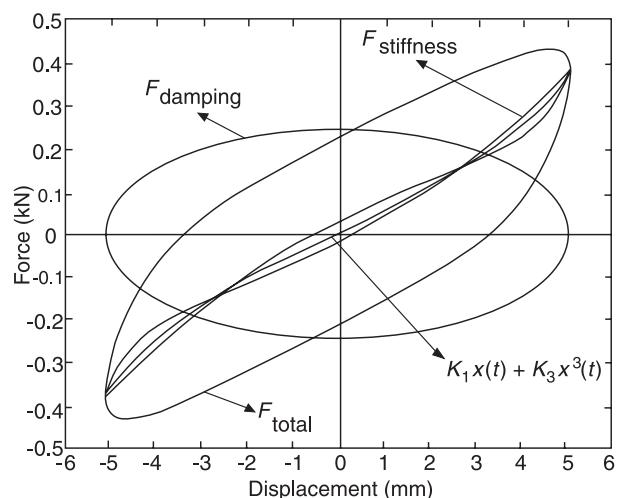

Figure 7 Contributions of the viscous damping force, and the elastic stiffness force to the total force.

$$J(K_1, K_3) = \sum_{i=1}^m (f_{s,i} - K_1 x_i - K_3 x_i^3)^2 \quad [15]$$

where m is the number of datapoints taken over one period. Because the force and displacement data are sampled data with sampling period Δt , we define $x_i = x(i\Delta t)$, and $f_{s,i} = f(i\Delta t)$. The two necessary conditions that must be satisfied are:

$$\frac{\partial J}{\partial K_1} = 0 \quad \text{and} \quad \frac{\partial J}{\partial K_3} = 0 \quad [16]$$

resulting in a solution of:

$$K_1 = \frac{1}{\Delta} (\Sigma_1 \Sigma_5 - \Sigma_2 \Sigma_4) \quad [17]$$

$$K_3 = \frac{1}{\Delta} (\Sigma_2 \Sigma_3 - \Sigma_1 \Sigma_4) \quad [18]$$

where:

$$\Sigma_1 = \sum_{i=1}^m f_{s,i} x_i \quad [19]$$

$$\Sigma_2 = \sum_{i=1}^m f_{s,i} x_i^3 \quad [20]$$

$$\Sigma_3 = \sum_{i=1}^m x_i^2 \quad [21]$$

$$\Sigma_4 = \sum_{i=1}^m x_i^4 \quad [22]$$

$$\Sigma_5 = \sum_{i=1}^m x_i^6 \quad [23]$$

$$\Delta = \Sigma_3 \Sigma_5 - \Sigma_4^2 \quad [24]$$

The equivalent stiffness is then given by the formula:

$$K_{eq} = K_1 + \frac{1}{2} K_3 X_{lag}^2 \quad [25]$$

We calculated the equivalent stiffness (Figure 8) and viscous damping (Figure 9) versus amplitude of sinusoidal excitation, ranging from 0.2 to 5 mm, using the above methods for the single frequency force vs displacement hysteresis cycle data. Clearly, both the equivalent stiffness and damping are strongly dependent on amplitude of excitation, as

evidenced by the substantial decrease in these quantities as amplitude increases. The rate of change of equivalent stiffness and damping with amplitude is very large up to $X_{lag} = 2$ mm, and becomes much more gradual for amplitudes $X_{lag} > 2$ mm. In addition, comparing zero preload and 10% preload conditions at room temperature, the addition of preload tends to increase the equivalent stiffness and damping over the entire amplitude range. This effect is due to the compressive preload increasing the friction response of the filler in the elastomer. Comparing the preloaded cases at room temperature and at 50°C, an increase in temperature tends to decrease the equivalent stiffness and damping. This is a manifestation of the so-called softening effect as temperature is increased.

Complex stiffness A second approach is to characterize the complex damper stiffness, K^* , as the in-phase or storage stiffness, K' , and quadrature or loss stiffness, K'' , so that:

$$K^* = K' + jK'' = K'(1 + j\eta) \quad [26]$$

where η is the loss factor. This is a common approach in the characterization of elastomeric dampers. Alternatively, is the effective or equivalent stiffness, while K''/Ω is related to the equivalent viscous damping of the damper. To determine the damper force:

$$f(t) = F_c \cos \Omega_{lag} t + F_s \sin \Omega_{lag} t \\ = K' x(t) + \frac{K''}{\Omega_{lag}} \dot{x}(t) \quad [27]$$

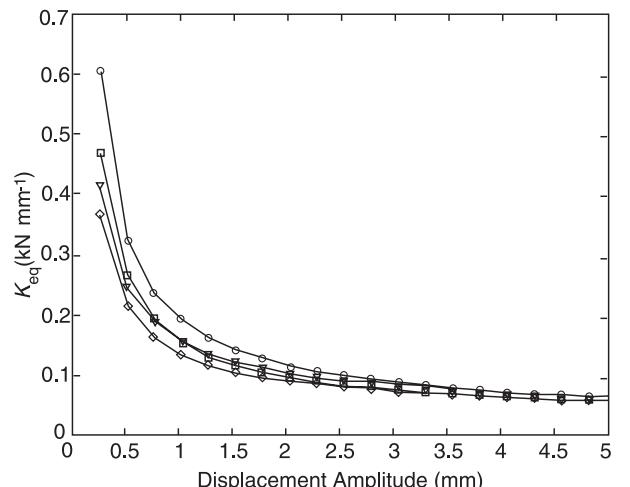

Figure 8 Single-frequency damper characterization of the equivalent elastic stiffness at $\Omega_{lag} = 5$ Hz. Circles, preloaded; squares, zero preload; diamonds, zero preload at 50°C; triangles, preloaded at 50°C.

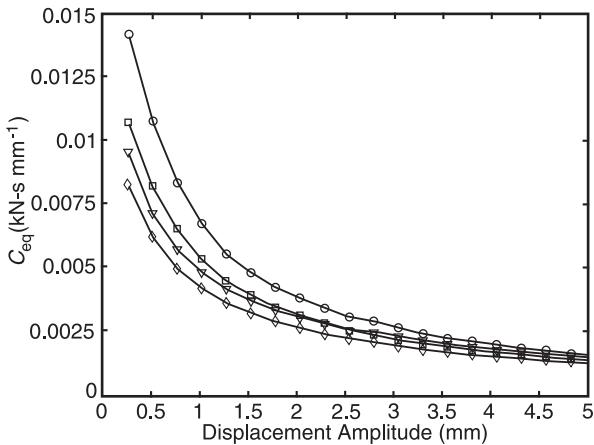

Figure 9 Single-frequency damper characterization of the equivalent viscous damping at $\Omega_{lag}=5\text{ Hz}$. Circles, preloaded; squares, zero preload; diamonds, zero preload at 50°C ; triangles, preloaded at 50°C .

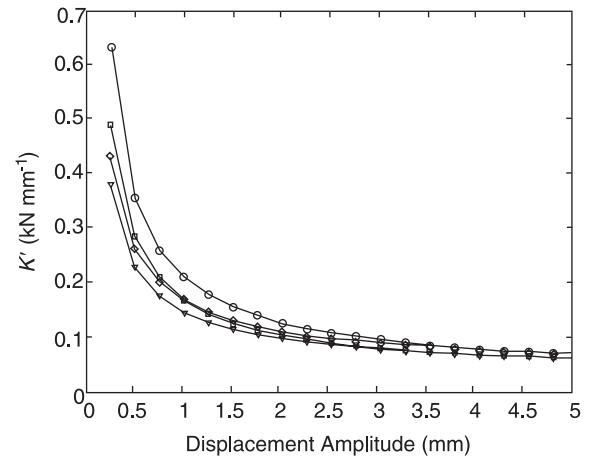

Figure 10 Single-frequency damper characterization of the stiffness at $\Omega_{lag}=5\text{ Hz}$. Circles, preloaded; squares, zero preload; triangles, zero preload at 50°C ; diamonds, preloaded at 50°C .

Here F_c and F_s are the cosine and sine Fourier coefficients of $f(t)$ at frequency Ω_{lag} . We assume that the displacement is sinusoidal:

$$x(t) = X_c \cos \Omega_{lag} t + X_s \sin \Omega_{lag} t \quad [28]$$

where X_c and X_s are the cosine and sine Fourier coefficients of $x(t)$ at frequency Ω_{lag} . Substituting $x(t)$ into the force equation and equating the sine and cosine terms yields the in-phase and quadrature stiffnesses as:

$$\begin{aligned} K' &= \frac{F_c X_c + F_s X_s}{X_c^2 + X_s^2} \\ K'' &= \frac{F_c X_s - F_s X_c}{X_c^2 + X_s^2} \end{aligned} \quad [29]$$

In general, this calculation would be performed for a sweep in the oscillation frequency, Ω , which included Ω_{lag} in its range. In our case, we are examining only a single harmonic excitation at Ω_{lag} . The quadrature stiffness of the damper is related to the equivalent viscous damping in an approximate way by:

$$C_{eq} \approx \frac{K''}{\Omega_{lag}} \quad [30]$$

The relation is approximate because the complex stiffness considers only the harmonic at frequency Ω_{lag} .

The results of this linear characterization are shown in Figures 10–12. Clearly, both the in-phase stiffness and quadrature stiffness (damping) are

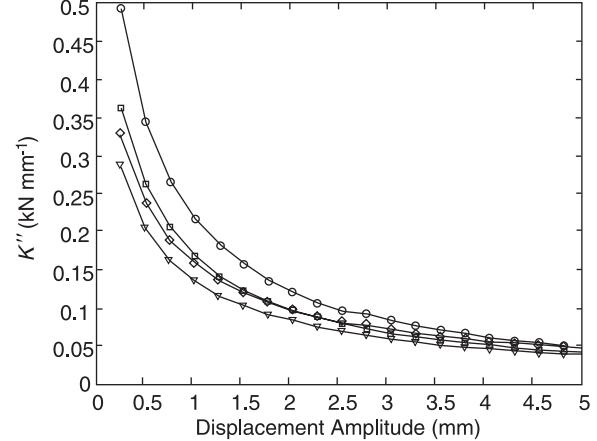

Figure 11 Single-frequency damper characterization of the damping at $\Omega_{lag}=5\text{ Hz}$. Circles, preloaded; squares, zero preload; triangles, zero preload at 50°C ; diamonds, preloaded at 50°C .

strongly dependent on amplitude of excitation. Again, the rate of change of these quantities with amplitude is very large up to $X_{lag}=2\text{ mm}$, and becomes much more gradual for amplitudes $X_{lag} > 2\text{ mm}$. In addition, comparing zero preload and 10% preload conditions at room temperature, the addition of preload tends to increase the complex modulus over the entire amplitude range, which is again because the compressive preload increases the friction response of the filler in the elastomer. The softening effect as temperature is increased can be observed by comparing the preload cases at room temperature and 50°C . This comparison shows that

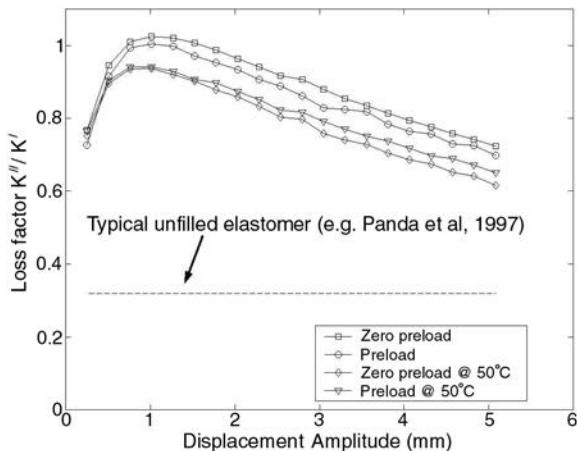

Figure 12 Single-frequency damper characterization of the loss factor at $\Omega_{\text{lag}} = 5 \text{ Hz}$. Circles, preloaded; squares, zero preload; diamonds, zero preload at 50°C ; triangles, preloaded at 50°C .

an increase in temperature tends to decrease the complex modulus. A final useful comparison comes from the loss factor, which is the ratio of the quadrature stiffness to the in-phase stiffness, or:

$$\eta = \frac{K''}{K'} \quad [31]$$

The loss factor, η , is a measure of the damping level relative to the stiffness, and it is desirable to have a high loss factor over a large amplitude range. The maximum value of the loss factor for this filled elastomer is as high as 1.025 for this material, which is much higher than the loss factor for elastomers used in existing dampers, which typically range from 0.4 to 0.8. A second observation is that the loss factor has its maximum effectiveness over a small amplitude range centered about an amplitude of 1 mm or, nominally, 10% shear strain, which is defined as the amplitude ($X_{\text{lag}} = 1 \text{ mm}$) over the specimen thickness (10 mm or 0.4 in). These trends are fairly typical of elastomeric materials.

Single-frequency Hysteresis Modeling

The single-frequency force vs displacement hysteresis cycle data of these double lap shear specimens can be modeled using a mechanisms-based modeling approach. Figure 13 shows a schematic of the mechanical stiffness-viscosity-elasto-slide (SVES) model used for the elastomers. The model consists of three elements: (1) a linear stiffness; (2) a nonlinear elasto-slip or triboelastic element that models the rate-independent part of the hysteresis behavior;

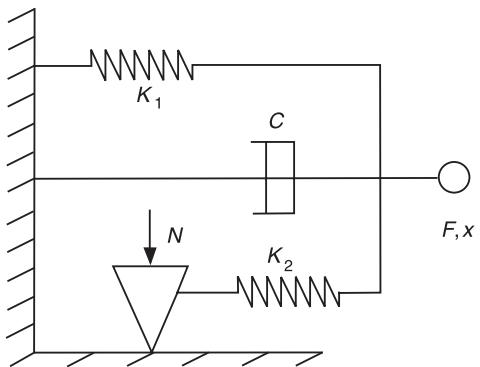

Figure 13 Schematic of the mechanisms-based stiffness-viscosity-elasto-slide analysis for the elastomeric damper.

and (3) a linear viscous damping that characterizes the rate-dependent hysteresis behavior. The model includes various physical aspects seen in elastomer hysteresis behavior, such as: (1) strong amplitude dependence of linearized coefficients; (2) linear behavior at low amplitudes; (3) mild frequency dependence; (4) deviation in hysteresis behavior from the linearized elliptical behavior near the zero-velocity points of the hysteresis cycle; and (5) presence of a rate-dependent and rate-independent part. The SVES model is typical of the class of elastomeric mechanisms-based models, in that it contains a Kelvin chain element (a spring and damper in parallel) and a triboelastic element (an elasto-slide element).

Figure 14 shows the effect of each of these mechanisms on the hysteresis cycles of the dampers. The nonlinear elasto-slip element accounts for the almost vertical drop in force near the zero-velocity region. It is modeled as a combination of a spring and Coulomb force. The slip element, which represents the friction components of the model, will be modeled such that its parameters are independent of both amplitude and frequency. The linear stiffness parameter must be modeled such that it is amplitude-dependent but frequency-independent. The linear viscous damping parameter must be modeled such that it is dependent on both the amplitude and frequency.

The linear stiffness and linear dashpot parameters give the necessary slope and area to the force vs displacement hysteresis cycle shape. The elasto-slide element represents a stiffness in the region where the velocity of the damper changes its sign and the displacement is less than a certain value $2X_s$ from the maximum amplitude. In the remaining portion of the hysteresis cycle, the elasto-slide element is equivalent to a Coulomb element. Two parameters are required to characterize the elasto-slide element completely. The linear stiffness and linear viscous damping

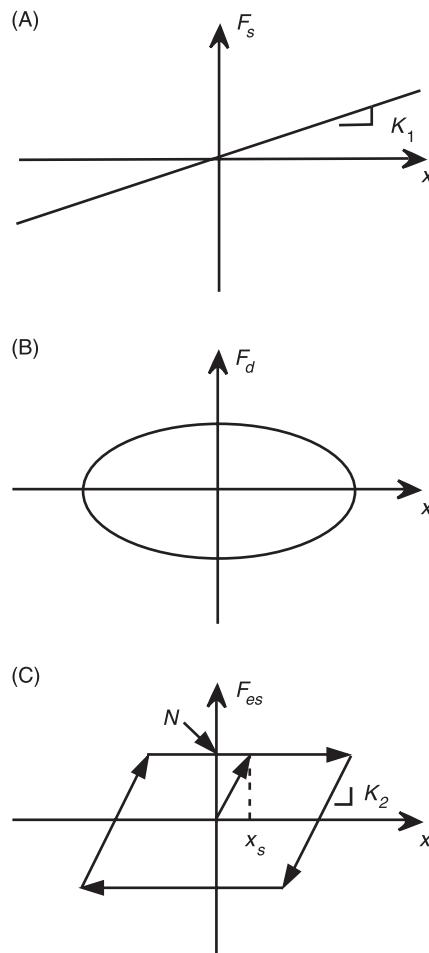

Figure 14 Mechanisms of the stiffness-viscosity-elasto-slide analysis and their influence on the shape of the force vs displacement hysteresis cycle. (A) Stiffness element; (B) damping element; (C) elasto-slide element (Lazan, 1968).

elements each require one parameter for complete characterization. Thus, the SVES model is a four-parameter model. Having established the model structure and model components, the parameters in the model need to be identified. The predicted force from the model is given by:

$$f(t) = f_s(t) + f_d(t) + f_{es}(t) \quad [32]$$

where $f_s(t)$, $f_d(t)$ and $f_{es}(t)$ are the forces in the stiffness, viscous dashpot, and elasto-slide element at any time, t . The stiffness and damping forces are as below:

$$f_s(t) = K_1 x(t) \quad [33]$$

$$f_d(t) = C \dot{x}(t) \quad [34]$$

The elasto-slide element has four branches as below:

$$f_{es} = \begin{cases} -N & x = -\bar{x} \quad \dot{x} = 0 \\ -N + K_2(x + \bar{x}) & x < -\bar{x} + 2X_s \quad \dot{x} > 0 \\ N & x > -\bar{x} + 2X_s \quad \dot{x} > 0 \\ N & x = \bar{x} \quad \dot{x} = 0 \\ N + K_2(x - \bar{x}) & x > \bar{x} - 2X_s \quad \dot{x} < 0 \\ -N & x < \bar{x} - 2X_s \quad \dot{x} < 0 \end{cases} \quad [35]$$

where \bar{x} is the amplitude over the cycle, and the slide force is given by:

$$N = K_2 X_s \quad [36]$$

The parameters N and K_2 of the elasto-slide element can be chosen *a priori* by careful observation of the force vs displacement hysteresis cycles. It was observed that, in the zero preload case, the value of the drop in force at maximum displacement was approximately 71.2 N. Hence, the Coulomb force corresponding to N was chosen to be 35.6 N. The stiffness K_2 was also fixed at 280.2 N mm⁻¹. Hence, the elasto-slide mechanism represents a Coulomb force of 35.6 N in parallel with a stiffness until the magnitude of the stiffening force becomes 35.6 N, but represents a Coulomb force of 71.2 N otherwise. This element is constant with respect to changing amplitude.

The remaining unknown parameters, K_1 and C , are estimated on the basis of minimizing the error between the predicted force, \hat{f} , and the measured force, f , obtained from experiments. The parameters of the model are obtained from a constrained minimization of the objective function, J , given by:

$$J(K_1, C) = \sum_{k=1}^m [\hat{f}(t_k) - f(t_k)]^2 \quad [37]$$

where m is the number of data points for each hysteresis cycle. A constrained minimization was performed using design optimization tools (DOT), which uses the Broyden–Fletcher–Goldfarb–Shanno algorithm to minimize the above objective function in eqn [37]. To obtain physically meaningful results with this technique, the identified parameters are constrained to have positive values: $K_1 > 0$, and $C > 0$. The parameters K_1 and C were identified at each amplitude at the lag/rev frequency. The identified parameters are plotted versus amplitude in Figure 15.

Using the parameters estimated from the identification process, the force vs displacement hysteresis cycles were reconstructed. Figure 16 shows the reconstructed hysteresis cycles for five different amplitudes at the lag/rev (5 Hz) frequency. The plots show that

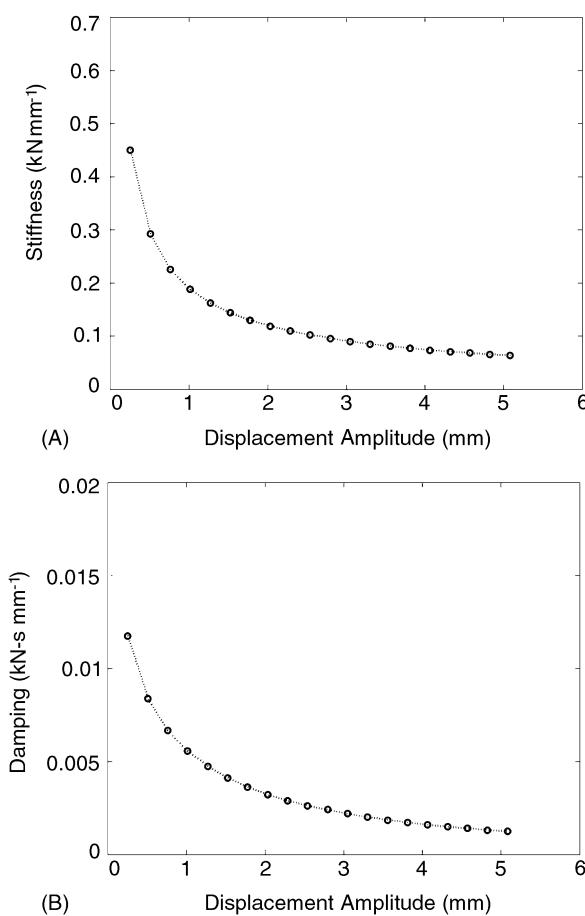

Figure 15 Identified stiffness and damping of the SVES model, assuming amplitude-independent elasto-slide element parameters, $N = 35.6 \text{ N}$, and $K_2 = 280.2 \text{ N mm}^{-1}$. (A) Stiffness parameter, K_1 ; (B) damping parameter, C .

the model accurately captures the hysteresis behavior of the damper.

Dual-frequency Characterization

In addition to testing the dampers at the lag/rev frequency, experiments are typically conducted at dual frequencies of the lag/rev (5 Hz) frequency and the 1/rev (7.5 Hz) rotor frequency. These tests are intended to assess the potential loss of damping at the lag/rev frequency due to dual-frequency motion. In this section, such a dual-frequency test is described, and typical test results are presented for the filled elastomer of our case study.

The dual frequency tests in our case study were carried out on an MTS servo-hydraulic testing machine with a digital control system. The range of lag/rev amplitudes is the same as for the single-frequency tests, that is, 0.25–5 mm (10–200 mil) in increments of 0.254 mm (10 mil). The 1/rev amplitudes tested were 0, 0.508, 1.524, 2.54 and 3.55 mm (0, 20, 60, 100 and 140 mil). An HP 8904A multi-function synthesizer was used to generate and sum the sinusoidal signals with the two individual frequencies. A function generator was used to have as accurate as possible the desired dual-frequency sinusoidal excitations. The force input and the displacement response were measured using the load cell and LVDT of the MTS machine, respectively, as in the single-frequency characterization tests.

To characterize the dampers under dual-frequency excitation conditions, the components of the complex stiffness $K^* = K' + jK''$ were determined at the lag/rev frequency. The stiffness, K' , and damping K'' at the

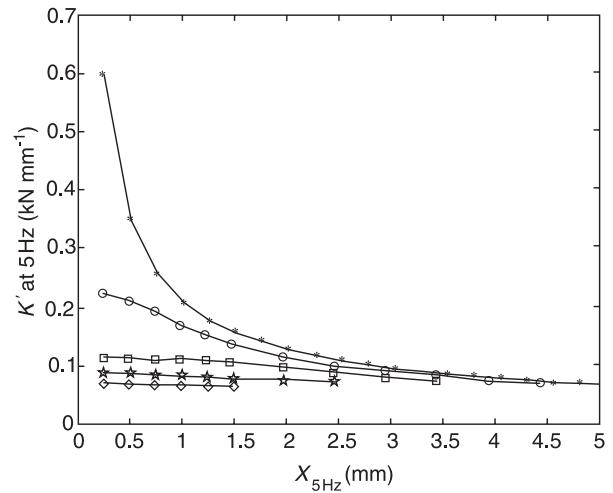

Figure 17 Dual-frequency damper characterization of stiffness at lag/rev = 5 Hz and 1/rev = 7.5 Hz. Amplitudes @ 7.5 Hz: Asterisks, 0 mm; circles, 0.508 mm (20 mil); squares, 1.524 mm (60 mil); stars, 2.54 mm (100 mil); diamonds, 3.556 mm (140 mil).

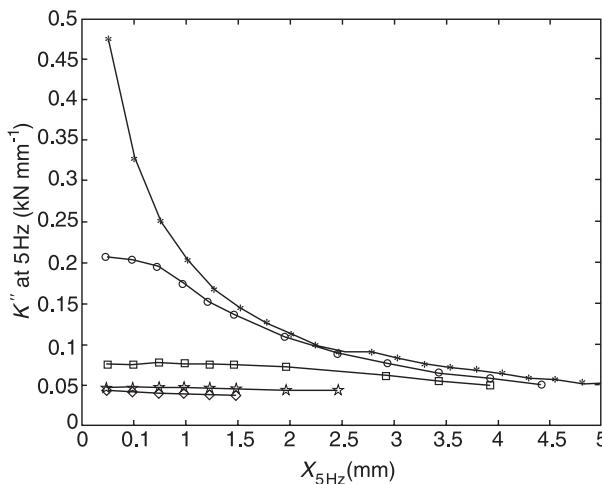

Figure 18 Dual-frequency damper characterization of the damping at lag/rev = 5 Hz and 1/rev = 7.5 Hz. Amplitudes @ 7.5 Hz: Asterisks, 0 mm; circles, 0.508 mm(20 mil); squares, 1.524 mm (60 mil); stars, 2.54 mm(100 mil); diamonds, 3.556 mm (140 mil).

lag/rev (5 Hz) frequency, shown in Figures 17 and 18, decrease as the 1/rev (7.5 Hz) amplitude increases. When the 1/rev (7.5 Hz) amplitude is 0.508 mm (20 mil), the reduction in stiffness and damping values is almost 50% compared to the single-frequency excitation at low 5 Hz amplitudes. The percentage reduction in these values gradually reduces with increasing amplitude of lag/rev (5 Hz) excitation and is not very significant (less than 10%) at high lag/rev (5 Hz) amplitudes. When the 1/rev (7.5 Hz) amplitude is 2.54 mm (100 mil), the stiffness and damping values at low lag/rev (5 Hz) amplitudes reduce by almost 80% and do not change substantially as the amplitude of 5 Hz excitation increases. Thus, it is clear that the 1/rev (7.5 Hz) excitation exerts a significant influence on the low-amplitude response at lag/rev (5 Hz). The elastomeric damper behavior exhibits strong nonlinearities and the nonlinearities degrade the performance of the damper. These effects of dual-frequency excitation are similar to the effects observed in other elastomeric damper studies.

Dual-frequency Hysteresis Modeling

To determine the dual frequency parameters, the Ω_{lag} (5 Hz) and $\Omega_{1/\text{rev}}$ (7.5 Hz) for each of the single frequency model parameters are used. First 10th order polynomials were used to fit the behavior of the linear damping and stiffness with respect to amplitude.

Once there are polynomials for both parameters at both the Ω_{lag} (5 Hz) and $\Omega_{1/\text{rev}}$ (7.5 Hz) frequencies, the polynomials are used to determine the parameter values for each frequency at the maximum displace-

ment for the dual frequency test case. This value will be less than sum of the two amplitudes. This is due to the testing machine and its inability to match the desired amplitude of the input signal. This problem was present for the single frequency testing, but becomes more apparent in the dual frequency testing. The problem is most visible for larger amplitude excitations, in dual frequency testing the sum of the desired amplitudes is large enough that the machine was unable to match the desired output.

Using the single frequency polynomial fits, preliminary dual frequency parameters are calculated by reevaluating the parameter curve at the maximum displacement of the dual frequency test. In order to calculate the dual frequency value for each parameter the values are scaled according to the amplitude for each frequency with respect to the maximum displacement for each test case. The equation used to determine the scaling for the damping and stiffness parameters can generally be written as

$$C = C(5 \text{ Hz}, \bar{X}) \frac{X_{5\text{Hz}}}{\bar{X}} + C(7.5 \text{ Hz}, \bar{X}) \frac{X_{7.5\text{Hz}}}{\bar{X}}$$

The dual-frequency correlation results for two dual-frequency excitation conditions are shown in Figures 19 and 20. Thus, the single-frequency model can be used to predict dual-frequency behavior.

Summary of Example

This example was presented describing how an elastomeric helicopter lag damper would be characterized and modeled using a mechanisms-based approach. The typical procedures used to character-

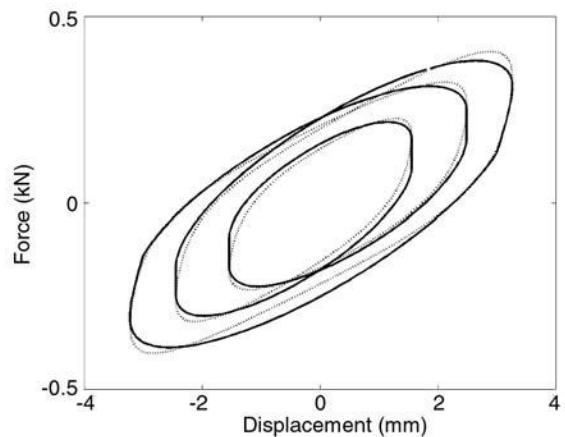

Figure 19 Dual-frequency damper analysis for 1/rev amplitude of 2.54 mm (100 mil) and lag/rev amplitude of 1 mm (40 mil). Continuous line, model; dashed line, experimental.

ize the steady-state behavior of elastomeric dampers under sinusoidal loading were described, including: (1) equivalent stiffness and equivalent viscous damping, and (2) complex stiffness and loss factor. The results of this linear characterization illustrated the amplitude-dependent nature of the linearized stiffness and damping. Additional effects of thermal softening, due to rising temperature, hardening due to lowering of temperature, and increases in stiffness and damping due to preload were illustrated using the linear stiffness and damping. A key component in the understanding of elastomeric helicopter lag dampers is the analysis of steady-state force response due to a sinusoidal displacement. A mechanisms-based tribo-viscoelastic analysis was outlined, specifically, the SVES analysis. Single-frequency (sinusoidal displacement at the lag mode frequency) and dual-frequency (sum of sinusoidal displacements at the lag mode frequency and the rotor rotational frequency) were analyzed. The SVES model worked well in predicting the behavior of the damper due to these classes of input displacement excitations.

Advanced Damper Concepts

New damping technologies are under development for application to the helicopter lag damping problem. Originally, hydraulic dampers were used to mitigate aeromechanical instabilities, where the damper force is proportional to the shaft velocity of the damper. However, these hydraulic dampers were prone to leakage problems. Because elastomeric dampers do not have comparable leakage problems, they were subsequently advocated for this application. The main problem, as described above, is that elas-

tomer damper properties are strongly dependent on amplitude and temperature. The linearized damping and stiffness of the elastomeric damper reduce substantially as amplitude is increased, or as temperature increases and the elastomer softens.

To reduce the impact of these amplitude-dependent damping and stiffness nonlinearities, hybrid fluid-elastomeric dampers have been proposed. The fluid which is passive, is used to linearize the damping and stiffness of the lag damper. As a result, the force vs displacement hysteresis cycles of these dampers are more linear, or elliptical in shape, as demonstrated for the Comanche model-scale wind tunnel damper (Figure 21). Using the same characterization methods described above, the equivalent viscous damping, C_{eq} , has been shown to be nearly constant as a function of excitation amplitude (Figure 22).

Another innovative concept is the introduction of adaptive or controllable fluids into lag dampers. Controllable fluids consist of a powder or particles dispersed in a carrier fluid. These fluids change their properties as electric field, as in electrorheological (ER) fluids, and magnetic field, as in magnetorheological (MR) fluids, is applied. This property change is manifested as a change in yield stress of the fluid, with a minimal change in plastic viscosity. This change in yield stress arises because the particles in the carrier fluid form chains, and resist shear stresses. The yield stress is the point in the shear stress versus shear rate behavior where the particle chains break or yield. This property of field-dependent yield stress can be exploited in the development of adaptive dampers.

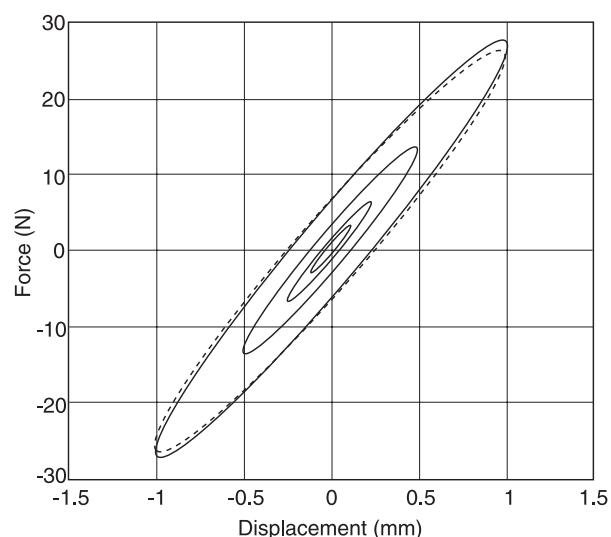

Figure 21 Force vs displacement hysteresis cycles of an elastomeric damper can be linearized via the addition of fluidic damping. Continuous line, model; dashed line, experiment.

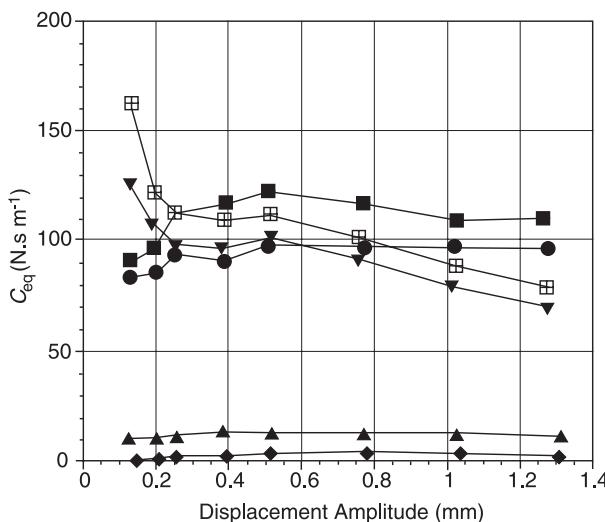

Figure 22 Linearized equivalent viscous damping constants for a pair of Comanche model-scale wind tunnel dampers under single-frequency excitation of the lag mode (in this case, 10 Hz). The MR on condition is comparable to a passive fluidic-elastomeric damper. The MR off condition has low damping. Circles, fluidelastic-zero preload; squares, fluidelastic-preloaded; diamonds, MR (off)-zero preload; triangles, MR (off)-preloaded; inverted triangles, MR (on)-zero preload; squares, MR (on)-preloaded.

To illustrate this, hybrid elastomeric MR lag dampers were fabricated for the Comanche wind tunnel model. The MR effect could be turned on and off in these dampers. The equivalent viscous damping for the MR on condition (Figure 22) is comparable to the fluidic-elastomeric case, however, the MR off condition has significantly reduced damping. This effect can have some interesting benefits.

Dampers must be matched sets for a given rotor so that it is balanced. However, due to manufacturing variations, dampers must be carefully matched, so that many dampers must be manufactured to achieve this matching of damper properties; that is, the properties of each damper are selected to be the same. Therefore, a damper that could adapt its properties to a fixed mechanical property specification would be of tremendous benefit. Damping augmentation is required only in certain flight regimes, which highlights the need for damping strategies that can be tailored to specific flight conditions. For example, when the helicopter is on the ground, and the rotor is spooling up to its operational rotational frequency of 1/rev, there are critical frequency ranges where the rotor can be marginally stable. Augmenting damping over these critical frequency ranges would be of benefit in increasing stability of the helicopter rotor. Also, the temperature-softening effect of elastomers can be mitigated

by increasing the damping as temperature increases using an MR fluid-based damping component. Thus, controllable fluid dampers are attractive choices for augmenting lag mode damping in helicopter rotor systems.

Nomenclature

C_{eq}	equivalent viscous damping
f	measured force
\hat{f}	predicted force
$f(t)$	damper restoring force
K^*	damper stiffness
K'	storage stiffness
K''	loss stiffness
K_{eq}	equivalent spring stiffness
$x(t)$	damper displacement
$\Delta(t)$	sampling period

Introduction

The Hilbert transform (HT), as a kind of integral transformation, plays a significant role in vibration signal processing. There are two common ways it can be used. First, the HT provides a direct examination of a vibration's instantaneous attributes: frequency, phase, and amplitude. It allows rather complex systems to be analyzed in the time domain. Second, the HT can find a system's real part of transfer function from the system's imaginary part and vice versa. This allows systems to be analyzed in the frequency domain. The HT can be used as an intermediate step in more elaborate system analysis. In addition to frequency response function analysis, it is useful for hysteretic damping characterizing and nonlinear system identification.

In the field of signal processing, the HT has also stimulated some progress. The classic example of this is signal demodulation, and also signal decomposition. Today the HT is taken as a standard procedure and has long been used widely in signal processing.

The Hilbert* transformation was first introduced to signal theory by Denis Gabor. He defined a generalization of the well-known Euler formula $e^{iz} = \cos(z) + i\sin(z)$ in the form of the complex function $Y = u(t) + iv(t)$, where $v(t)$ is the HT of $u(t)$. In signal processing, when the independent variable is time, this associated complex function is known as the analytic signal and the HT $v(t)$ is called quadrature (or conjugate) function of $u(t)$. For example, the quadrature function of $\cos(t)$ is $\sin(t)$ and the corresponding analytic signal is e^{it} .

The application of the HT to the initial signal provides some additional information about ampli-

tude, instantaneous phase, and frequency of vibrations. This information can be useful when applied to analysis of vibrational motions, including an inverse problem – the problem of vibration system identification.

Notation

The HT of the function $u(t)$ is defined by an integral transform:

$$H[x(t)] = \tilde{x}(t) = \pi^{-1} \int_{-\infty}^{\infty} \frac{x(\tau)}{t - \tau} d\tau \quad [1]$$

Because of the possible singularity at $t = \tau$, the integral is to be considered as a Cauchy principal value. The HT is equivalent to an interesting kind of filter, in which the amplitudes of the spectral components are left unchanged, but their phases are shifted by $-\pi/2$ (Figure 1).

Properties of the HT

The HT of a real-valued function $x(t)$ extending from $-\infty$ to $+\infty$ is a real valued function defined by eqn [1]. Thus, $\tilde{x}(t)$ is the convolution integral of $x(t)$ with $1/\pi t$, written as $\tilde{x}(t) = x(t) * 1/\pi t$. The HT of a constant is zero. The double HT (the HT of a HT) yields the original function having the opposite sign, hence

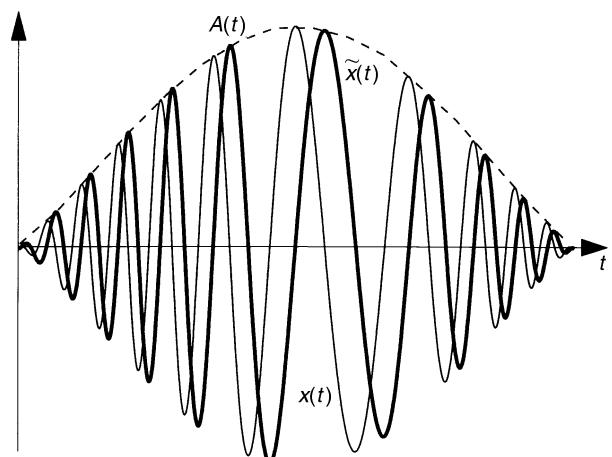

Figure 1 Real signal $x(t)$, Hilbert transform $\tilde{x}(t)$, and the signal envelope $A(t)$.

*David Hilbert, born 23 January 1862 in Königsberg, Prussia (now Kaliningrad, Russia), died 14 February 1943 in Göttingen, Germany. David Hilbert was one of the world's greatest mathematicians. Hilbert contributed to many branches of mathematics, including invariants, algebraic number fields, functional analysis, integral equations, mathematical physics, and the calculus of variations. He invented the space of wave functions used in quantum mechanics.

it carries out a shifting of the initial signal by $-\pi$. The power (or energy) of a signal and its HT are equal. A function and its HT are orthogonal over the infinite interval $\int_{-\infty}^{\infty} x(t)\tilde{x}(t)dt = 0$.

For $n(t)$ low-pass and $x(t)$ high-pass signals with nonoverlapping spectra $H[n(t)x(t)] = n(t)\tilde{x}(t)$. More generally, the HT of the product of two arbitrary functions with overlapping spectra can be written in the form of a sum of two parts:

$$\begin{aligned} H[n(t)x(t)] &= H\{[\bar{n}(t) + n_1(t)]x(t)\} \\ &= \bar{n}(t)\tilde{x}(t) + \tilde{n}_1(t)x(t) \end{aligned}$$

where $\bar{n}(t)$ is the slow (low-pass), $n_1(t)$ is the fast (high-pass) signal component, and $\tilde{n}_1(t)$ is the HT of the fast component. The proof of the decomposition of a signal into a sum of low- and high-pass terms is based on Bedrosian's theorem for the HT of a product. For example, the HT of the cube of the harmonics $x^3 = (A \cos \varphi)^3$ is equal to $H[x^3] = H[x^2x] = A^3(3 \sin \varphi + \sin 3\varphi)/4$.

Analytic Signal

The complex signal whose imaginary part is the HT of the real part is called the analytic signal. The term 'analytic' is used in the meaning of a complex function of the complex variable. When dealing with general modulated signals, it is often convenient to define the analytic signal $X(t) = x(t) + i\tilde{x}(t)$, where $\tilde{x}(t)$ is related to $x(t)$ by the HT. In order to return from a complex form of the analytic signal $X(t)$ back to the real function $x(t)$, one has to use the substitution

$$x(t) = \frac{X(t) + X^*(t)}{2}$$

where $X^*(t)$ is the complex conjugate signal of $X(t)$. The analytic signal has a one-sided spectrum of positive frequencies. The conjugate analytic signal has a one-sided spectrum of negative frequencies.

Polar Notation

According to analytic signal theory, a real vibration process $x(t)$ measured by, say, a transducer, is only one of possible projections (the real part) of some analytic signal $X(t)$. Then the second projection of the same signal (the imaginary part) $\tilde{x}(t)$ will be conjugated according to the HT. The analytic signal has a geometrical representation in the form of a phasor rotating in the complex plane, as shown in Figure 2.

Using the traditional representation of the analytic signal in its trigonometric or exponential form:

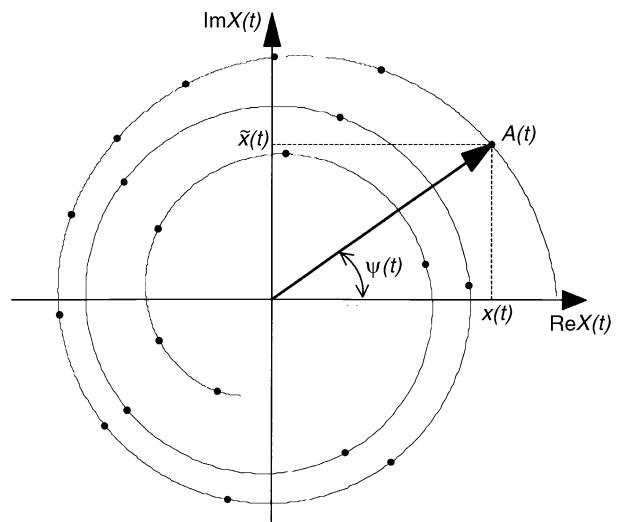

Figure 2 Analytic signal representation.

$$X(t) = |X(t)|[\cos \psi(t) + i \sin \psi(t)] = A(t)e^{i\psi(t)} \quad [2]$$

one can determine its instantaneous amplitude (envelope, magnitude):

$$A(t) = |X(t)| = \sqrt{x^2(t) + \tilde{x}^2(t)} = e^{\text{Re}[\ln X(t)]} \quad [3]$$

and its instantaneous phase:

$$\psi(t) = \arctan \frac{\tilde{x}(t)}{x(t)} = \text{Im}[\ln X(t)] \quad [4]$$

The change of coordinates from rectangular (x, \tilde{x}) to polar (A, ψ) gives $x(t) = A(t) \cos [\psi(t)]$, $\tilde{x}(t) = A(t) \sin [\psi(t)]$. The HT is used, almost without exception, for vibration processes with zero mean value (in the absence of a trend or DC offset). Otherwise, the instantaneous characteristics of the signal turn into fast oscillation functions and they are liable to have a much more complex configuration than the initial signal.

Instantaneous Phase

The instantaneous phase notation (eqn [4]) indicates the multibranched character of the function, as shown in Figure 3 line 2, when the phase angle jumps between π and $-\pi$. These phase jumps can be unwrapped into a monotone function by an artificial changing of the phase values (see Figure 3 line 1). The instantaneous relative phase shift in the case of two different real signals $x_1(t)$ and $x_2(t)$ can be estimated as the instantaneous relative phase between them according to the formula

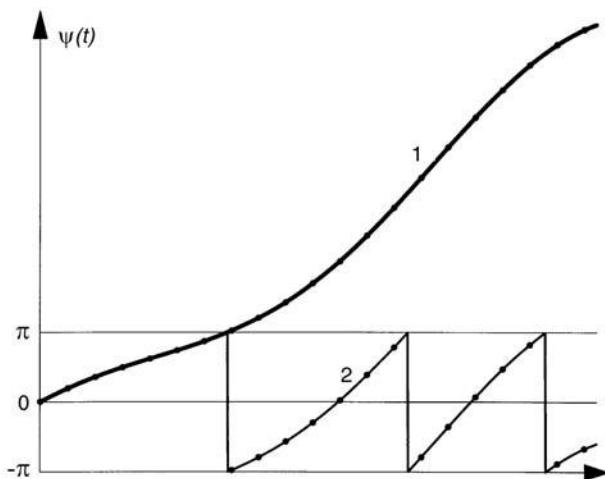

Figure 3 Instantaneous phase: 1, unwrapped; 2, wrapped.

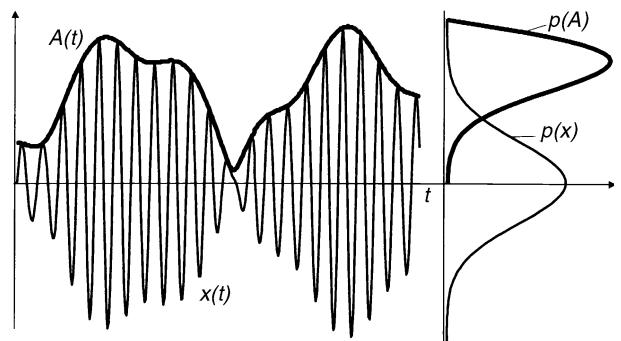

Figure 4 Random signal with envelope and their distributions.

of the random vibration which conforms to the Rayleigh probability density of the vibration envelope is shown in Figure 4.

$$\psi_2(t) - \psi_1(t) = \arctan \frac{x_1(t)\tilde{x}_2(t) - \tilde{x}_1(t)x_2(t)}{x_1(t)x_2(t) + \tilde{x}_1(t)\tilde{x}_2(t)}$$

Signal Envelope

The amplitude of the oscillation varies slowly with time, and the shape of the slow time variation is called the envelope $A(t)$ (eqn [3]). The initial signal and its envelope have common tangents at points of contact (extrema points), but the signal never crosses the envelope. The envelope often contains important information about the signal. By using the HT, the rapid oscillations can be removed from the signal to produce a direct representation of the envelope alone. For example, the impulse response of a linear single-degree-of-freedom (SDOF) system is an exponentially damped sinusoid. The envelope of the signal is determined by the decay rate.

Narrow-band vibration signals can be described with the constant carrier frequency $\psi(t) = \omega_0 t + \psi_0(t)$. Then the initial complex signal (eqn [2]) will be given by $X(t) = A_0 e^{i\psi(t)} = A_0 e^{i\psi_0(t)} e^{i\omega_0 t}$, where a new complex expression is introduced as the complex envelope $A_0 e^{i\omega_0 t}$. The spectrum of the complex envelope can be obtained by shifting an initial signal spectrum to the left toward the origin of axes. The envelope probability density $p(A)$ is related to the signal probability density function

$$p(x) = \pi^{-1} \int_{|x|}^{\infty} \frac{p(A)dA}{(A^2 - x^2)^{1/2}}$$

As an example of this relation a typical classical Gaussian (normal) form of the probability density

Instantaneous Frequency

The first derivative of the instantaneous phase $\omega(t) = \dot{\psi}(t)$, called the instantaneous angular frequency, plays an important role. The angular frequency $\omega(t) = 2\pi f(t)$ has the dimension radian per second and the cycle frequency $f(t)$ has the dimension Hertz. There is a simple way to avoid the whole phase-unwrapping problem. It can be done when finding the instantaneous frequency (IF) by differentiation of the signal itself

$$\omega(t) = \frac{x(t)\tilde{x}(t) - \dot{x}(t)\tilde{x}(t)}{A^2(t)} = \text{Im} \left[\frac{\dot{X}(t)}{X(t)} \right]$$

For narrow-band signals there is another alternative to the signal differentiation by direct estimation of the phase angle corresponding to the unit time shift $X(t)X^*(t + dt) = [A(t) + dA]e^{i\omega(t)dt}$, where $\omega(t)$ is the phase angle (eqn [2]), $dt = 1$, and X^* is the complex conjugated signal. Thus it is seen that for narrow-band signals, small time delays may be represented as phase shifts of the complex envelope.

Naturally, for a simple monoharmonic signal, the instantaneous amplitude and frequency are constant values. In the general case, the IF of a signal is a varying function of time. Moreover, the IF of wide-band analytic signals may change sign in some time intervals. This corresponds to the change of rotation of the phasor of Figure 2 from the counterclockwise to the clockwise direction.

Signal Time Representation

For more complicated vibration signals, the instantaneous amplitude and frequency are nonconstant; they

vary in time. While the IF is positive function, the signal itself has the same numbers of zero crossings and extrema. When the IF takes a negative value the signal has multiple extrema between successive zero crossings. It corresponds to the appearance of a complex riding wave (complicated cycle of alternating signal). Vibration signal with positive IF is considered as a monocomponent signal. A slow frequency-modulated and a random narrow-band signal are two typical different examples of the monocomponent signal. In this case the IF will not have the fast fluctuations induced by asymmetric waveforms. With this definition, the monocomponent signal in each cycle, defined by the zero crossing, involves only one mode of oscillation; no complex riding waves are allowed.

Since the IF may be considered to be the average of the signal frequency at a given time instant, it seems reasonable to inquire about the probability density function or spread at that time. Actually, the probability density function of the IF of the random normal narrow-band signal, defined by $p(\omega) = \Delta\omega_2^2/2[(\omega - \omega_{01})^2 + \Delta\omega_2^2]^{3/2}$, where ω_{01} and $\Delta\omega_2$ is the central frequency and the spectrum width parameter (see below), is spread about only one central frequency. A composition of several monocomponent signals is considered as a multicomponent signal. There exists a method to decompose the initial data into intrinsic components, for which the instantaneous frequency can be defined as positive function.

Taking into account these representations of analytic signals enables one to consider a vibration process, at any moment of time, as a quasiharmonic oscillation, amplitude- and frequency-modulated by time-varying functions $A(t)$ and $\omega(t)$: $x(t) = A(t) \cos \int_0^t \omega(t) dt$. For random signals, the envelope and the IF are statistically independent functions. Thus the dynamic component of the signal is described by a variance and for such a case is given by a product of two statistically independent functions: the envelope and the fast oscillated function: $\cos[\cdot]$. The signal variance, after transformation, reduces to $\sigma_x^2 = [\sigma_A^2 + \bar{A}^2]/2$ where σ_x is the signal standard deviation, σ_A is the envelope standard deviation, and \bar{A} is the envelope mean value. This means that the signal variance depends only on the envelope variation.

The instantaneous parameters are functions of time and can be estimated at any point of the vibration signal. The total number of these points which map the vibration is much greater than that of the peak points of the signal. This opens the way for averaging and for other statistical processing procedures, making vibration analysis more precise.

Signal Spectrum Representation

The normalized power spectrum ($\int_0^\infty S(\omega) = 1$) may be interpreted as a geometric figure or the probability density function of the frequency ω , and may be used to define the spectral moments. Of particular interest is the mean value of the IF. The mean value is equal to the coordinate of the center of mass of the signal spectrum $\omega_{01} = \int_0^\infty \omega S(\omega) d\omega$. In some cases of vibration analysis only the positive IF values are significant, therefore the mean absolute value of the IF should be applied: $\omega_{02} = [\int_0^\infty \omega^2 S(\omega) d\omega]^{1/2}$. The mean absolute value is the second-order spectral moment which corresponds to the radius of inertia of the signal spectrum. It is equal to the zero crossing of a vibration random signal. Some typical examples of the central frequency estimation based on the IF are shown in Table 1.

It is notable that, in the case of the SDOF vibration system, its free vibration natural frequency value $(\omega_0^2 - c^2)^{1/2} \approx \omega_0 - c^2/2\omega_0$, where c is the viscous damping, lies between these central moments of the IF (Table 1).

It was mentioned that the IF can take negative values that correspond to the appearance of complicated cycles of alternating load. A probabilistic prerequisite to the formation of the negative value of IF is $p[\omega(t) < 0] = 0.5(1 - \omega_{01}/\omega_{02})$, from whence it follows, for example, that the probability of a negative value of the IF of random vibration of the SDOF system (Table 1) is proportional to the system-damping coefficient.

The IF can also be interpreted from the time-frequency distribution point of view as the average frequency at each time, because, for an unlimited number of time-frequency distributions of the analytic signal, the first conditional moment in frequency, which gives the average frequency at each time, equals the average derivative of the instantaneous phase.

There are several techniques for estimation of the spectrum bandwidth. Probably the most familiar and simplest is the half peak level width. Also, the spectrum bandwidth could be estimated as a width of a hypothetical square with the same energy and the

Table 1 The spectral central frequencies

Vibration signal	Central frequency	
	ω_{01}	ω_{02}
Harmonics $\cos \omega_0 t$	ω_0	ω_0
Random vibration of the system $\ddot{y} + 2c\dot{y} + \omega_0^2 y$	$\omega_0 - 2c/\pi$	ω_0
Narrow-band random noise	ω_0	$\omega_0(1 + \Delta\omega^2/24\omega_0^2)$
$\omega_0 - \frac{1}{2}\Delta\omega < \omega < \omega_0 + \frac{1}{2}\Delta\omega$		

Table 2 The spectral bandwidth

Vibration signal	Spectral bandwidth	
	$\Delta\omega_1$	$\Delta\omega_2$
Random vibration of the system $\ddot{y} + 2c\dot{y} + \omega_0^2 y$	πc	$2(c\omega_0/\pi)^{1/2}$
Narrow-band random noise $\omega_0 - \frac{1}{2}\Delta\omega < \omega < \omega_0 + \frac{1}{2}\Delta\omega$	$\Delta\omega$	$\Delta\omega \frac{1}{2}\sqrt{3}/6$

peak value $\Delta\omega_1 = \int_0^\infty S(\omega)d\omega/S_{\max}$. In the case of the IF analysis it is useful to introduce one more width parameter that is equal to the mean absolute value of the IF deviation from its central value $\Delta\omega_2 = [\int_0^\infty (\omega - \omega_0)^2 S(\omega)d\omega]^{1/2} = (\omega_{02}^2 - \omega_{01}^2)^{1/2}$. Some typical examples of the spectral bandwidth estimation are shown in Table 2.

These relations between the spectral bandwidth and the central frequency enable us by convention to divide vibration signals into two groups: narrow-band ($\Delta\omega \ll \omega_0$) and wide-band ($\Delta\omega \gg \omega_0$) signals.

The HT and Vibration Systems

Frequency Response Function

The HT presents an interesting property for a causal function $h(t)$. The property implied by causality is that the imaginary part of the Fourier transform is completely determined by a knowledge of its real part and vice versa. If the impulse function of the linear dynamic system $h(t)$ contains no singularity at the origin, then $F(g(t)) = R(\omega) + iQ(\omega)$ is its Fourier transform, and $R(\omega)$ and $Q(\omega)$ are the HTs that satisfy the equations:

$$Q(\omega) = -\frac{1}{\pi} \int_{-\infty}^{\infty} \frac{R(\omega')}{\omega - \omega'} d\omega',$$

$$R(\omega) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{Q(\omega')}{\omega - \omega'} d\omega'$$

We can associate a complex frequency response function whose real part is the function $R(\omega)$ and the imaginary part is the HT of this function. To obtain the complete function of the system, we have to apply the HT to the magnitude frequency response to obtain the phase frequency response. In other words, the real and imaginary parts of the transfer function form a Hilbert pair. Any departure from an initial linear frequency response function, i.e., distortion, can be attributed to nonlinear effects.

Hysteretic Damping

Most real materials show an energy loss per cycle with a less pronounced dependency on frequency. In fact, many materials indicate force-deformation relations that are independent of the deformation rate amplitude – so-called hysteretic relations. A known mechanical element model shows frequency-independent storage and loss moduli. This implies that the Fourier transforms of both the element force $F(\omega)$ and the element deformation $\Delta(\omega)$ satisfy $F(\omega) = k[1 + \eta \operatorname{sgn}(\omega)]\Delta(\omega)$, where k is the stiffness and η is the loss factor (ratio of the loss and storage moduli of element). In this model the dissipated energy in a harmonic deformation cycle of amplitude Δ_0 is independent of the frequency of deformation $W = \pi k \eta \Delta_0^2$. Only the HT gives a correct time domain expression for the concept of linear hysteretic. This representation of the SDOF structure with linear hysteretic damping is $\ddot{y}(t) + \omega^2 y(t) + \omega^2 \eta \ddot{y}(t) = 0$, where $\ddot{y}(t)$ is the HT of the deformation. This transform can be used to replace complex-valued coefficients in differential equations modeling mechanical elements.

Nonlinear System Identification

The HT method enables us to estimate instantaneous modal parameters (the natural frequency and the instantaneous damping coefficient) as functions of vibration amplitude for systems under test. The HT identification method extracts directly the backbone of a nonlinear system as a dependency between free vibration frequency and displacement amplitude and also the corresponding damping curve. This enables us to solve an inverse identification problem, namely, the problem of estimation of the initial nonlinear static elastic and damping force characteristics. Most well-known cases of nonlinearity occur in large-amplitude oscillations of elastic systems; for instance, nonlinear spring elements with hardening or softening restoring force, or nonlinear damping quadratic or cubic force.

The HT and Vibration Signals

The analytic signal method is equally applicable to deterministic and random processes, although, generally speaking, it doesn't divide them into two separate groups. Thanks to this, it enables us to investigate any oscillating time function from a general point of view. The method is also good for solving problems concerning linear and nonlinear vibration systems typical of mechanical engineering structures. It allows analysis, from the general point of view, of stationary vibrations as well as nonstationary

narrow- and/or wide-band ones. It also allows analysis of the dissipation of vibration energy, and vibration effects on machine durability.

Signal Differentiation and Integration

The analytic signal notion (eqn [2]) allows us to describe a relationship between an initial complex signal and its first derivative as

$$\dot{X} = X \left(\frac{\dot{A}}{A} + i\omega \right)$$

It is noted that all the information on the first derivative of an analytic signal is carried by the analytic signal itself (its envelope and IF). This formula defines a new notion of the instantaneous complex frequency $\Omega(t) = \alpha(t) + i\omega(t)$, where

$$\alpha(t) = \frac{\dot{A}(t)}{A(t)} = \frac{x(t)\dot{x}(t) + \tilde{x}(t)\tilde{x}(t)}{A^2(t)} = A(t) \operatorname{Re} \left[\frac{\dot{X}(t)}{X(t)} \right]$$

is the instantaneous radial velocity of the phasor in Figure 2. The second derivative of the signal takes the form

$$\ddot{Y} = X \left(\frac{\ddot{A}}{A} - \dot{\psi}^2 + 2i \frac{\dot{A}}{A} \dot{\psi} + i\ddot{\psi} \right)$$

Integration of analytic signals may be also of importance for signal processing. A complex function of a real variable t is an integral of the analytic signal if the real and the imaginary parts of the function are corresponding integrals forming a pair of the HT.

Signal Demodulation

The basic equation of frequency properties of the signal can be expressed as $\Delta\omega^2 = \sigma_\omega^2 + \sigma_A^2/\sigma_A^2$ where $\Delta\omega$ is the bandwidth of the spectrum, σ_ω is the IF standard deviation, σ_A is the standard deviation of the first derivative of the envelope, and σ_A is the envelope standard deviation. The physical meaning of the basic equation is that the spectral bandwidth is described by the sum of two components: the variance of the IF and the variance of the envelope velocity. Actually, the spectral band is defined by both the frequency and the amplitude modulation. For signals which are only amplitude-modulated, the spectral bandwidth is equal to the mean square value of the velocity of the amplitude change. For signals which are only

frequency-modulated, the spectral bandwidth is equal to the mean square value of the IF.

Traditional Fourier analysis simply assumes that the signal is the sum of a number of sine waves. The HT allows a complex demodulation analysis, adapted to signals of the form of a single, but perturbed sine wave. Since a vibration signal is exactly of the model that the method assumes, it is no wonder that in some cases it performs better than Fourier analysis.

Signal Decomposition

A new empirical mode decomposition method allows any complicated data set to be decomposed into a finite and often small number of intrinsic mode functions that admit well-behaved Hilbert transforms. Since the decomposition is based on the local characteristic time scale of the data, it is applicable to nonlinear and nonstationary processes.

Fatigue Estimation under Random Wide-band Loading

The HT approach can be used to count fatigue cycles in an arbitrary loading waveform. It processes a time history representing the loading condition to generate the number of cycle-counts with their corresponding amplitudes. The approach is general, is accurate within any desirable degree of accuracy, and is amenable to modern signal processing.

Hilbert Transformers

We can form the HT by designing a filter with the frequency response corresponding to the impulse response. This response is $H(\omega) = -j \operatorname{sgn}(\omega)$. This frequency response describes a wide-band 90° phase shifter whose positive frequencies are shifted by -90° and whose negative frequencies are shifted by $+90^\circ$. There are two methods for obtaining the Hilbert transformer: frequency domain and time domain. The phase shift can be implemented by a convolution filter, obtainable by the convolution theorem relating convolution to multiplication in the frequency domain.

Frequency Domain

If $x(t)$ is the real input data record of length N , then the analytic signal $X(t)$ can be obtained by: $X(t) = \text{IFFT}[B(n) \cdot \text{FFT}(x(t))]$ where: $B(n) = 2$, for $n = \{0, N/2 - 1\}$; $B(n) = 0$, for $i = \{N/2, N - 1\}$. FFT is the Fourier transform and IFFT is the inverse Fourier transform. The imaginary portion of $X(t)$ contains the HT $\tilde{x}(t)$; the real portion contains the

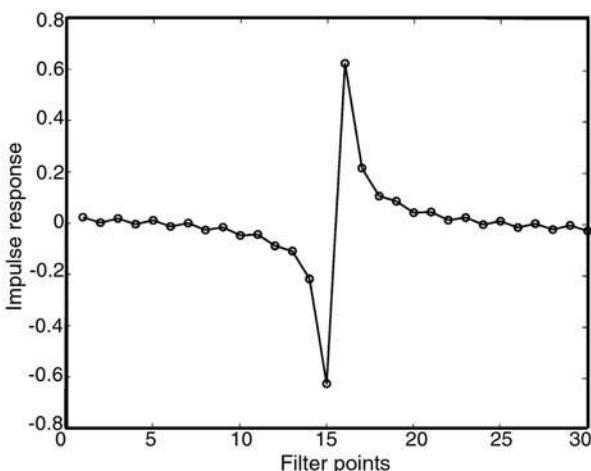

Figure 5 Length 35 Hilbert transformer.

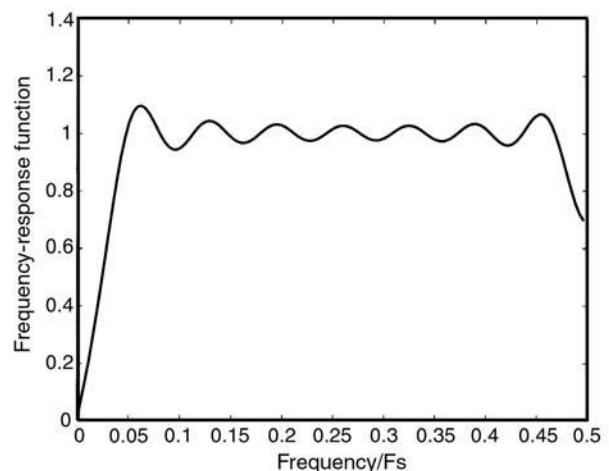

Figure 6 Frequency-response function of the Hilbert transformer.

real input signal $x(t)$. Windowing and/or zero padding may have to be used to avoid ringing.

Time Domain

The HT formulation can be used to build an approximation to an analytic signal generator by designing a finite impulse response (FIR) filter approximation to the HT operator. The analytic signal can be computed by adding the appropriately time-shifted real signal to the imaginary part generated by the Hilbert filter. Since an ideal Hilbert filter impulse response extends infinitely in both directions, approximations are necessary which yield some acceptable amplitude and phase ripples. If a type III (even impulse response length) FIR Hilbert filter is designed, then the group delay will not be a whole number of samples. The real signal will have to be resampled at the points halfway between the existing samples before it can be added to the imaginary part. This problem does not occur for type IV (odd length) Hilbert filters (Figure 5), but these must be designed to be band-pass, rather than high-pass (Figure 6). The FIR digital Hilbert transformers have the advantage of providing exactly linear phase, but at the expense of requiring a higher filter order as compared to the infinite impulse response (IIR) designs, to achieve a given negative frequency attenuation level.

Introduction

Traditionally, structural vibration control techniques have been categorized into two categories, namely, passive and active. Classical passive methods include material damping enhancement, viscoelastic dampers, frictional dampers and joints, and various vibration absorbers and isolation schemes. The advantages of the passive approach are that the devices are relatively simple and cheap, and the system will always be stable since the control is realized by energy dissipation and/or energy redistribution with no external power being added to the system. However, since it produces fixed designs, such schemes might not be optimal or even effective when the system or the operating condition changes. In addition, these schemes usually work well at the high-frequency region or within a narrow frequency range, but often have poor low-frequency performance. Due to the rapid progress in modern electronics and digital signal-processing technique, active systems with feedback/feedforward control schemes have become a viable means for vibration suppression. A typical active control system consists of the plant, actuator(s), sensor(s), and the control electronics. The vibration control is achieved by applying a secondary input to the structure, thereby modifying the system dynamic response to a desirable pattern. While active systems are generally more effective than passive methods, they have the disadvantages such as being complicated and expensive, having the potential to destabilize the system, and being sensitive to system modeling error and uncertainties.

It is clear that the passive and active vibration suppression approaches both have respective strength and weaknesses. This gives rise to the idea of active-passive hybrid vibration controls. In a hybrid system, the active and passive components are synthesized in

an integrated manner such that their combined effect would be superior to that of the individual active or passive actions. If properly designed, hybrid controls could outperform the purely passive and active approaches while requiring much less control power input than active systems. Also, since energy is almost always being dissipated/redistributed by the passive components, they are much more robust and stable than the active approach. In other words, they could have the advantages of both the passive (stability, fail-safe, lower power consumption, good high-frequency performance) and active (high performance, especially in the low-frequency range, feedback/feedforward actions) schemes.

In general, the design of a hybrid vibration control system involves the selection/determination of the active and passive components. It is a natural thought first to identify the relations and performance trade-offs between the active and passive control mechanisms, and then to have the two complement each other such that a system with the best control performance and least control effort can be achieved. There are two schools of thoughts in designing a hybrid system. One is to integrate individual active and passive devices on to the host structure to synthesize a global hybrid control. The other is to design hybrid devices at a local level, such that the actuators will have self-contained active-passive hybrid actions. For both approaches, design strategies need to be developed such that the active and passive actions can be integrated in an optimal manner. A discussion of the design methodologies is presented in the following section. These strategies are generic and are not tied to specific passive control mechanisms and active control actuator/sensor selections. Lastly, some representative self-contained hybrid actuator configuration will be presented.

Design Strategies

In early time, the term hybrid control often referred to the general procedure for an integral design of the structure and its active controller. The original rationale behind this design philosophy is to take into

account the strong dynamic interaction between the structure and the controller. This concept provides the very basic foundation for synthesizing active-passive hybrid control systems. The key idea here is to treat the passive control elements as part of the structure to be synthesized, and develop the active-passive hybrid action in an integrated manner. It has been shown that the combined effect of the active and passive mechanisms can meet vibration suppression requirements that cannot be otherwise achieved by a purely active or purely passive approach alone, since the interaction between them can often be utilized to improve their individual effects.

Depending on specific applications and performance requirements, different design variables, constraints, and objective function(s) can be formulated for an active-passive hybrid system design. For example, one may define the following objective function:

$$J_a = \sigma_1 + \sigma_2 \text{ subject to } m_p \leq m_p^* \quad [1]$$

where σ_1 and σ_2 are the measurements of structural response and control input, respectively:

$$\sigma_1 = E[q^T R_1 q], \quad \sigma_2 = E[u^T R_2 u] \quad [2a, b]$$

where q is the structural response vector, u is the active control input, R_1 and R_2 are weighting

matrices, m_p is the added mass of the passive control device, m_p^* is the maximum allowable value, and $E[\cdot]$ is the expected value operator.

A nested optimization process, which is essentially a simultaneous optimal control/optimization procedure, can be formulated to minimize the above objective function. For a given set of passive parameters (these could include the locations of the active, passive, and/or hybrid actuators, and the device component design and dimensions), the inner optimization loop consists of an optimal linear quadratic (LQ) control problem to determine the active control gains that minimize J_a . The outer optimization loop consists of a search for the passive parameters to minimize further the objective function J_a subject to the constraint on m_p . With this procedure, the active and passive design variables (active gains and passive parameters) are determined simultaneously through iteration between the inner and outer loop optimizations (Figure 1). An interesting feature of this formulation is that the inner and outer loops share the same objective function, which implies that the passive and active mechanisms directly complement or compromise with each other to reach the same goal.

Following along the similar line, one may formulate a different type of optimization procedure where the inner loop and outer loop do not share exactly the same goal. For example, a second objective function can be selected as the total added mass of the passive

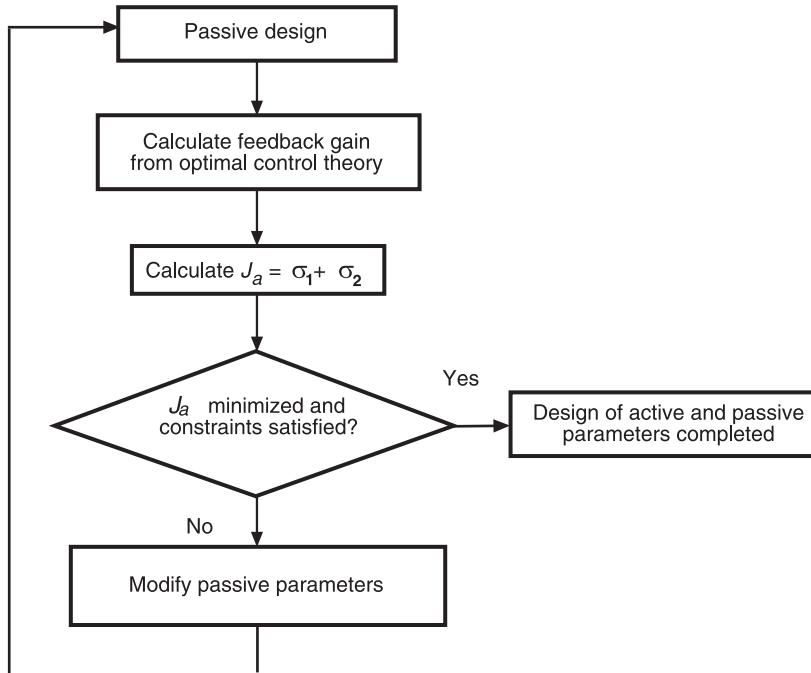

Figure 1 Simultaneous optimal control/optimization for active-passive hybrid system design. Objective function: $J_a = \sigma_1 + \sigma_2$ subject to constraint: $m_p \leq m_p^*$ (mass of passive damping treatment).

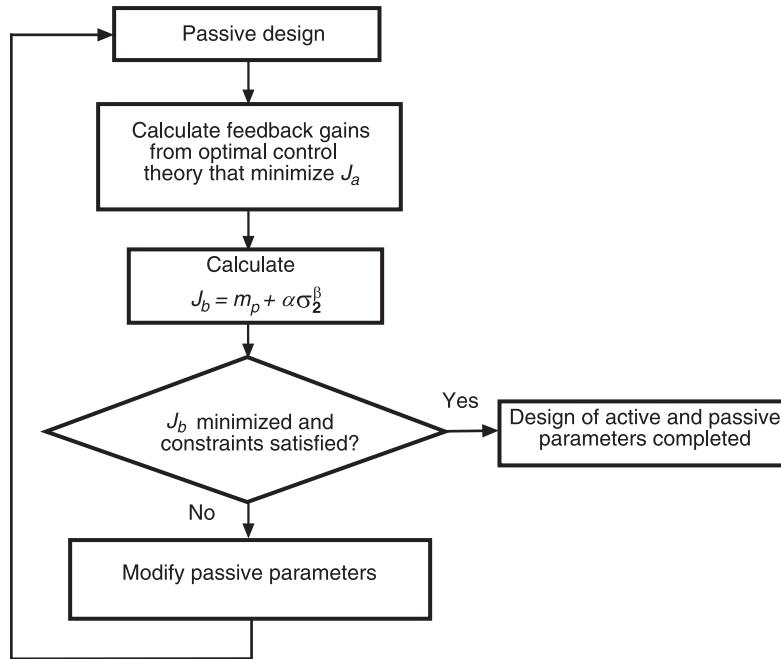

Figure 2 Integrated optimization for active–passive hybrid system design. Inner loop uses optimal control theory to minimize $J_a = \sigma_1 + \sigma_2$, and outer loop uses nonlinear programming to minimize total added mass $J_b = m_p + \alpha\sigma_2^\beta$, subject to constraint $\sigma_1 \leq \sigma_1^*$ (structural response).

control treatment and the active control hardware/power plant:

$$J_b = m_p + \alpha\sigma_2^\beta \text{ subject to } \sigma_1 \leq \sigma_1^* \quad [3]$$

where the mass of the active control hardware/power plant is assumed to be a linear function of σ_2^β , and σ_1^* is the maximum allowable response. An optimization procedure for minimizing J_b is illustrated in Figure 2, which iterates between the two loops for determining the active and passive parameters. While the inner loop still uses the linear optimal control to solve for the active control gains that minimize J_a , the outer loop now aims at minimizing the total added mass (J_b).

The above formulations both resort to the optimal control theory to determine active gains. This is preferred for applications with large number of degrees of freedom, as the well-established optimal control theory can greatly simplify the numerical calculation. On the other hand, one may use other feedback control laws to replace the optimal control theory. In that case, one can have two design options. The first option is to synthesize the active control law (which might not involve an objective function) in the inner loop. The outer loop still consists of a search for passive parameters, to minimize a design objective function, and yields certain compromise through iterations between the two loops (similar to the case

shown in Figure 2). The second one is to fix *a priori* the active controller structure (e.g., a state-feedback or output-feedback structure) and treat the active gains and passive parameters together as design variables in an overall nonlinear programming optimization process, such that certain objective function is minimized. With this process, only one loop is needed. In general, H_2 or H_∞ norms of closed-loop transfer functions from external disturbance to structural response can be good candidates as design objectives. Still, depending on specific mission, one may use other criteria to form the objective function, such as the sensitivity of closed-loop eigenvalues (robustness), closed-loop modal damping factor, and eigenvector optimization/placement for systems with multiple inputs.

In most vibration control problems, design engineers are interested in optimizing one specific property only, and require other properties to fall within a certain range. These problems can be posed as single objective optimizations with various constraints, such as those mentioned above. A great advantage enjoyed by this kind of problem is numerical simplicity, and usually an iteration-type procedure (iteration between the passive design parameters and active control gains) suffices for solving these problems. Under certain circumstances, however, several properties might need to be simultaneously optimized to yield a successful active–passive hybrid control design. For example, one might need to minimize

the mass of passive control device and the structural response simultaneously, thus having a vector-type objective function:

$$J_c = \begin{Bmatrix} m_p \\ J_a \end{Bmatrix} \quad [4]$$

The design procedure then becomes a multiobjective or vector optimization process. Since there might exist no unique solution that would give an optimum for all the objective functions simultaneously, the concept of Pareto optimality has been found useful in this context. In a brief definition, a set of design variables is said to be Pareto-optimal if there exists no other feasible design variable set that would reduce some objective function without causing an increase in at least one objective function. A commonly used method for solving a vector optimization problem is to form a scalar objective as a weighted sum of individual objective functions. Usually, several Pareto optima exist for a multiobjective optimization problem, and by varying the relative weightings in the scalar objective one can generate an entire family of Pareto optima. It is then up to the design engineers to use additional information to make the final decision.

While in this section the optimization-based methodology is discussed as a means for active-passive hybrid control design, it should be noted that many practical designs are accomplished not completely from these analytical and numerical methods but rather based on engineering intuition. Oftentimes the design decisions come, at least partially, from

experience and understanding of respective merits and limitations of the active and passive components, as well as performance tradeoffs between them in specific applications.

Active-Passive Hybrid Control Devices

In some cases, particular passive damping mechanisms/materials can be organically integrated with active control means at the local device level, which could significantly improve the overall system performance. This section presents some of the representative self-contained active-passive hybrid actuator configurations.

Proof-Mass Hybrid Actuator

The key feature of a reaction-type actuator is that the force generator acts between a proof mass and the host structure or, in other words, it creates a force by reacting against an inertial mass. A generic model of a single-degree-of-freedom structure attached with such an actuator is shown in Figure 3A. The equations of motion are:

$$\begin{bmatrix} M & 0 \\ 0 & m_p \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} c_s + c_p & -c_p \\ -c_p & c_p \end{bmatrix} \begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix} + \begin{bmatrix} K + k_p & -k_p \\ -k_p & k_p \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} -f_g \\ f_g \end{Bmatrix} + \begin{Bmatrix} F_m \\ 0 \end{Bmatrix} \quad [5]$$

Hereafter, M , K , and c_s denote the mass, stiffness, and damping of the main structure, m_p is the proof

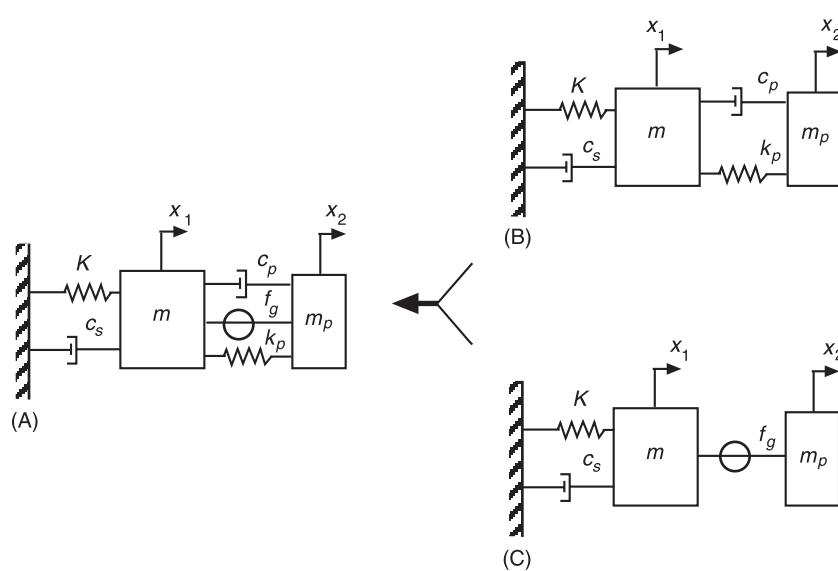

Figure 3 (A) Proof-mass hybrid actuator: design c_p , k_p , and f_g for hybrid control. (B) Tuned vibration absorber: design c_p and k_p for passive control. (C) Active control: design f_g (inherent stiffness and damping of the actuator are not shown).

mass, x_1 and x_2 are the displacements of the main structure and proof-mass, f_g is the output of the force generator, and F_m is the external disturbance. It is easy to recognize that the active and passive parameters f_g , k_p (stiffness), and c_p (damping) can be tuned together to modify the system/actuator dynamics, which gives rise to the proof-mass hybrid actuator concept. If one removes the active component, which in this case is the force generator, the remaining passive component when properly tuned can form a damped vibration absorber, as shown in **Figure 3B**, where the absorber spring-mass will transfer/store part of the kinetic energy and the damper will dissipate it. On the other hand, if one removes the passive damping mechanism, one has a purely active system, as shown in **Figure 3C**. Hereafter, a reaction-type actuator with both the passive and active control abilities is referred to as proof-mass hybrid actuator.

Under the linear system assumption, the response of a structure attached with a proof-mass hybrid actuator is the summation of that caused by the external disturbance and that caused by the control force input. The passive damping ability can be evaluated from the transfer function between the external disturbance and structural response which, in fact, is the frequency response of a system with a tuned vibration absorber. Such a frequency response function depends on the passive parameters m_p , c_p , and k_p . For broadband excitations, one method of optimizing these parameters is to minimize the maximum of the transfer function, known as the classical vibration absorber tuning (for a detailed discussion on dynamic vibration absorbers, refer to **Absorbers, active**). Moreover, in proof-mass hybrid actuator applications, the actuator dynamics can be explicitly included in the system model or even modified by selecting different passive parameters, which could have a positive effect on system performance and robustness.

An *ad hoc* method of designing the proof-mass hybrid actuator is first to select the passive parameters using the optimal passive absorber tuning results, which give the best passive damping, and then determine the active gain based on the control law used. This method obviously does not take into account the performance tradeoff between the active and passive mechanisms (this tradeoff will be illustrated in detail in a later discussion on the active-passive hybrid piezoelectric network that is analogous to the proof-mass hybrid actuator). Indeed, the passive and active parameters of a proof-mass hybrid actuator can be determined by using the simultaneous optimal control/optimization procedure outlined in the previous section. In most applications, the mass of the actuator is predetermined, and one only needs to solve for k_p and c_p as passive parameters. To simultaneously opti-

mize the passive components and active gain, a gradient search can be performed for a range of values of the actuator's stiffness and damping. For each set of k_p and c_p , the optimal control gain is calculated from the optimal control theory. The iteration continues until the minimum objective function value is obtained.

Active-Passive Hybrid Piezoelectric Network

Because of their electromechanical coupling characteristics, piezoelectric materials have been explored extensively for both active and passive damping applications. Some of the advantages of such materials include high bandwidth, high precision, compactness, and easy integration with existing host structures to form the so-called smart structures. A piezoelectric material produces a strain when subjected to an electrical field and, conversely, produces a charge when strained mechanically (for a detailed discussion on piezoelectric material, refer to **Piezoelectric materials and continua**). For an application as shown in **Figure 4A**, under a single mode assumption, the equations of motion for the integrated system are:

$$\begin{aligned} M\ddot{q} + c_s\dot{q} + Kq + k_1Q &= F_m \\ k_2Q + k_1q &= V_a \end{aligned} \quad [6a, b]$$

where q is the structural generalized displacement, Q the charge flowing into the patch electrodes, k_1 the electromechanical coupling coefficient, k_2 the inverse of the capacitance of the piezoelectric patch, and V_a the voltage across the piezoelectric patch.

For active control, a control voltage V_i is applied across the piezoelectric patch, thus $V_a = V_i$ and eqns [6a] and [6b] can be combined as:

$$M\ddot{q} + c_s\dot{q} + Kq - \frac{k_1^2}{k_2}q = F_m - \frac{k_1}{k_2}V_i \quad [7]$$

The two-way electromechanical coupling exhibited by piezoelectric materials have also made them useful as passive structural dampers/absorbers. In such applications, the electrodes of the piezoelectric patch are shunted with a passive electric network that is designed to store/dissipate the electrical energy converted from mechanical energy by the piezoelectric patch. One popular scheme of passive piezoelectric network is to shunt the piezoelectric patch with a resistor and inductor. These two elements, along with the inherent capacitance of the piezoelectric patch, create a resonant RLC circuit, as shown in **Figure 4B**. The equations of motion for such system are:

$$\begin{aligned} M\ddot{q} + c_s\dot{q} + Kq + k_1Q &= F_m \\ L\ddot{Q} + R\dot{Q} + k_2Q + k_1q &= 0 \end{aligned} \quad [8a, b]$$

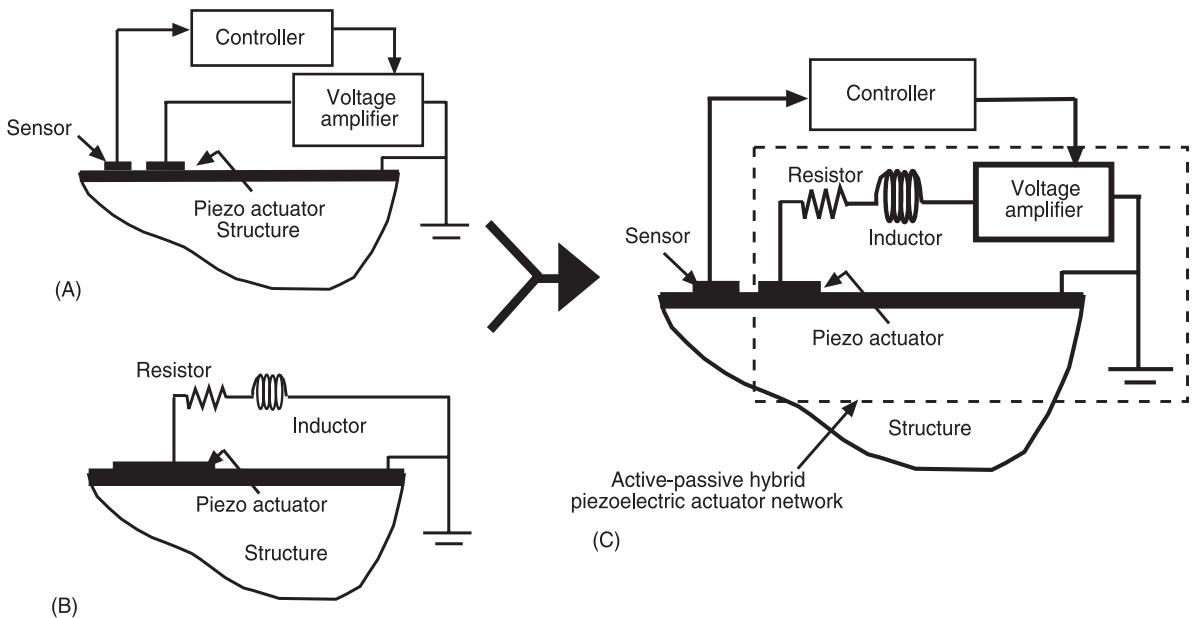

Figure 4 (A) active, (B) passive, and (C) active–passive hybrid piezoelectric controls.

where L and R are the inductance and resistance values, respectively. Clearly, this resonant piezoelectric shunt is analogous to the tuned vibration absorber shown in Figure 3B, except that it counters vibration strain energy instead of kinetic energy. This similarity also gives rise to the idea of combining the passive piezoelectric network and the active voltage input together to form an active–passive hybrid piezoelectric network (APPN), as shown in Figure 4C, which is again fundamentally analogous to the proof-mass hybrid actuator (Figure 3C). The equations of motion for a system integrated with the hybrid network are:

$$\begin{aligned} M\ddot{q} + c_s\dot{q} + Kq + k_1Q &= F_m \\ L\ddot{Q} + R\dot{Q} + k_2Q + k_1q &= V_i \end{aligned} \quad [9a, b]$$

On one hand, the APPN preserves the passive damping ability of the shunt circuit. The transfer function between the external disturbance and the structural response is plotted in Figure 5A, where the continuous line corresponds to the result under optimal passive tuning. This optimal passive tuning is obtained from a min–max criterion similar to that of a tuned vibration absorber. On the other hand, the actuator dynamics caused by the circuit elements may improve the active control performance. Specifically, the second-order effect of the RLC circuit can greatly increase the control authority around the circuit-tuned frequency. Figure 5B shows the ratio between the voltage across the piezoelectric patch and the voltage applied from the driving source. One may easily conclude that an integrated APPN will have better actuation authority

than the configuration with separated active and passive piezoelectric actuators, as illustrated in Figure 6. While the integrated and separated configurations have the same passive damping ability, the former can drive the host structure much more effectively than the latter does, which demonstrates the merit of the self-contained APPN design.

Comparing Figure 5A and 5B, one can observe a performance tradeoff between the passive and active mechanisms. While the resistance in the shunt circuit is needed to provide passive damping, it tends to reduce the voltage amplification effect by dissipating a portion of the control power. To balance between these different requirements and achieve an optimal design, one may again resort to the simultaneous optimal control/optimization procedure discussed in the previous section. Parametric analyses on APPN showed that, when the weighting on control effort increases, the optimal resistance (R) and inductance (L) values using the simultaneous design would approach those derived from the passive optimization procedure. It is also shown that the optimal resistance and inductance values for the hybrid system could be quite different from those of the passive system. In general, when the demand on control performance is high, the resistance value becomes smaller to enhance the active authority amplification effect, and inductance reduces to push the actuator frequency response up to cover a wider-frequency bandwidth. The excitation bandwidth also plays an important role, as it determines to which frequency range or modes the RL values will be tuned.

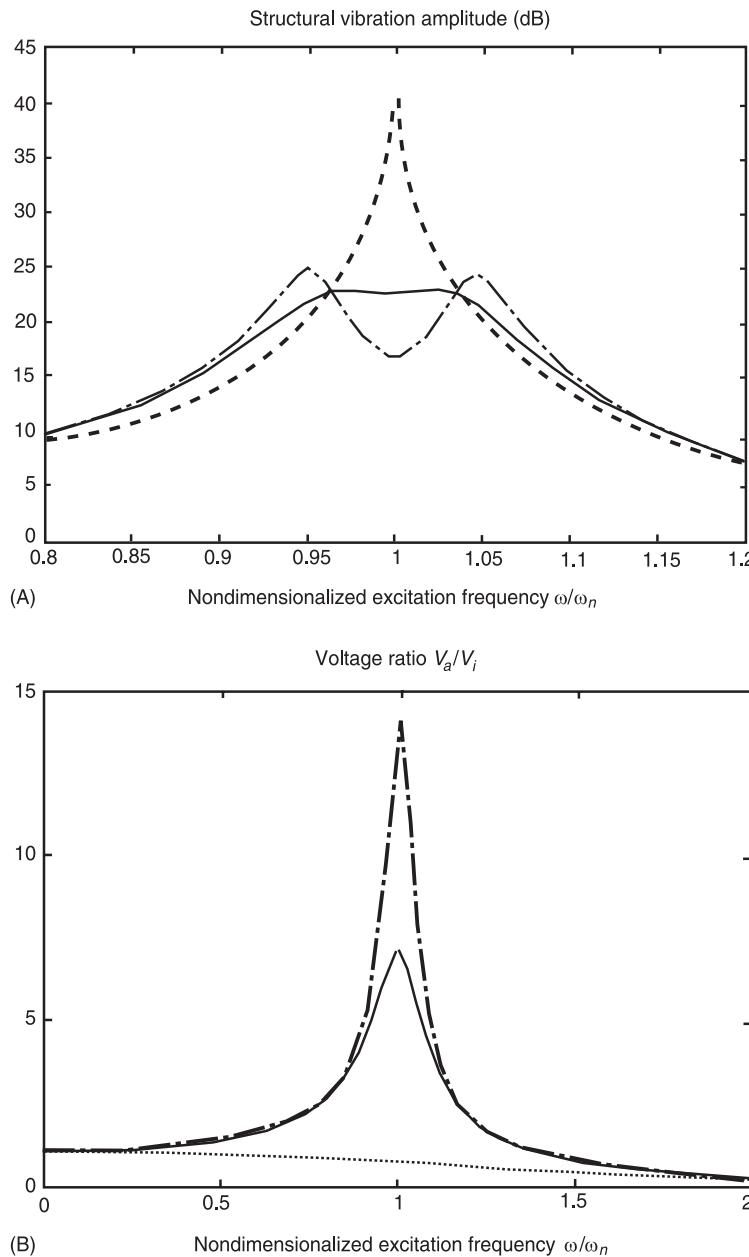

Figure 5 Results of active–passive hybrid piezoelectric network. (A) Passive damping frequency response. (B) Voltage ratio versus actuation frequency (V_a is the voltage across the piezoelectric patch, and V_i the voltage from the external voltage source). Let $\omega_n = \sqrt{K/M}$, $\omega_e = \sqrt{k_2/L}$. The nondimensional passive parameters are defined as:

$$\delta = \frac{\omega_e}{\omega_n} = \sqrt{\frac{k_2/L}{K/M}} \text{ and } r = \frac{R}{k_2} \omega_m = \frac{R}{k_2} \sqrt{\frac{K}{M}}$$

Here the passive parameters are selected as: $\delta = \delta_{opt} = 1$ (optimal passive value). Continuous line, $r = r_{opt} = \sqrt{2}(k_1/\sqrt{Kk_2})$ (optimal passive value); dots and dashes, $r = 0.5r_{opt}$; dashed line, $r = 10r_{opt}$.

Active Constrained Viscoelastic Layer

Basic active constrained layer treatments One of the popular passive damping treatments in industrial applications is to use the viscoelastic materials

(VEM). VEM are elastomeric materials whose long chain molecules cause them to convert mechanical energy into heat when they are deformed. One traditional form of surface damping utilizing the viscoelastic materials is the passive constrained layer (PCL)

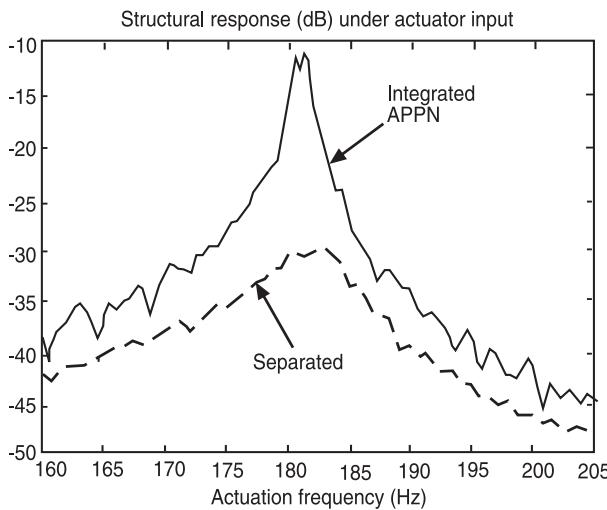

Figure 6 Experimental results on active authority comparison (open-loop structural response/actuator input) between integrated APPN and the configuration with separated active and passive actuators. The two configurations have the same passive damping ability.

treatment (Figure 7A), where a cover sheet is bonded on top of the viscoelastic layer to increase its shear strain under vibration, thus enhancing its passive damping ability (for detailed discussions on VEM and PCL, see **Damping materials**.

Piezoelectric materials are capable of inducing the in-plane tensile strain. Combining this in-plane actuation mechanism with the constrained layer damping, one can form another self-contained hybrid control treatment, the active constrained layer (ACL) damping. A schematic of the ACL system is shown in Figure 7B, where a viscoelastic layer is sandwiched in between a piezoelectric cover sheet and the vibrating host structure. The damping mechanism of ACL can be understood by considering a typical cyclic vibration motion. When the beam moves downward away from its equilibrium position, a control voltage is applied to the piezoelectric cover sheet to result in its shrinkage. This can create a shear angle in the viscoelastic layer that is larger than the angle developed by a passive constraining layer, as illustrated in Figure 7A. When the beam moves upward, an opposite-sign voltage is applied to the piezoelectric cover sheet to result in extension. Again, a larger shear angle than that of a passive constraining layer case can be expected. The increase of the shear deformation of the viscoelastic layer during the entire motion cycle leads to more energy dissipation. In the meantime, the tensile deformation (shrinkage during the downward half-cycle and extension during the upward half-cycle) of the piezoelectric layer produces a bending moment on the host structure that tends to

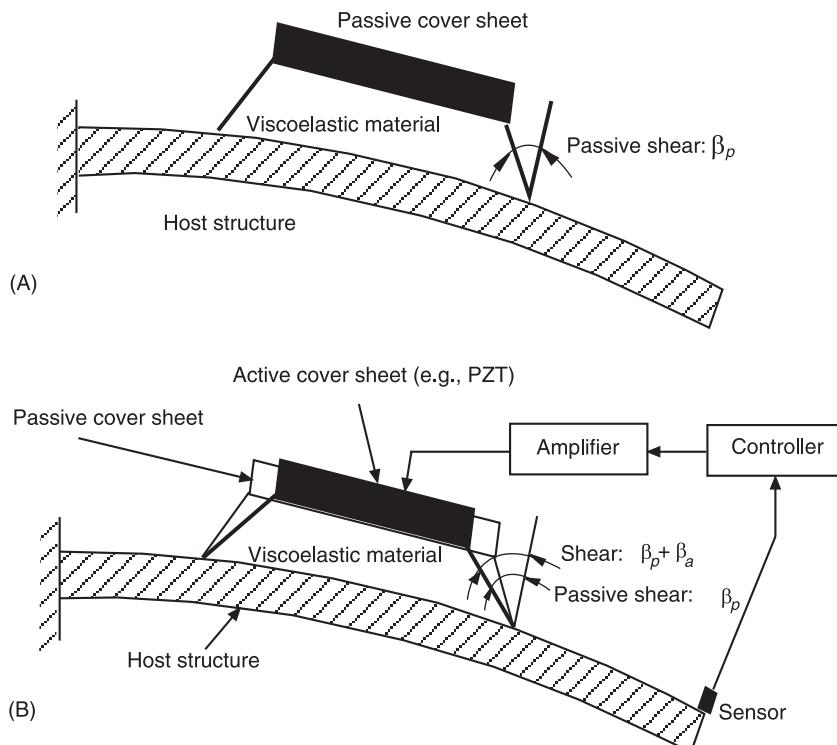

Figure 7 (A) Passive constrained layer (PCL) and (B) active constrained layer (ACL) treatments. The in-plane tensile strain induced by the piezoelectric cover sheet results in an additional shear β_a . The piezoelectric tensile deformation also creates direct active moments to bring the beam back to its original equilibrium position.

bring it back to its original equilibrium position. Therefore, ACL has a twofold vibration control mechanism, the actively enhanced passive energy dissipation and the additional active control moment.

Although straightforward in terms of its basic mechanism, the design of ACL has proven to be challenging. One major complexity is the performance tradeoffs between ACL's passive and active control abilities. While the active action of the piezoelectric constraining layer can indeed enhance the viscoelastic layer's passive damping ability, the viscoelastic material (due to its softness) will also reduce the direct active authority of the piezoelectric material. Compared with a purely active control system where the piezoelectric material is bonded directly to the host structure without the viscoelastic layer, an ACL system might require more control power while achieving less vibration reduction. That is, the passive damping enhancement of the viscoelastic material due to the piezoelectric action may not be significant enough to compensate for the active control authority loss.

The detailed tradeoffs between the active and passive actions in an ACL treatment depend on many system parameters as well as the control law employed. Some qualitative guidelines for ACL designs using linear optimal control are summarized in the following paragraphs:

- It is desirable to let the VEM loss factor be as large as possible to obtain good passive damping abilities and active-passive hybrid actions in ACL designs.
- One can categorize the VEM shear modulus into three regions: low, medium, and high. In the low shear modulus region, both the passive damping ability and active action authority are low for the ACL structure, and therefore the overall performance of the active-passive hybrid system is poor.
- To obtain large vibration reduction with high demand on performance (little concern of control effort), high active gains (high weighting on performance) are usually used. In such cases, one could

select VEM with high shear modulus to achieve high active piezoelectric actions. However, the difference between the ACL and the purely active configurations might not be obvious. Another point worth noting is that, when the VEM becomes too stiff, the passive VEM damping could become ineffective, and the ACL's fail-safe ability (which is a desirable feature of such active-passive hybrid structures) could be significantly reduced.

- To achieve good vibration reduction performance under significant constraints on control effort, the active gain values are usually limited. This is the best scenario for applying ACL, where the benefits of both the passive damping and active action could be obtained. In this case, we should choose the VEM shear modulus in the medium region. Generally, this is the most useful region for ACL designs.

Enhanced active constrained layer treatments The main shortcoming of the basic ACL treatments is the active authority reduction due to the insertion of VEM. There have been recent proposals to use edge elements (boundary elements that directly connect the piezoelectric cover sheet to the host structure) to improve the active action (Figure 8A). Studies have shown that with sufficiently stiff edge elements, this enhanced active constrained layer (EACL) treatment can achieve more vibration suppression with less control effort than both the ACL and purely active systems. It should be noted that the selection of edge element stiffness could also introduce new tradeoff factors into the design of constrained layer treatments. In general, if closed-loop versus open-loop (without active action contributions) damping contributions (or active versus passive action contributions) are not of concern, a properly designed symmetrical EACL with equal and stiff edge elements could achieve maximum hybrid damping for different combinations of vibration modes (host structure strain distribution) (Figure 9). However, an asymmetrical EACL design could provide a better mixture of active and passive damping

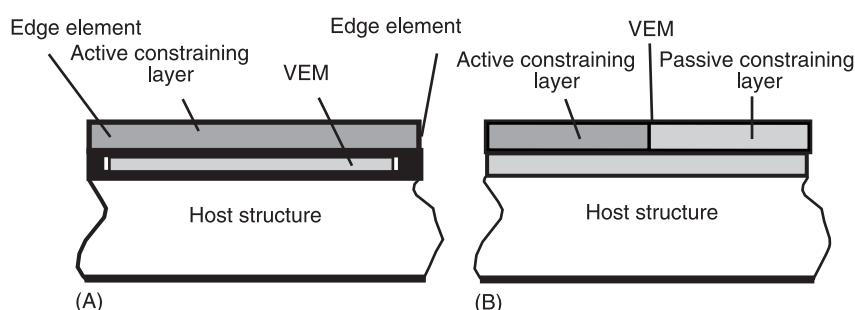

Figure 8 (A) The enhanced active constrained layer (EACL) with edge elements and (B) the hybrid constrained layer (HCL) treatment.

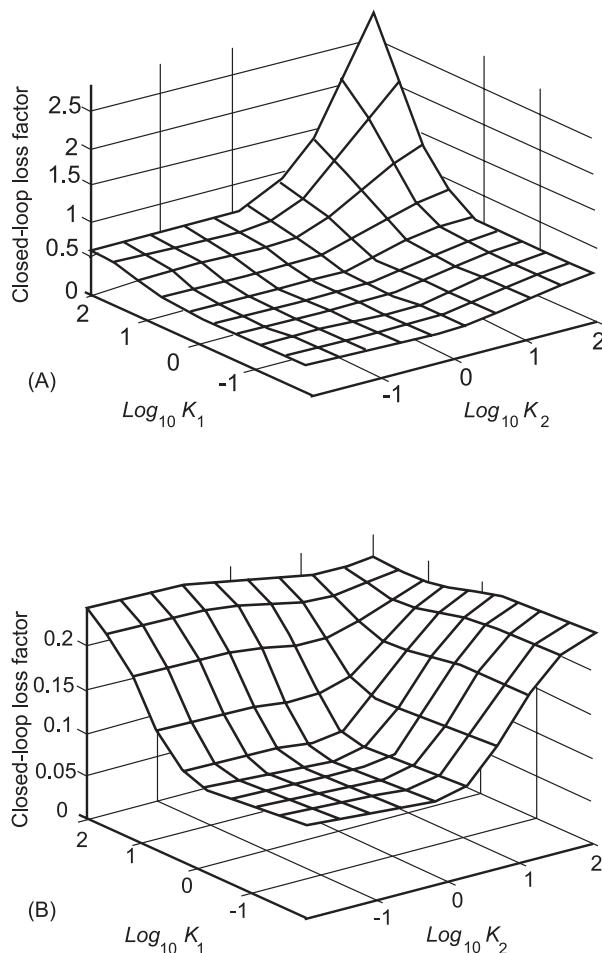

Figure 9 Closed-loop hybrid loss factor versus edge element stiffness K_1 and K_2 in EACL. (A) Constant strain field in host structure. (B) Asymmetric strain field in host structure.

(or closed-loop and open-loop damping), but could reduce the overall hybrid damping ability (Figure 9).

Hybrid constrained layer treatments In both the ACL and EACL treatments, the constraining layer is completely made of piezoelectric materials (e.g., lead zirconate titanate (PZT) ceramics or polyvinylidene fluoride (PVDF) polymer). PZT materials are in general much better than PVDF polymers for this purpose. Nevertheless, having a density similar to

steel (relatively heavy) and a modulus close to aluminum (moderate stiffness), PZTs are not ideal as constraining materials. Due to the limited selections of active materials, it is difficult to find one with strong active action and, at the same time, good material property for constraining action. Another set of treatments recently being proposed is the HCL configuration (Figure 8B). In the HCL, the active segment is made of PZTs and the passive segment could use different materials under different circumstances. By selecting a passive material stiffer than PZT, the HCL could obtain higher open-loop damping than the treatment with a pure PZT cover sheet. Furthermore, it can be shown that when the active-to-passive constraining length ratio is optimally selected, the overall closed-loop damping of the HCL could also be higher than that of the configuration with a pure PZT coversheet.

Nomenclature

c	damping
$E(\cdot)$	expected value operator
K	stiffness
L	inductance
M	mass
q	structural generalized displacement
Q	charge
R	resistance
V	voltage

HYSTERETIC DAMPING

H T Banks and G A Pinter, North Carolina State University, Raleigh, NC, USA

doi:10.1006/rwvb.2001.0018

Definition of Hysteretic Damping

Vibrational damping is associated with the dissipation of energy during mechanical vibrations/deformations of an elastic body, usually via the conversion of mechanical energy to thermal energy producing heat

in the body which is readily dissipated. Damping is most properly embodied in constitutive laws that relate a body's deformation (strain ε) or displacement to the stress σ or force associated with this deformation. These are most often given in terms of stress/strain laws $\sigma = \mathcal{F}(\varepsilon)$, the most elementary of which is Hooke's law:

$$\sigma = E\varepsilon \quad [1]$$

where E is the material-dependent Young's modulus or modulus of elasticity. Here and throughout, we discuss concepts in a one-dimensional formulation such as occurs for example in the case of elongation of a simple uniform rod. In more general deformations one must use tensor analogs of the stress σ , the strain ε , and parameters such as the modulus of elasticity E . We shall also assume small deformations throughout so that infinitesimal strain theory can be used.

Hooke's law (which is an idealization) does not allow for dissipation, which occurs to some extent in all materials. The most widely accepted model which does is the Voigt model:

$$\sigma = E\varepsilon + C\dot{\varepsilon} \quad [2]$$

where $\dot{\varepsilon} = d\varepsilon/dt$ is the strain rate. To characterize stress-strain laws, it is common to consider material behavior during cyclic loading-unloading and plot the associated stress-strain curves as given in Figure 1 for the Voigt law.

Whenever the material behaves differently under unloading than under loading (as in the case for eqn [2] but not for eqn [1]), the material is said to be viscoelastic and to exhibit the phenomenon of

hysteresis. Hysteresis is present in many materials such as filled rubber and filled rubber-like composites (often referred to as elastomers), shape memory alloys (SMAs) such as Nitinol (a nickel-titanium alloy) and CuZnAl (a copper-zinc-aluminum alloy), piezoelectrics (e.g., PZTs or lead zirconate titanates), electrostrictives (e.g., PMNs or lead magnesium niobates) and magnetostrictives (e.g., Terfenol-D, a terbium iron dysprosium alloy). The Voigt law [2] is inadequate in characterizing the hysteresis in such materials under many conditions where the hysteresis loop can be quite complex, as depicted in Figures 2 and 3.

A number of different modeling approaches and resulting models have been developed to describe quantitatively the various hysteretic dissipation mechanisms such as that manifested in hysteresis loops similar to those shown in Figures 2 and 3.

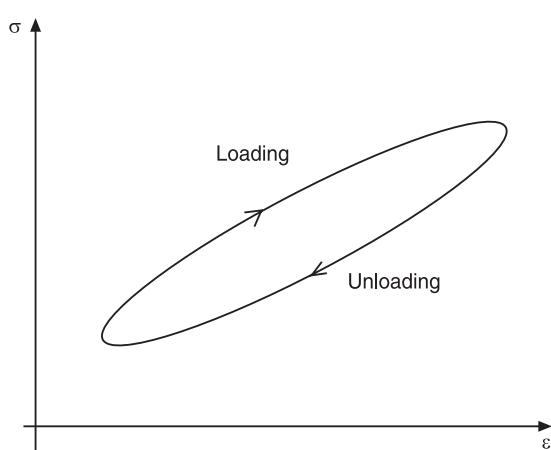

Figure 1 Loading/unloading for a Voigt material.

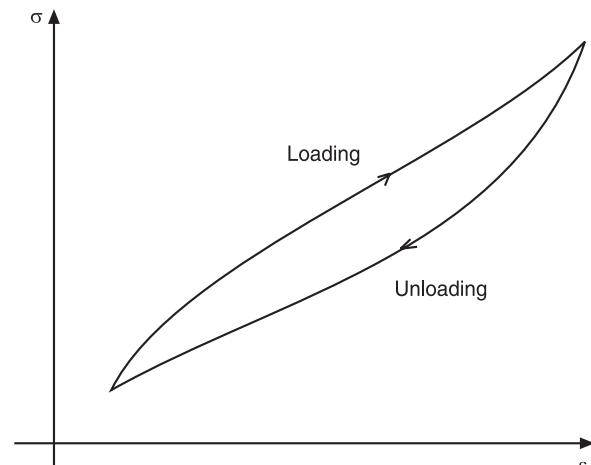

Figure 3 Loading/unloading of filled rubber.

Models for Hysteresis

The most fundamental model that correctly describes the hysteretic behavior of a number of materials is the standard linear model due to Kelvin (and therefore sometimes also referred to as the Kelvin model). This model (to be discussed below), along with a number of others, is frequently developed and analyzed in the context of the phenomena of relaxation and creep which, along with hysteresis, constitute the features of general viscoelasticity. If a viscoelastic rod is suddenly stressed (for example, with a unit step force) and held at this level of stress, the rod will continue to deform (as depicted in Figure 4 for the Kelvin model) in a phenomenon called creep.

On the other hand, if a rod is suddenly strained (for example, with a unit step displacement) and this strain is then maintained, the resulting stress in the rod will decrease over time, as depicted for one model (the Kelvin model) in Figure 5. This phenomenon is called *relaxation*. While the specific shape of the creep and relaxation responses are highly dependent on the particular constitutive law chosen, the general qualitative features represented in Figures 4 and 5 are typical.

The Kelvin or Standard Linear Model

The simplest constitutive model describing the phenomenon of hysteresis which incorporates empirically observed creep and relaxation in materials is the Kelvin or standard linear model given by:

$$\sigma + \tau_\varepsilon \dot{\sigma} = E_r(\varepsilon + \tau_\sigma \dot{\varepsilon}) \quad [3]$$

where E_r is called the relaxed modulus of elasticity.

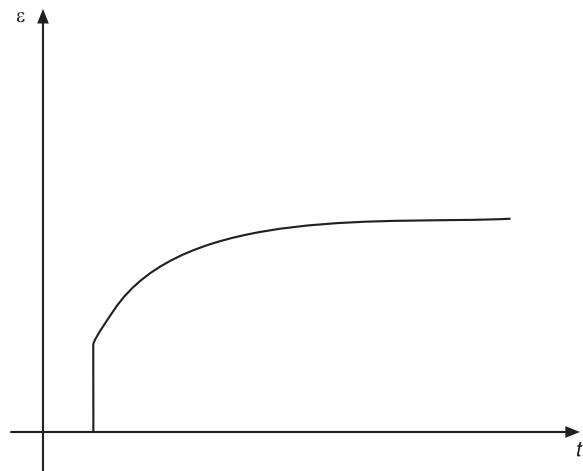

Figure 4 Standard linear model creep response.

This model can be depicted in the context of spring-dashpot analogies, as shown in Figure 6.

The creep solution (or creep function) $\Delta\varepsilon(t)$ of eqn [3] is the solution corresponding to step stress $\Delta\sigma$ at time $t = s$. That is, $\Delta\varepsilon(t)$ is the solution of eqn [3] corresponding to $\sigma_s(t) = H(t - s)\Delta\sigma$, $\dot{\sigma}_s(t) = \delta(t - s)\Delta\sigma$, where H is the Heaviside function and δ is the Dirac delta distribution, and is given by:

$$\Delta\varepsilon(t) = \frac{1}{E_r} \left\{ 1 + \left(\frac{\tau_\varepsilon}{\tau_\sigma} - 1 \right) e^{-(t-s)/\tau_\sigma} \right\} H(t-s)\Delta\sigma \quad [4]$$

For obvious reasons, τ_σ is called the constant stress relaxation time.

The relaxation solution (or relaxation function) $\Delta\sigma(t)$ of [3] is the solution corresponding to a step elongation $\varepsilon_s(t) = H(t - s)\Delta\varepsilon$, $\dot{\varepsilon}_s(t) = \delta(t - s)\Delta\varepsilon$ at time $t = s$ and is given by:

$$\Delta\sigma(t) = \frac{1}{E_r} \left\{ 1 + \left(\frac{\tau_\sigma}{\tau_\varepsilon} - 1 \right) e^{-(t-s)/\tau_\varepsilon} \right\} H(t-s)\Delta\varepsilon \quad [5]$$

where τ_ε is called the constant strain relaxation time.

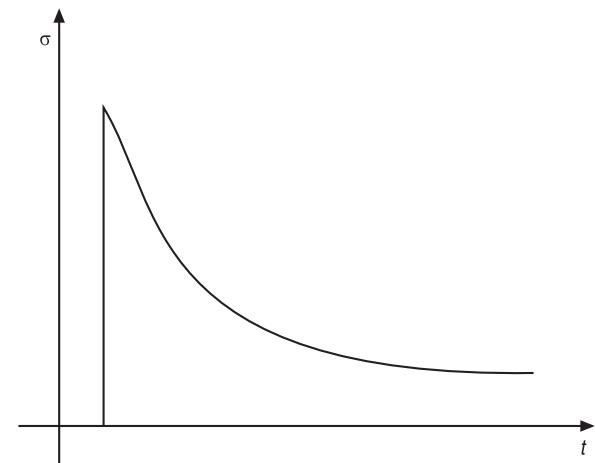

Figure 5 Standard linear model relaxation response.

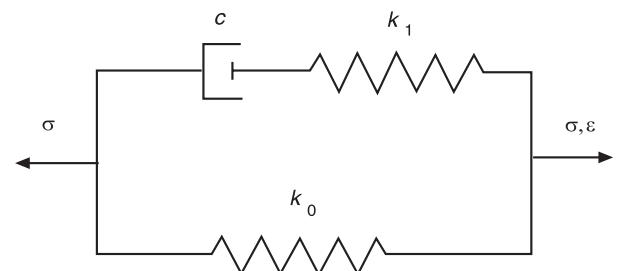

Figure 6 The Kelvin spring-dashpot model.

The Boltzmann Superposition Model

The most direct generalization of the Kelvin or standard linear model is due to Boltzmann and assumes superposition of a continuum of the relaxation solution responses to a continuum of elemental step increments in strain. The stress-strain law (in differential form) is given by:

$$\begin{aligned} d\sigma(t) &= E_0 d\varepsilon(t) + k(t-s) d\varepsilon(s) \\ &= E_0 d\varepsilon(t) + k(t-s) \dot{\varepsilon}(s) ds \end{aligned} \quad [6]$$

for the incremental stress at time t due to a continuum of elemental elongations $d\varepsilon(s)$ for $s \leq t$. The constant of proportionality E_0 represents the instantaneous response while the proportionality constant $k = k(t-s)$ is dependent on the length of elapsed time $t-s$ and is called the generalized relaxation function. Invoking the linear superposition hypothesis of Boltzmann and summing over the past life of the structure, one obtains (assuming $\sigma(-\infty) = 0, \varepsilon(-\infty) = 0$) the Boltzmann hysteretic constitutive law:

$$\sigma(t) = E_0 \varepsilon(t) + \int_{-\infty}^t k(t-s) \frac{d\varepsilon}{ds}(s) ds \quad [7]$$

where E_0 represents an instantaneous modulus of elasticity and k is the relaxation response kernel. The standard linear model is a special case of the Boltzmann model with the choice $k(t-s) = E_\varepsilon e^{-(t-s)/\tau_\varepsilon}$. More general special cases that are often encountered include a generalization of the single spring-dashpot paradigm of Figure 6 to one with multiple spring-dashpot systems in parallel, which results in the relaxation response kernel:

$$k(t-s) = \sum_{j=1}^N E_j e^{-(t-s)/\tau_j} \quad [8]$$

We observe that eqns [7] and [8] are equivalent to the formulation:

$$\sigma(t) = E_0 \varepsilon(t) + \sum_{j=1}^N E_j \varepsilon_j(t) \quad [9]$$

$$\begin{aligned} \dot{\varepsilon}_j(t) + \frac{1}{\tau_j} \varepsilon_j(t) &= \dot{\varepsilon}(t) \\ \varepsilon_j(-\infty) &= 0 \quad j = 1, 2, \dots, N \end{aligned} \quad [10]$$

since the solution of eqn [10] is given by:

$$\varepsilon_j(t) = \int_{-\infty}^t e^{-(t-s)/\tau_j} \dot{\varepsilon}(s) ds \quad [11]$$

The formulation [9]–[10] is sometimes referred to as an internal variables model since the variables ε_j can be thought of as internal strains that are driven by the instantaneous strain according to eqn [10] and that contribute to the total stress via eqn [9]. Such models can be viewed as phenomenological in nature in that one does not attempt to identify any physical basis for the internal strains ε_j or they can be viewed as physical models wherein the strains ε_j are identified with specific mechanisms and/or molecules in a complex composite material with dynamics described by [10].

Generalization of the Standard Linear/Boltzmann Models

The Boltzmann model [7] is one of many generalizations of the standard linear model [3]. One such generalization due to Burger (later studied by Golla-Hughes-McTavish) is frequently encountered in the engineering literature wherein one attempts to introduce additional coordinates (essentially internal variables) into state space models to account for hysteresis. The general approach is in the frequency domain (as opposed to the time domain formulations discussed here) and employs complex modulus or loss factor data to fit rational polynomials representing the Laplace transform of hysteresis stress-strain relationships. Specifically, hysteresis is approximated by adjoining a state variable with frequency domain representation:

$$h(s) = \frac{\alpha s^2 + \beta s}{s^2 + bs + c} \quad [12]$$

This is equivalent to an internal dynamics of the form (the Burger model):

$$\ddot{\sigma} + b\dot{\sigma} + c\sigma = \alpha\ddot{\varepsilon} + \beta\dot{\varepsilon} \quad [13]$$

in the time domain, or $\hat{\sigma}\{s^2 + bs + c\} = \{\alpha s^2 + \beta s\}\hat{\varepsilon}$ in the frequency domain. This can be thought of as a direct generalization of the standard linear model [3] or can be reformulated as a generalization of internal variable/Boltzmann models such as [9]–[10] by defining generalized stress $\tilde{\sigma} = (\sigma, \dot{\sigma})$ and generalized strain $\tilde{\varepsilon} = (\varepsilon, \dot{\varepsilon}, \ddot{\varepsilon})$ vectors and writing [13] as:

$$\dot{\tilde{\sigma}} = A\tilde{\sigma} + B\tilde{\varepsilon} \quad [14]$$

so that:

$$\tilde{\sigma}(t) = \int_{-\infty}^t e^{A(t-\tau)} B \tilde{\varepsilon}(\tau) d\tau \quad [15]$$

with:

$$A = \begin{pmatrix} 0 & 1 \\ c & b \end{pmatrix} \quad B = \begin{pmatrix} 0 & 0 & 0 \\ 0 & \beta & \alpha \end{pmatrix}$$

Nonlinear Hysteresis Models

For many materials the linear models for hysteresis discussed above are inadequate to describe experimental data. In particular, many composite materials exhibit nonlinear behavior such as that seen in Figure 2 for SMAs and in Figure 3 for highly filled rubbers. Biological soft tissue is also known to exhibit nonlinear hysteretic behavior.

There are several standard generalizations found in the literature in attempts to treat nonlinear behavior. The most direct one is to allow nonlinear instantaneous strain as well as nonlinear strain rate dependence in [7]. This yields models of the form:

$$\sigma(t) = f_e(\varepsilon(t)) + \int_{-\infty}^t k(t-s) f_v(\dot{\varepsilon}(s)) ds \quad [16]$$

and:

$$\sigma(t) = f_e(\varepsilon(t)) + \int_{-\infty}^t k(t-s) \frac{d}{ds} f_v(\varepsilon(s)) ds \quad [17]$$

where f_e represents the instantaneous elastic nonlinear response and f_v represents the viscoelastic nonlinear response function. This can be written in terms of internal strains similar to [9] and [10] where [8] defines k and:

$$\sigma(t) = f_e(\varepsilon(t)) + \sum_{j=1}^N E_j \varepsilon_j(t) \quad [18]$$

whenever we assume linear internal dynamics of the form:

$$\dot{\varepsilon}_j(t) + \frac{1}{\tau_j} \varepsilon_j(t) = f_j(\dot{\varepsilon}(t)), \quad j = 1, 2 \dots N \quad [19]$$

or:

$$\dot{\varepsilon}_j(t) + \frac{1}{\tau_j} \varepsilon_j(t) = \frac{d}{dt} f_0(\varepsilon(t)), \quad j = 1, 2 \dots N \quad [20]$$

with $f_j = f_v$ for each j . Models of the form [18] and [20] have been successfully used to describe data for highly filled rubber such as that depicted in Figure 3 and data involving nested hysteresis loops, as shown in Figures 7 and 8.

A more general nonlinear model results if one assumes different nonlinearities f_j for different j in [19] or [20]. If one assumes nonlinear internal dynamics of the form:

$$\dot{\varepsilon}_j(t) + g_j(\varepsilon_j(t)) = f_j(\dot{\varepsilon}(t)), \quad j = 1, 2 \dots N \quad [21]$$

in place of [19], then the model combining this with [18] cannot be written as a Boltzmann generalization in the form [16] and thus constitutes a nontrivial generalization of the Boltzmann superposition approach. A related but somewhat different generalization of the standard linear/Boltzmann approach has

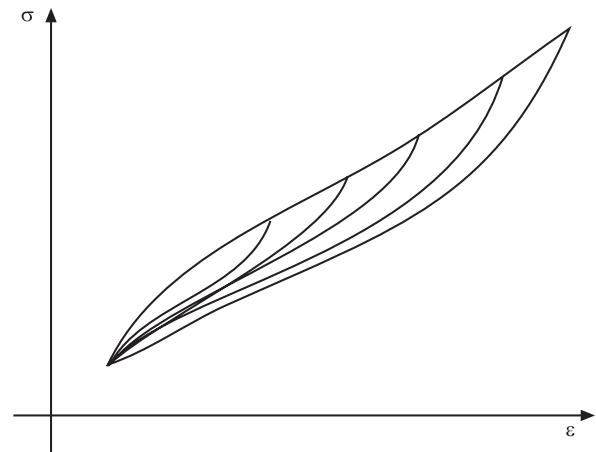

Figure 7 Complete nested hysteresis loops.

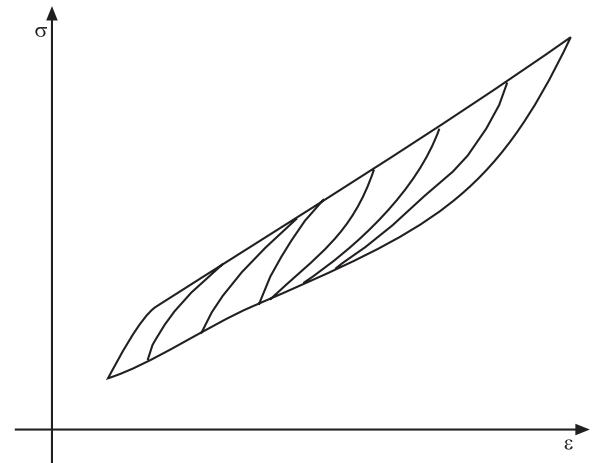

Figure 8 Incomplete nested hysteresis loops.

been used to model biological soft tissues where the hysteresis loop is independent of strain rate in a finite range of rate variation. In models due to Fung one replaces [7] by:

$$\sigma(t) = \int_{-\infty}^t G(t-\tau) \dot{\sigma}^e(\tau) d\tau \quad [22]$$

where σ^e is the instantaneous elastic response to a step elongation and G is a reduced relaxation kernel defined by:

$$G(t) = \{1 + c[\mathcal{E}(t/\tau_1) - \mathcal{E}(t/\tau_2)]\} / \{1 + c \ln(\tau_2/\tau_1)\} \quad [23]$$

where:

$$\mathcal{E}(t) = \int_t^\infty \frac{e^{-\tau}}{\tau} d\tau$$

The generalized kernel G defined in eqn [23] is a decreasing function that has constant slope in the interval (τ_1, τ_2) and produces constant damping in the frequency range $\tau_1 \leq 1/\omega \leq \tau_2$. It effectively replaces the finite spectrum associated with relaxation kernels of the form given in [8] by a continuous spectrum over a finite range. The Fung model is obtained by considering a large number of Kelvin-type units as shown in Figure 6 in series, where in each unit the springs are nonlinear functions of the elongation while the dashpots are linear functions of the tension in the springs.

The standard linear/Boltzmann models and their generalizations discussed above all entail a physics-based approach in that they are usually derived and used in connection with some (perhaps unknown) internal physics hypothesized for the viscoelastic body. There is however a large literature on purely phenomenological approaches to hysteresis wherein one attempts to approximate directly the hysteresis loops depicted in Figures 2 and 3. The best known of these involve Preisach models and their generalizations due to Krasnosel'skii and Pokrovskii. The approach uses ideal relay operators such as that given in Figure 9 in parallel connections to produce hysteresis loops similar to that shown in Figure 10. These are then smoothed to produce a smoothed ideal relay, as depicted in Figure 11.

Families of these relays (which depend on 'switch points' s_1, s_2) can then be used to construct a hysteresis operator of the form:

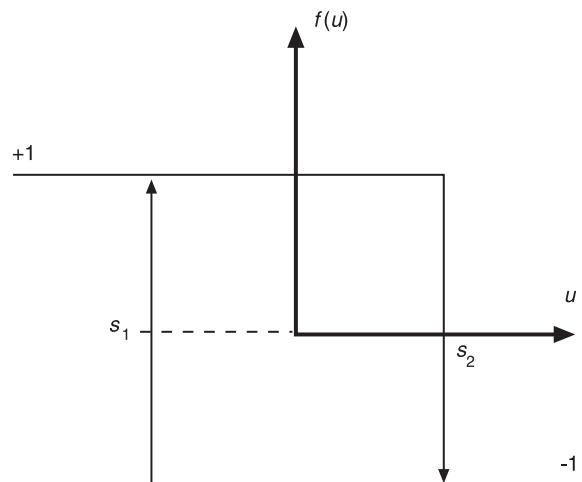

Figure 9 Ideal delayed relay operator.

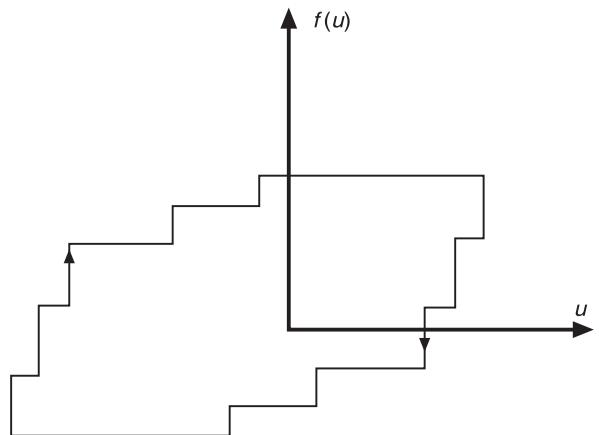

Figure 10 Parallel connection, multiple ideal relays.

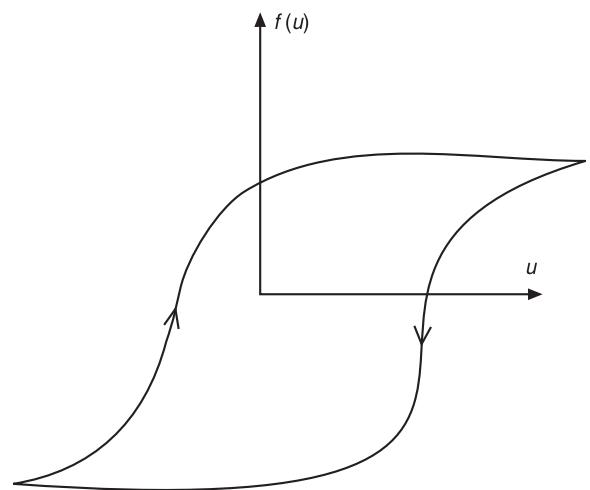

Figure 11 Smoothed ideal relay operator.

$$\sigma(t) = [P_\mu(\varepsilon, \xi)](t) = \int_{\bar{S}} [k_s(\varepsilon, \xi(s))](t) d\mu(s) \quad [24]$$

where μ is a signed Borel measure on the closed Preisach plane $\bar{S} = \{(s_1, s_2) | s_1 \leq s_2\}$ of switches, k_s is a generalized Preisach kernel, and ξ contains initial state information. In the classical Preisach formulation, the kernel is defined in terms of linear combinations of relays as depicted in **Figure 10**, while smoothed relays as in **Figure 11** are used in the generalized Krasnosel'skii–Pokrovskii kernels. In addition to the perhaps unsatisfying aspect of being purely phenomenological, this approach has serious difficulties if used as a means to model damping in viscoelastic structures. First, there are a large number of nonphysical parameters (defining the switches and relays) that must be identified. More importantly, the resulting operator in the stress–strain relationship [24] is rate-independent and hence cannot be expected to yield adequate models to describe hysteretic damping in most viscoelastic structures which usually exhibit strong frequency (and hence rate) dependence.

Nomenclature

E	Young's modulus
G	generalized kernel
H	Heaviside function
s_1, s_2	switch points
t	time

δ	Dirac delta distribution
ε	strain
σ	stress

doi:10.1006/rwvb.2001.0120

Identification of vibrating systems is in a sense the inverse of the analysis problem. In the analysis, a response is predicted based on knowledge of the system's model and the excitation (Figure 1). The identification extracts a model based on knowledge of an excitation and the response. It is usually based on experimentally acquired data, and measurement aspects have to be considered when performing such tasks. Identification methods thus utilize sampled data.

A major part of the identification task assumes that the vibrating system is linear, and thus draws heavily on the well-established discipline of linear system identification. As such we encounter cases of single input/single output (SISO), multiple input/single output (MISO) and multiple input/multiple output (MIMO). In this section it is mainly the SISO case that is addressed.

There are two basic types of identification methods: parametric (often referred to as model-based) and nonparametric. In the parametric methods, a

model structure is assumed (or known) and the model's parameters are extracted by the identification procedure. The parameters can be mathematical, for example, the coefficients linear differential (or difference) equation. They can be physical, for example, natural frequencies and damping ratios. In general, the number of parameters identified in the parametric approach is significantly smaller than the number of points in the describing functions resulting from the nonparametric approach. In the nonparametric methods, an identifying function is sought. Examples are frequency response functions (FRFs) and impulse responses. This section deals with nonparametric frequency domain methods only.

Identification methods are also categorized according to the excitation signal used. The term 'rich' is used for excitations that enable one to identify more or less the complete system characteristics. In terms of the FRF, a rich excitation would cover the frequency range of interest. Rich excitations include transients, periodic, and random functions. Harmonic excitations, usually termed sine excitations, are very powerful, but not rich. A classification according to excitation methods thus covers stepped sine testing, impulse testing (transient), random testing, periodic burst, multisine, etc. The identification procedure and characteristics may be heavily dependent on the type of excitation used.

In utilizing experimentally acquired data, the various uncertainties associated with experiments necessitate a variety of approaches to the identification task. The majority of identification approaches address uncertainties that can be modeled as additive error, usually referred to as noise, to the measured signals. The assumptions made concerning such noise can dictate the type of identification procedure to be used. A specific procedure is geared to situations where uncertainties can be modeled as white noise added to the response measurement only. Other procedures would handle noise added to the input or more general cases.

The accuracy of the results will depend heavily on the procedure, the correctness of assumptions, the type of excitation.

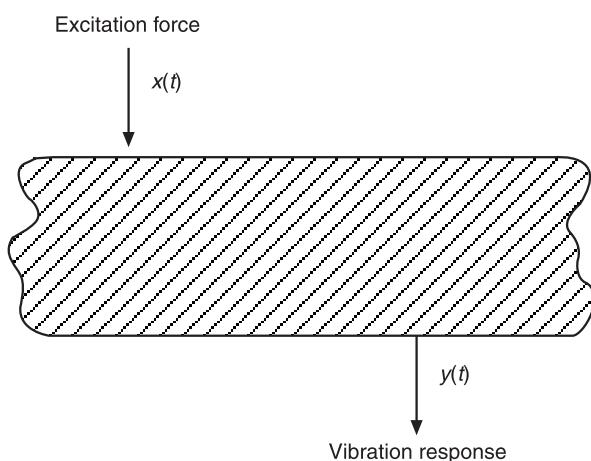

Figure 1 Identification test.

Frequency Domain Identification

This is a nonparametric identification. Frequency domain information is based on Fourier methods. Applying a Fourier transform to the differential equation describing the linear system results in an algebraic one.

The noiseless case: Such a case is rarely assumed, but merits fundamental consideration (Figure 2).

$$\begin{aligned} Y(i\omega) &= H(i\omega)X(i\omega) \\ H(i\omega) &= \frac{Y(i\omega)}{X(i\omega)} \end{aligned} \quad [1]$$

The FRF $H(i\omega)$ is a complex number. For the steady-state response to a sine excitation of frequency ω , its magnitude is the gain at this frequency, and its phase is the corresponding phase shift. Bode or Nyquist plots are usually used to depict H graphically. The procedure would consist of computing the transforms of the excitations and responses and performing the division of eqn [1]. The advantage of the frequency domain approach is evident from eqn [1]: H is identified separately at each frequency. In principle, a partial identification is possible, for limited frequency ranges.

A time domain identification, the system's impulse response, can be derived similarly via the frequency domain identification. This is based on the relation between the impulse response and the FRF via an inverse Fourier transform:

$$h(t) = F^{-1}[H(i\omega)] \quad [2]$$

For a sine excitation, H is computed at a single frequency. Using a stepped sine a function, $H(\omega)$ would be computed step by step.

For a transient excitation, both the excitation and the response would be broadband, covering a range of frequencies. In contrast to the sine excitation, a complete FRF can be extracted from a single test, at least in principle. The identification can be performed as long as the absolute magnitude of $X(\omega)$ exceeds a minimum level. For too small $|X(\omega)|$ (and obviously for $|X(\omega)| = 0$) the problem is ill conditioned and the resultant H problematic. The frequency range of the

identification is dictated by the richness of the excitation, i.e., by the region where excitation energy exists. Periodic rich signals can also be used. One example are periodically repeating random bursts, another example is the multisine signal, a combination of sines of different frequencies but where the sum has a periodicity of its own. The spectrum of such signals is discrete. Using eqn [1], H can again only be identified at these discrete frequencies, where $|X(\omega)|$ differs from zero.

A random excitation is also usually broadband, i.e. rich, and a complete FRF can again be identified. Owing to the statistical character of the excitation and response, the functions $X(\omega)$ and $Y(\omega)$ will have a probability distribution, which may be quite complex. The variance of spectral functions is significant, hence H as computed by eqn [1] may also have a large variance. The variance can be reduced by averaging, but some care is needed to apply this technique correctly. Averaging of separately acquired functions $X(\omega)$ and $Y(\omega)$ would be incorrect, as their expectations $E[X(\omega)]$ and $E[Y(\omega)]$ are zero. Averaging for the noiseless case would be done as:

$$\frac{1}{M} \sum_{k=1}^M \frac{Y_k(i\omega)}{X_k(i\omega)}$$

where X_k and Y_k are samples of complete frequency domain functions (Fourier transform), and M the number of sections used for averaging.

Identification with Noise-corrupted Signals

The general case, even when purely additive noise is assumed, is deceptively straightforward. For noises with given (or assumed) probability distributions, the maximum likelihood function approach can be used to estimate the 'best' FRF values. This leads to a nonlinear weighted least-squares problem, which must be solved via appropriate iterative minimization of a cost function. While appropriate commercial software packages aimed specifically at vibrating systems have been developed, this approach is not widespread in practice.

Identification for Output Additive Noise

This is probably the most popular model, even if the assumption that the noise can be modeled in such a way is not always justified (Figure 3):

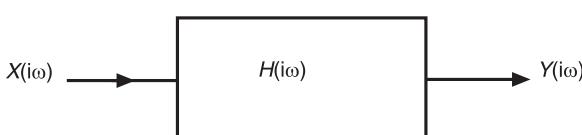

Figure 2 Frequency domain linear model.

$$Y(i\omega) = H(i\omega)X(i\omega) + N(i\omega) \quad [3]$$

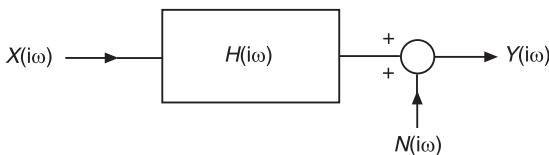

Figure 3 Additive noise at output.

While the excitation can be deterministic or random, we assume that some additive random noise exists. A ‘best’ identification is usually a least-squares estimate of H . This is found to be:

$$\hat{H}_1(i\omega) = \frac{\Sigma X^*(i\omega)Y(i\omega)}{\Sigma X^*(i\omega)X(i\omega)} = \frac{\Sigma S_{xy}}{\Sigma S_{xx}} \quad [4]$$

This estimator is often designated as H_1 , equal to the ratio of the cross-spectrum to the auto-spectrum of the input.

According to the model described by eqn [3], the identification of $H(i\omega)$ enables us to interpret $Y(i\omega)$ as comprising two parts: $H(i\omega)X(i\omega)$, the part of the response linearly related to the excitation, and an unrelated residual. In terms of signal terminology, $Y(i\omega)$ is considered to be composed of two orthogonal components. $H(i\omega)X(i\omega)$ is the coherent part of the response; $N(i\omega)$ the residual (**Figure 4**).

A coherence function $\gamma^2(i\omega)$ is then defined as:

$$\begin{aligned} \gamma^2(i\omega) &= \frac{\text{Coherent response power}}{\text{Total output power}} = \frac{|S_{xy}|^2}{S_{xx}S_{yy}} \quad [5] \\ &= 0 \leq \gamma^2 \leq 1 \end{aligned}$$

The fact that the coherence function is both bounded and normalized to 1 makes it an extremely valuable criterion for the quality of identification. A value of 1 indicates an ideal noiseless case, where all the response is linearly related (via the system’s dynamics) to the excitation. A value of zero indicates a meaningless result, when there is no linear relation of any part of the response to the excitation. The coherence function thus shows the degree to which the response

is linearly related to the excitation. In practice a minimum value of 0.8–0.95 is considered necessary for a mechanical identification, depending on the specific application at hand. The existence of any noise in the measurements or of additional responses to other (linearly unrelated) excitations will decrease the coherence.

A coherence function less than unity may of course indicate that the basic assumption, that of testing a linear system, is not correct. Any nonlinearity existing in the system will reduce the coherence function. It should be noted that, while a nonlinearity will exhibit its presence by reducing the coherence function, the inverse does not follow: a coherence value of less than unity may be due to other causes, notwithstanding the perfectly linear system. As a final comment, we note that for a nonlinear system excited by a random input, the resultant FRF is just the best linear approximation that can be based on the measured signals.

A coherence function of unity will also result when a single pair of signals is used in eqn [4]. No residual can be computed for a least-squares estimate based on a single pair of observations.

It would be meaningless to evaluate the coherence function for purely periodic excitation and responses. Power then exists only at discrete frequencies, and the coherence between two harmonic components of equal frequency must be equal to unity.

The coherence function can be considered as the frequency domain equivalent of the normalized input/output (time domain) cross-correlation function. The advantage of identification in the frequency domain is again noticeable: the coherence function can be evaluated independently for different frequencies. The identification results can then be considered as meaningful for some frequency ranges, and unacceptable for others. The procedure is shown in **Figure 5** with the addition of the capability of computing the impulse response.

The data acquisition must be geared to the type of data at hand. For random excitation and responses, a free-running mode would be normal. For periodic signals, a triggered mode is needed, in order to avoid the randomization of the signals in the averaging process by M summations.

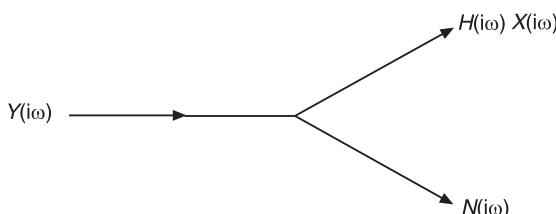

Figure 4 Response decomposition into coherent and residual components.

Identification for Input Additive Noise

The assumption that most of the additive disturbances can be modeled as occurring at the response point is not always justified. Around structural resonances, especially for cases of low damping, large responses occur with low excitation levels. The signal-to-noise ratios in data acquisition tasks will decrease when the signal level is low compared to the instrumentation

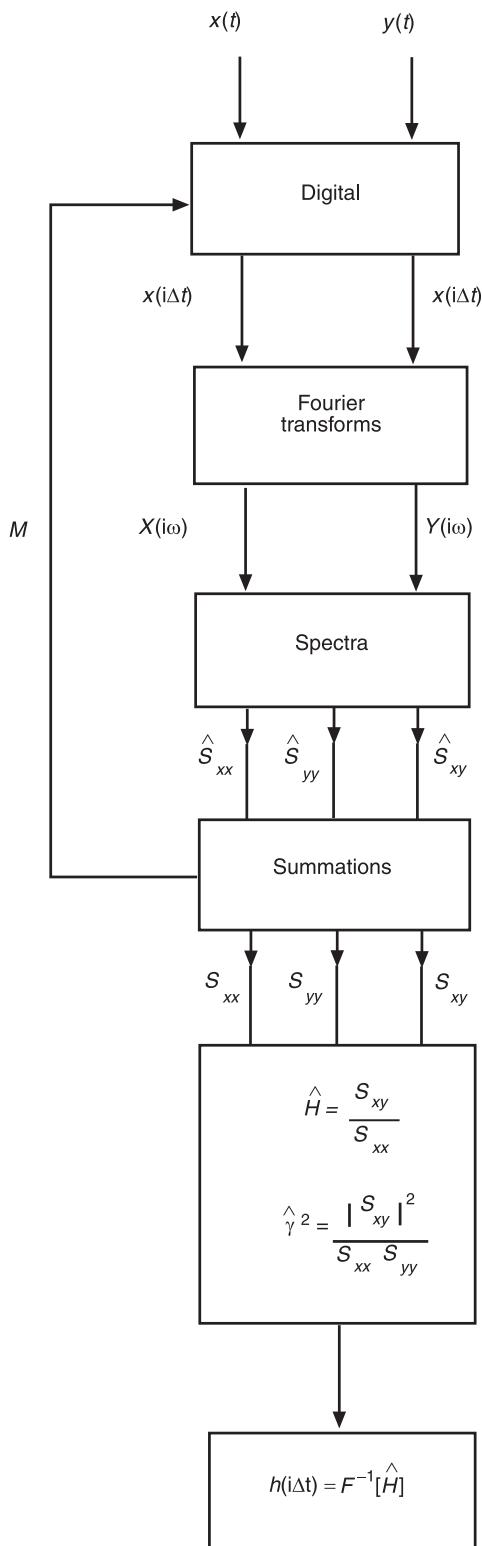

Figure 5 Identification scheme.

dynamic range. The signal-to-noise ratio in the frequency regions around resonances may thus be small, and modeling the noise as being at the input point may be justified (Figure 6).

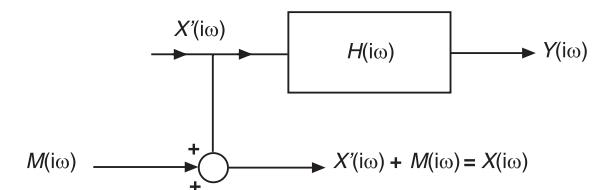

Figure 6 Additive noise at output.

$$M(i\omega) = X(i\omega) - \frac{Y(i\omega)}{H(i\omega)}$$

The least-squares solution for this model, usually known as H_2 , is computed from:

$$H_2(i\omega) = \frac{\sum Y^*(i\omega)Y(i\omega)}{\sum X^*(i\omega)Y(i\omega)} = \frac{\sum S_{yy}}{\sum S_{xy}} = \frac{H_1(i\omega)}{\gamma^2(i\omega)} \quad [6]$$

Both H_1 and H_2 can basically be computed from the same information and the general procedure of Figure 5. Some judgment is needed to decide on which model, and hence which estimate to use. Each of the two estimators H_1 and H_2 corresponds to different methods of noise modeling. Bias errors in the identification will occur if the estimator used does not correspond to the actual noise situation.

Sometimes the model noise to be used cannot be ascertained. Additional estimators then exist for cases where noise is modeled as additive at both the input and the output. A total least-squares estimator is one possibility. Improved least-squares methods can be used when *a priori* knowledge of the input and output RMS ratio is available. Another possibility is to average the H_1 and H_2 estimators. An estimator, usually denoted by H_v , is the geometrical mean:

$$H_v(i\omega) = [H_1(i\omega) H_2(i\omega)]^{1/2}$$

Multiple Excitations/Responses

Multiple Input/Single Output Systems

For linear systems, the response is the superposition of all excitation effects (Figure 7):

$$\mathbf{Y} = \sum_{i=1}^n H_i \mathbf{X}_i + \mathbf{N}$$

The least-squares solution for the $(n \times 1)$ FRF is:

$$\begin{aligned} \mathbf{S}_{xy} &= \mathbf{S}_{xx} \mathbf{H} \\ \mathbf{H} &= \mathbf{S}_{xx}^{-1} \mathbf{S}_{xy} \end{aligned} \quad [7]$$

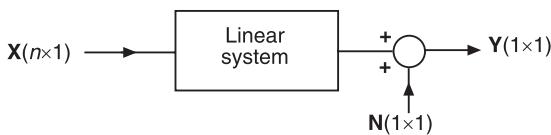

Figure 7 Multiple input/single output system.

where the dimensions of \mathbf{S}_{xy} are $(n \times 1)$, of \mathbf{S}_{xx} are $(n \times n)$. The elements of \mathbf{S}_{xy} and \mathbf{S}_{xx} are $E[X_k X_q]$ and $E[X_k Y]$, $k, q = 1 \dots n$. This expression would not be the one to use from the computational point of view. The components of the spectral matrices are computed at all frequencies, and ill-conditioning can easily occur for some frequencies. Modern computational methods, usually incorporating the SVD, would be applied in practice to avoid the matrix inversion.

The quantitative measure of the degree of linear relation between the response and all excitations can be based on the multiple coherence function. This is again based on the ratio of the coherent output power (linearly related to all excitations) to the total output power. This scalar function can be computed via the spectral matrices. The notation is often awkward, and that used below is only one of those existing:

$$\gamma_{y,x}^2 = \frac{\text{Coherent response power}}{\text{Total output power}}$$

$$= \frac{(\mathbf{S}_{xx}^{-1} \mathbf{S}_{xy})^T \mathbf{S}_{xx} (\mathbf{S}_{xx}^{-1} \mathbf{S}_{xy})}{\mathbf{S}_{yy}}$$
[8]

A low value of the multiple coherence may be an indication that not all excitations acting on the system to be identified are monitored and measured. Matrix inversions are again avoided in practice by appropriate computational schemes.

The question whether the number of excitation monitored is appropriate can be of importance. While the multiple coherence functions may indicate an undetermined model, possible overdetermination has to be determined otherwise. The rank of the matrix \mathbf{S}_{xx} can give an indication of the number of linearly independent excitation sources. The accepted way of rank determination is via the SVD, and this has to be computed for each frequency. For vibrating structures, such SVD functions may be heavily frequency-dependent, especially for resonating systems with narrowband spectral peaks. A simulated example is shown in Figure 8 for a system where four responses are measured. The SVD functions indicate that only three linearly independent excitations are at hand.

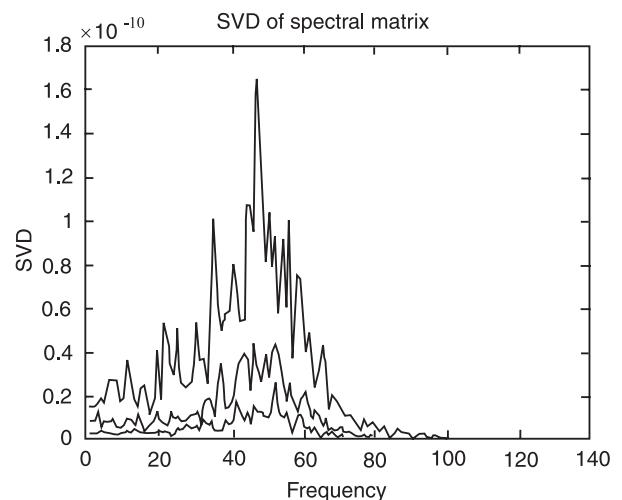

Figure 8 Singular value decomposition of spectral matrix.

Multiple Input/Multiple Output Systems

The extension from MISO leads to similar expressions. For m inputs and n outputs:

$$\mathbf{Y} = \mathbf{H}\mathbf{X}$$

with $\mathbf{Y}(n \times 1)$, $\mathbf{X}(m \times 1)$ and $\mathbf{H}(n \times m)$ (Figure 9). Then:

$$\mathbf{S}_{xy} = \mathbf{S}_{xx} \mathbf{H}^T$$

$$\mathbf{H}^T = \mathbf{S}_{xx}^{-1} \mathbf{S}_{xy}$$
[9]

which is similar to eqn [7] but with dimensions $\mathbf{S}_{xy}(m \times n)$, $\mathbf{S}_{xx}(m \times m)$, $\mathbf{H}^T(m \times n)$, where \mathbf{H}^T is Hermitian as for the elements of \mathbf{H} : $H_{ij} = H_{ji}^*$.

The computation of \mathbf{H} will again use procedures avoiding matrix inversions. Also, specific difficulties may occur as some correlation often exists between some of the exciting forces, causing the cross-spectrum matrix to be rank-deficient.

Error Mechanisms and Their Control in the Identification Process

The general types are similar to those occurring in nonparametric spectral analysis. These are: aliasing traceable errors; bias errors; random errors; and

Figure 9 Multiple input/multiple output system.

leakage. An essential quantifier of the identification is the coherence function. Hence errors have to be considered for both the FRF and γ .

Aliasing Errors

These are due to too low a sampling frequency. They are a potential source of error in any signal-processing task, and thus also in digital identification tasks.

Bias Errors

These are often considered as the most severe error, especially if resonance peaks in the FRF are underestimated. In spectral analysis, bias errors are due to insufficient analysis resolution. Additional mechanisms occur in the identification process.

Bias errors due to insufficient frequency resolution

Most estimators, computed with the FFT, will be biased if insufficient frequency resolution is used. This resolution, Δf , must be small enough to follow local details of the estimated function. For vibrating systems local changes within resonance bandwidth have to be resolved. This bandwidth is approximately $2\xi f_n = BW$ for small damping ratios, where ξ is the damping ratio and f_n is the natural frequency, and the following is usually required:

$$\Delta f \leq \frac{1}{4} BW \quad [10]$$

and Δf can be chosen by the parameters of the Fourier analysis.

Insufficient frequency resolution will also introduce bias errors in the coherence function. The coherence will then be underestimated. The type of window used has a significant effect on this underestimation. When a Hanning window is used, too large a Δf will cause the coherence function to exhibit sharp minima at those frequencies where H peaks, i.e., at resonances. With a rectangular window, the coherence function would show gradually decreasing values.

Bias errors due to additive noise sources These errors are a function of the noise location as well as the estimator used. For input and output noises n and m , and for noise power spectral densities S_{nn} and S_{mm} , respectively, the following results are given for the estimators \hat{H}_1 and \hat{H}_2 , where H_0 is the true FRF:

$$\begin{aligned} |\hat{H}_1| &= |H_0| \left(1 + \frac{S_{mm}}{S_{xx}} \right)^{-1} \\ |\hat{H}_2| &= |H_0| \left(1 + \frac{S_{nn}}{|H_0|^2 S_{xx}} \right) \end{aligned} \quad [11]$$

and:

$$|\hat{H}_1| < |H_0| < |\hat{H}_2|$$

These bias errors occur for the magnitude only. No bias error is introduced by the noise in the phase of the estimated FRFs.

In practice, the noise levels are dependent on the achievable signal-to-noise (S/N) ratios. For vibrating systems with small damping ratios, the input S/N decreases at resonance, where low-level excitations are used. Similarly, the output S/N decreases at anti-resonances, where low response levels occur. The bias error in H_1 results in an underestimation of the maximum peaks (resonances), with those in H_2 overestimating the minima (antiresonances).

Bias due to unmonitored additional excitations

Usually it is assumed that the monitored excitation $x(t)$ is responsible for the monitored output $y(t)$. In vibration tests, additional excitations may exist through unidentified paths. Should this additional excitation not be fully coherent with the monitored one, the output will not be fully coherent with the excitation, resulting in a coherence function less than unity. In addition, the FRF will be biased. For example, for H_1 :

$$\hat{H}_1 = H_0 \left(1 + \frac{Sx_1x_2}{Sx_2x_2} \right)$$

where x_1 is the monitored excitation and x_2 the unmonitored one. No bias error in \hat{H}_1 will occur if x_1 and x_2 are uncorrelated. \hat{H}_2 too will be biased, according to a slightly more complicated expression.

Bias due to delays between excitation and response A time delay can occur in many identification tasks. One classic example occurs in acoustic output measurements, where a propagation delay might exist for the response. Delays can also occur owing to linear-phase shifts in some part of the measurement system. A bias error will then be introduced in the identified coherence function, which will be underestimated by an amount dependent on the ratio of the time delay to that of the time duration of basic signal record (i.e., the signal to be repeated for averaging purposes).

Such a situation can sometimes be identified by noting a linear trend in the phase of the identified FRF. A ‘realignment’ in the form of a negative delay can then reduce or cancel this bias error.

Random Errors

These errors are due to the statistical variability of frequency domain estimates according to eqn [4] when the excitations and responses are random or include a random component. They do not occur with purely noise-free deterministic signals, either periodic or transient.

Similarly to autospectral estimates, FRF estimates based on purely random signals not only exhibit a large statistical variance but are also inconsistent, i.e., this variance does not decrease with record length, hence the need for the averaging process shown in Figure 5. Based on some simplifying assumptions, the normalized RMS error for the estimators have been developed as follows:

$$e[\hat{H}] = \frac{1 - \gamma^2}{|\gamma| \sqrt{2M}} \quad [12]$$

As expected, this error is inversely proportional to the square root of M , the number of records used in the averaging process. It is also dependent on the coherence function, and very large errors occur when coherence values are low and hence no strong linear relationship exists.

The use of eqn [12] is at best as a guideline, as the coherence function itself can only be estimated by the data at hand. This estimate itself is prone to statistical errors and bias as well as the random error noted.

It is usually the practice to apply windows to the data. This has the effect of increasing the correlation between adjacent spectral estimates. The number of degrees of freedom on which the FRF values are estimated increases, and hence the statistical variability decreases.

Leakage Errors

These errors, traceable to basic Fourier transform properties, occur owing to the induced periodicity of the signal spanned by the analyzed signal duration. It is usually effectively reduced by applying a window, which in this case has to be applied to both the excitation and the responses. A Hanning window is often the preferred choice for random signals. As mentioned, this also has the extra beneficial result of reducing the random errors. For periodic excitations and responses, leakage can be avoided by ascertaining that integer numbers of periods are spanned, but this

necessitates a sampling frequency that must be adapted to the frequency by appropriate hardware. Otherwise, a Hanning window would be applied to this as well.

The Hanning window, centered around the analyzed signals, is not appropriate for many transient signals. A typical example would be that of exponentially decaying oscillatory responses, such as those responding to impact excitation. The S/N then decreases along with the decay.

A basic statistical approach is one giving less weight to uncertain (in this case, noisy) information. This can be achieved by using an exponential window of the form:

$$w(i\Delta T) = \exp\left(-\alpha \frac{i}{n}\right) \quad [13]$$

for the response, where α is a constant chosen so as to follow approximately the oscillating decay and n is the number of samples in the analyzing window. The modification introduced by multiplying the signal by this window is one of artificially increasing the effective damping. An appropriate correction is then necessary when damping ratios are identified from FRFs. For the case of a shock-excited single-degree-of-freedom system with natural radian frequency of ω_n , the damping ratio would be artificially increased by α/ω_n . This value must then be subtracted from any identified damping ratio.

Similarly, a rectangular window, spanning only the excitation duration (thus giving zero weight outside this span), could be used to enhance the effective S/N at the input.

Example

Some of the characteristics discussed can be seen from simulation-based results. The simulated system exhibits two resonances, separated by one antiresonance. The excitation is white. To reduce resolution attributable bias errors, the frequency spacing is approximately 1/6 of the narrowest bandwidth. The estimates are based on 10 averages, and some random errors can be seen in Figure 10, computed with a rectangular window. The coherence drops at the antiresonance frequency, where the coherent output is negligible. Applying a Hanning window reduces the random errors. The effect of the window on the coherence function can be seen clearly: a sharp drop at the resonance frequencies, in addition to a minimum at the antiresonant frequency (Figure 11).

Introduction

Parametric identification of vibrating systems is the process of developing finitely parametrized models for such systems based upon measured excitation and/or response signals. Typically, the excitation is force and the response vibration displacement, velocity, or acceleration. A typical identification experiment is depicted in Figure 1. The structural dynamics are represented by a transfer matrix $G(s)$, with s indicating the Laplace transform variable. The measurable force excitation vector is $\{x(t)\}$, while the measurable vibration response vector (forced if $x(t) \neq 0$, free if $x(t) \equiv 0$) is $\{y(t)\}$ and is assumed to be corrupted by stochastic zero-mean noise $\{n(t)\}$, which is uncorrelated with $\{x(t)\}$ (t indicating continuous time).

In contrast to nonparametric identification, which leads to nonparametric representations such as frequency or impulse response functions, parametric identification (also called model-based) leads to finitely parametrized models such as difference/differential equation and modal models. Such models provide important benefits due to their: (1) direct relationship with differential equation or physically significant modal representations used in engineering analysis; (2) improved accuracy and frequency resolution; (3) compactness/parsimony of representation, that is, their ability to provide complete system characterization by relatively few parameters; and (4) their suitability for analysis, prediction, fault diagnosis, and control. The price paid for these benefits includes a generally increased identification complexity and dependence of the results on the assumed model form and the estimation criterion.

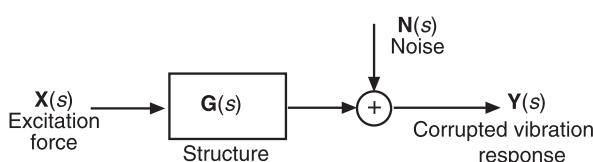

Figure 1 Typical identification experiment.

The Elements of Parametric Identification

The essential elements of any parametric identification method are:

1. the data set
2. the selected model class
3. the estimation criterion
4. the model validation procedure
5. the modal parameter extraction procedure.

The data set consists of suitable excitation and/or response signals. The model class is a selected family of models parametrized in terms of an (unknown) parameter vector Θ – for instance, the class of rational transfer function models. Upon its optimization, the estimation criterion maps the data set into a specific value of the parameter vector Θ – a common choice is the least squares criterion. The model validation procedure aims at accepting or rejecting the estimated model; in the latter case the estimation is repeated with proper modifications. Modal parameter extraction refers to the determination of the modal parameters from the estimated model and the distinction of structural from extraneous (false) modes. The general identification procedure, based upon sampled signals, is outlined in Figure 2.

Classification of Identification Methods

The parametric identification methods may be classified according to one of the first three of the foregoing essential elements. Hence, depending upon the type of data, they may be classified as discrete or continuous time, transient or forced response, single-input single-output (siso) or general multiple-input multiple-output (mimo). Depending upon the model class they may be classified as deterministic or stochastic, distributed or lumped parameter, linear or nonlinear, with the linear being further classified as complex exponential, polynomial (transfer function), or state space. Depending upon the estimation criterion they may be broadly classified as prediction error, least squares related, correlation, and subspace methods. Depending upon the estimator realization, they may be further classified as batch (in which the complete data record is used at once) or recursive (the data record is processed sequentially in time).

This section deals with linear, lumped parameter, and batch discrete time identification based upon sampled versions of the excitation and response signals. For simplicity the siso case is treated, although

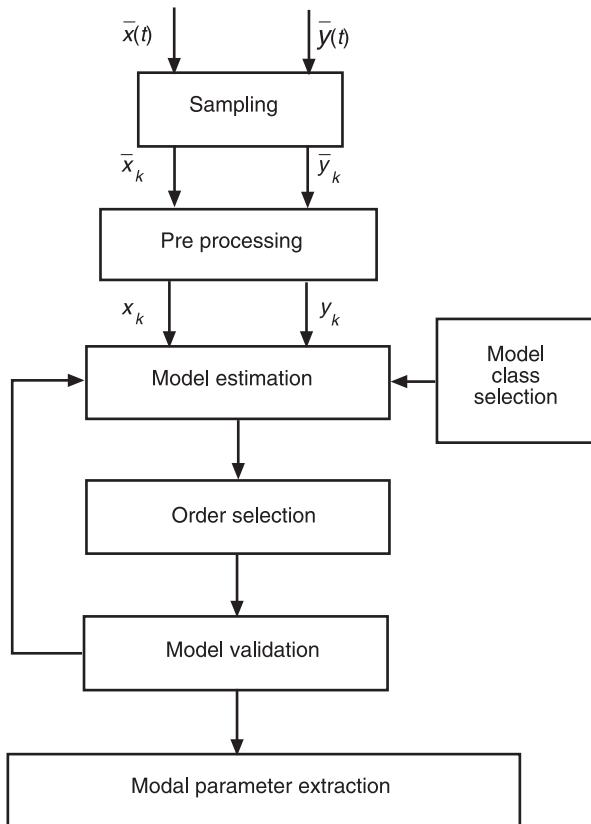

Figure 2 The general identification procedure.

the mimo case is considered within the context of the state space model class and the Eigensystem Realization Algorithm. The identified discrete time model is subsequently transformed back into the continuous time domain for modal parameter extraction.

Before embarking on our discussion of the essential elements of parametric identification methods, it is useful to note the similarity of the identification with the signal modeling problem (see the section on **Signal processing, model based methods**). The two become essentially identical when the force excitation $\{x(t)\}$ is zero, or random unobservable uncorrelated (white) noise, and the noise $\{n(t)\}$ is absent (Figure 1). Hence, the model classes used in signal modeling are either the same as those used in identification (for instance, the complex exponential model class) or suitable subsets (for instance the AutoRegressive (AR), or AutoRegressive Moving Average (ARMA) model classes). Many identification and signal modeling methods are thus closely related, as the underlying estimation theory principles are common. Yet, the presence of measured excitation in the identification problem introduces certain requirements, such as excitation richness, low cross-correlation among scalar excitations, and uncorrelatedness with the corrupting noise.

The Data Set

The siso data set consists of sampled excitation and/or noise-corrupted vibration response signals:

$$Z_0^{N-1} \triangleq \{x_k, y_k | k = 0, 1, 2, \dots, N-1\} \quad [1]$$

with k indicating discrete time (the corresponding analog time being $k \cdot dt$, with dt standing for the sampling period) and N the number of data samples used in identification.

The force excitation needs to be sufficiently rich to excite the system over the frequency range (bandwidth) of interest. Written in Fourier form, it should incorporate at least as many frequencies as the order of the model to be estimated. A single harmonic excitation is, therefore, not rich, whereas a superposition of harmonic excitations, with a sufficient number of distinct frequencies, may be used. Commonly used excitations include chirp, impulsive, periodic burst, and random. In certain cases identification is based upon free response measurements, whereas, in others, the excitation is not measured (but is assumed to be uncorrelated random; see the section on **Signal processing, model based methods**).

In generating the data set to be used in identification, signal low-pass filtering and sampling, with a period satisfying the Shannon sampling theorem ($\omega_s = 2\pi/dt > 2\omega_{\max}$, with ω_{\max} (rads per time unit) indicating the maximum frequency present in the analog signal), is followed by signal pre-processing (Figure 2). This may include further (digital) low or band-pass signal filtering, signal subsampling, scaling (so that all scalar signals assume values in a common range), and mean value removal. In case of multiple excitations it is important to ensure that the excitation forces are not collinear (linearly dependent); their mutual normalized cross-correlations should be far from absolute unity (values as close to zero as possible are recommended) in order to avoid numerical problems.

The Model Class

Time discretization of $G(s)$ (Figure 1) leads to a discrete transfer matrix $G(z)$, with z designating the z -transform variable. It is useful to note that z^{-1} is interpreted as a unit delay operator, which means that if $X(z)$ is the z -transform of $\{x_k\}$ (defined as $X(z) \triangleq \sum_{k=0}^{\infty} x_k \cdot z^{-k}$), $z^{-1} \cdot X(z)$ is the z -transform of the delayed sequence $\{x_{k-1}\}$. Generalizing this, $z^{-l} \cdot X(z)$ is the z -transform of $\{x_{k-l}\}$. In the siso problem each scalar component (transfer function)

of $G(z)$ is identified separately, with each scalar stochastic system to be identified written as:

$$\begin{aligned} Y(z) &= G(z) \cdot X(z) + N(z) \\ N(z) &= H(z) \cdot W(z) \\ Y(z) - \hat{Y}(z) &= W(z) \end{aligned} \quad [2]$$

In these expressions $X(z)$, $Y(z)$ are the z -transforms of the sequences $\{x_k\}$, $\{y_k\}$, respectively, $N(z)$ the z -transform of $\{n_k\}$, which is a stochastic zero-mean noise generated by driving an uncorrelated (white) sequence $\{w_k\}$ (referred to as the innovations sequence and having z -transform $W(z)$) through a noise transfer function $H(z)$, and $\hat{Y}(z)$ the z -transform of $\{\hat{y}_{k/k-1}\}$, which is the sequence of the system's one-step-ahead predictions of $\{y_k\}$, each one made at the previous $(k-1)$ time instant. The first of eqns [2] represents the input-output (structural) dynamics, the second the noise dynamics, and the third indicates that the innovations sequence $\{w_k\}$ that generates the stochastic noise $\{n_k\}$ may be interpreted as the system's one-step-ahead prediction error sequence. Finally, notice that $\{n_k\}$ is assumed to be uncorrelated with the excitation $\{x_k\}$.

Letting $G(z, \boldsymbol{\theta})$, $N(z, \boldsymbol{\theta})$, and $H(z, \boldsymbol{\theta})$ represent suitable models of $G(z)$, $N(z)$, and $H(z)$, respectively, parametrized in terms of a suitable parameter vector $\boldsymbol{\theta}$, the system to be identified may be generally modeled as (compare with eqns [2]):

$$\begin{aligned} Y(z) &= G(z, \boldsymbol{\theta}) \cdot X(z) + N(z, \boldsymbol{\theta}) \\ N(z, \boldsymbol{\theta}) &= H(z, \boldsymbol{\theta}) \cdot E(z, \boldsymbol{\theta}) \\ Y(z) - \hat{Y}(z, \boldsymbol{\theta}) &= E(z, \boldsymbol{\theta}) \end{aligned} \quad [3]$$

with $E(z, \boldsymbol{\theta})$, $\hat{Y}(z, \boldsymbol{\theta})$ indicating the z -transforms of $\{e_k(\boldsymbol{\theta})\}$ and $\{\hat{y}_k(\boldsymbol{\theta})\}$; the first designating the sequence of model-based one-step-ahead prediction errors (modeling $\{w_k\}$), and the second that of the model-based one-step-ahead predictions of $\{y_k\}$ (modeling $\{\hat{y}_{k/k-1}\}$). A block diagram representation of the general system and model is presented in Figure 3.

The various model classes, resulting from various possible parametrizations of $G(z, \boldsymbol{\theta})$ and $H(z, \boldsymbol{\theta})$, may be broadly classified as complex exponential, polynomial, and state space.

The Complex Exponential Model Class

In this case the excitation is impulsive (or zero), so that $\{y_k\}$ represents the noise-corrupted vibration impulse (or free) response which may be expressed as a sum of complex exponential functions, that is:

$$y_k = \sum_{l=1}^n A_l \cdot e^{\mu_l k dt} + e_k(\boldsymbol{\theta}) \quad [4]$$

Obviously, $H(z, \boldsymbol{\theta}) \equiv 1$, while μ_l represents the l th continuous-time pole, $\lambda_l \stackrel{\Delta}{=} e^{\mu_l dt}$ the corresponding discrete-time pole, A_l the amplitude of the l th vibration component, n the model order, and $\boldsymbol{\theta} \stackrel{\Delta}{=} [\mu_1 \dots \mu_n : A_1 \dots A_n]^T$.

Polynomial Model Classes

Polynomial model classes are based upon rational transfer function representations of $G(z, \boldsymbol{\theta})$ and $H(z, \boldsymbol{\theta})$. The main such classes are:

1. The ARX (AutoRegressive with eXogenous input) model class:

$$\begin{aligned} Y(z) &= \frac{B(z, \boldsymbol{\theta})}{A(z, \boldsymbol{\theta})} \cdot X(z) + \frac{1}{A(z, \boldsymbol{\theta})} \cdot E(z, \boldsymbol{\theta}) \\ \Rightarrow A(z, \boldsymbol{\theta}) \cdot Y(z) &= B(z, \boldsymbol{\theta}) \cdot X(z) + E(z, \boldsymbol{\theta}) \end{aligned} \quad [5]$$

with:

$$\begin{aligned} A(z, \boldsymbol{\theta}) &\stackrel{\Delta}{=} 1 + a_1 z^{-1} + \dots + a_{na} z^{-na} \\ B(z, \boldsymbol{\theta}) &\stackrel{\Delta}{=} b_0 + b_1 z^{-1} + \dots + b_{nb} z^{-nb} \end{aligned}$$

referred to as the AutoRegressive (AR) and eXogenous (X) polynomials, respectively, and $\boldsymbol{\theta} \stackrel{\Delta}{=} [\text{coef } A, \text{coef } B]^T$. The positive integers na , nb are the AR and X orders of the model. Notice that the coefficient b_0 of $B(z, \boldsymbol{\theta})$ may be identically zero in certain cases, implying the presence of unity time delay in the input-output (structural) transfer function. The limitation of the ARX model class is that the noise transfer function is restricted to $H(z, \boldsymbol{\theta}) = 1/A(z, \boldsymbol{\theta})$.

2. The ARMAX (AutoRegressive Moving Average with eXogenous input) model class:

$$\begin{aligned} Y(z) &= \frac{B(z, \boldsymbol{\theta})}{A(z, \boldsymbol{\theta})} \cdot X(z) + \frac{C(z, \boldsymbol{\theta})}{A(z, \boldsymbol{\theta})} \cdot E(z, \boldsymbol{\theta}) \Rightarrow \\ A(z, \boldsymbol{\theta}) \cdot Y(z) &= B(z, \boldsymbol{\theta}) \cdot X(z) + C(z, \boldsymbol{\theta}) \cdot E(z, \boldsymbol{\theta}) \end{aligned} \quad [6]$$

in which $C(z, \boldsymbol{\theta})$ is referred to as the Moving Average (MA) polynomial (of a form similar to that of $A(z, \boldsymbol{\theta})$) and $\boldsymbol{\theta} \stackrel{\Delta}{=} [\text{coef } A, \text{coef } B, \text{coef } C]^T$. Although the noise transfer function $H(z, \boldsymbol{\theta})$ is still restricted to have common characteristic polynomial with $G(z, \boldsymbol{\theta})$, the ARMAX model class is substantially more flexible due to the incorporation of the MA polynomial in it. Yet, a high MA order (nc) may be necessary in properly capturing the noise dynamics.

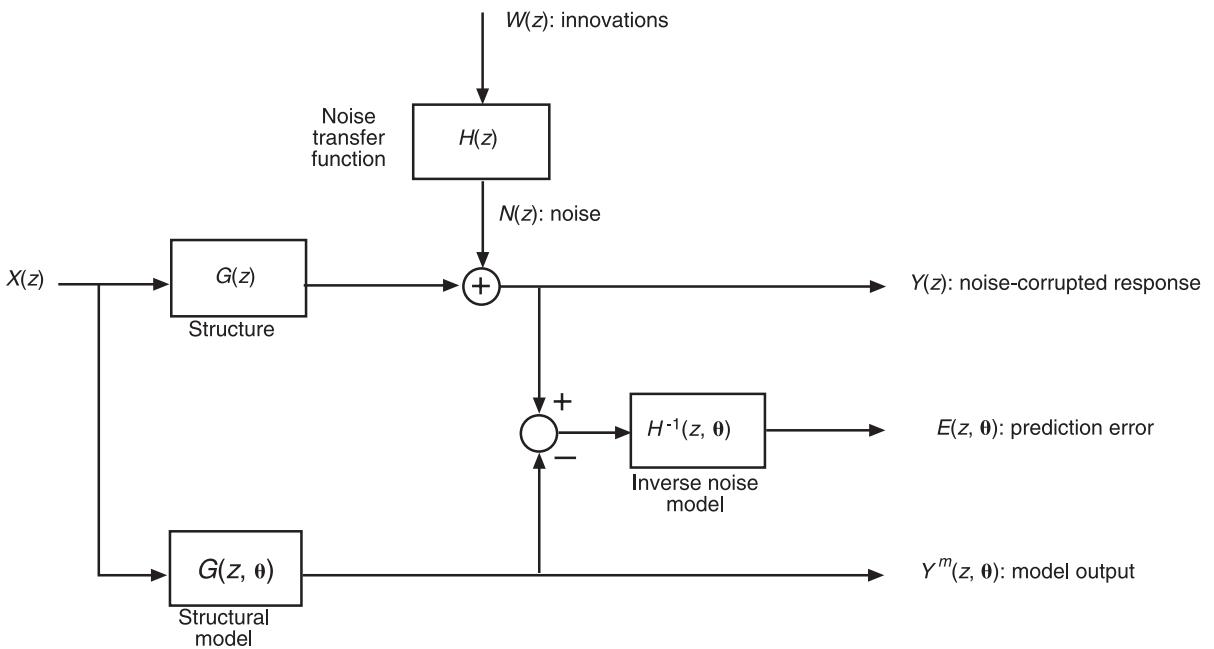

Figure 3 Block diagram representation of the general siso system and model.

3. The Box–Jenkins model class:

$$Y(z) = \frac{B(z, \theta)}{A(z, \theta)} \cdot X(z) + \frac{D(z, \theta)}{C(z, \theta)} \cdot E(z, \theta) \quad [7]$$

in which $D(z, \theta)$ is of a form similar to that of $C(z, \theta)$, and $\theta \triangleq [\text{coef } A, \text{ coef } B, \text{ coef } C, \text{ coef } D]^T$.

This model class offers complete decoupling between the noise and structural transfer functions.

4. The Output Error model class:

$$Y(z) = \frac{B(z, \theta)}{A(z, \theta)} \cdot X(z) + E(z, \theta) \quad [8]$$

in which $\theta \triangleq [\text{coef } A, \text{ coef } B]^T$. This model class avoids modeling the noise, thus limiting its scope to the structural transfer function.

The State Space Model Class

In this case a first-order vector representation is used:

$$\begin{aligned} z_{k+1} &= \mathbf{A}(\theta) \cdot z_k + \mathbf{B}(\theta) \cdot x_k + \mathbf{K}(\theta) \cdot e_k(\theta) \\ y_k &= \mathbf{C}(\theta) \cdot z_k + \mathbf{D}(\theta) \cdot x_k + e_k(\theta) \end{aligned} \quad [9]$$

in which x_k ($r \times 1$), y_k ($p \times 1$), z_k ($n \times 1$), and $e_k(\theta)$ ($p \times 1$) are the input, output, state, and prediction error vectors, respectively, and \mathbf{A} , \mathbf{B} , \mathbf{C} , \mathbf{D} , \mathbf{K} the state, input, output, direct transmission, and Kalman gain matrices, respectively. $\theta \triangleq [\text{col } \mathbf{A}, \text{ col } \mathbf{B}, \text{ col } \mathbf{C}, \text{ col } \mathbf{D}, \text{ col } \mathbf{K}]^T$, with $\text{col}(\cdot)$ indicates column vector consisting of the elements of the indicated

matrix. The model class [9] is known as the innovations form, and incorporates both the structural and noise dynamics. An advantage of this class is its versatility in accounting for either siso or mimo systems.

The Estimation Criterion: Identification Methods

Following the estimation criterion classification, four main families of identification methods may be distinguished:

1. Prediction Error methods
2. Least squares related methods
3. Correlation methods
4. Subspace methods

Prediction Error Methods

The Prediction Error methods postulate parameter estimation based upon minimization of a scalar function of the model-based one-step-ahead prediction error sequence $\{e_k(\theta)\}$, that is:

$$\hat{\theta} = \arg \min_{\theta} \frac{1}{N} \sum_{k=0}^{N-1} f(e_k(\theta)) \quad [10]$$

in which the hat denotes estimate, $\arg \min$ minimizing argument, N the number of data samples (per signal) used in estimation, and $f(\cdot)$ a scalar positive function. The usual choice for $f(\cdot)$ is the quadratic:

$$f(e) = \frac{1}{2} e^2 \quad [11]$$

whereas in certain cases a linearly filtered version of $\{e_k(\boldsymbol{\theta})\}$ is used in eqn [10]. Depending upon the selected model class, different types of Prediction Error methods are possible.

ARX models: Linear Least Squares identification

The ARX model (eqn [5]) may, in the time domain, be expressed as:

$$\begin{aligned} y_k + \sum_{i=1}^{na} a_i \cdot y_{k-i} &= \sum_{i=0}^{nb} b_i \cdot x_{k-i} + e_k(\boldsymbol{\theta}) \\ \hat{y}_k(\boldsymbol{\theta}) \\ \Rightarrow y_k &= \underbrace{\boldsymbol{\Phi}_k^T \cdot \boldsymbol{\theta}}_{\hat{y}_k(\boldsymbol{\theta})} + e_k(\boldsymbol{\theta}) \end{aligned} \quad [12]$$

with:

$$\begin{aligned} \boldsymbol{\Phi}_k &= \left[-y_{k-1} \dots -y_{k-na} \mid x_k \dots x_{k-nb} \right]^T \\ \boldsymbol{\theta} &= \left[a_1 \dots a_{na} \mid b_0 \dots b_{nb} \right]^T \end{aligned}$$

Because of the linearity of the predictor $\hat{y}_k(\boldsymbol{\theta})$ with respect to the parameter vector $\boldsymbol{\theta}$ (eqn [12]), minimization of the quadratic Prediction Error (Least Squares) criterion of eqns [10]–[11] leads to the celebrated Linear Least Squares (linear regression) estimator:

$$\hat{\boldsymbol{\theta}} = \left(\frac{1}{N} \sum_{k=0}^{N-1} \boldsymbol{\Phi}_k \cdot \boldsymbol{\Phi}_k^T \right)^{-1} \cdot \left(\frac{1}{N} \sum_{k=0}^{N-1} \boldsymbol{\Phi}_k \cdot y_k \right) \quad [13]$$

where the signal values outside the $[0, N - 1]$ range are customarily set to zero. It is also worth observing that the quantities within the parentheses in eqn [13] are composed of sample auto- and cross-covariances of the excitation and response signals.

Assuming correct model orders, the estimator [13] converges asymptotically ($N \rightarrow \infty$) to the true parameter vector (consistency property) as long as the true system is amenable to an ARX representation, that is, the noise transfer function is $H(z) = 1/A(z)$ with the characteristic polynomial $A(z)$ being shared with the structural transfer function.

Other model structures: Prediction Error identification Because of the nonlinear dependence of the predictor $\hat{y}_k(\boldsymbol{\theta})$ on the parameter vector $\boldsymbol{\theta}$ for alternative model structures (such as the ARMAX, Box-Jenkins, Output Error, or state space), the minimization of the Prediction Error criterion of eqns

[10]–[11] is a nonlinear problem lacking closed-form solution. Estimates are thus obtained via iterative numerical optimization, based upon algorithms such as the Gauss–Newton or Levenberg–Marquardt. The strong point of Prediction Error identification is its achieved (under weak conditions) consistency and asymptotic ($N \rightarrow \infty$) statistical optimality (the latter in the special case of Maximum Likelihood identification; see the third remark, below). Drawbacks include the computational complexity, the need for initial guess parameter values, the presence of local minima, and potential algorithmic instabilities.

Remarks

1. It may be shown that the prediction error estimator based upon N data samples, say $\hat{\boldsymbol{\theta}}_N$:

$$\hat{\boldsymbol{\theta}}_N \rightarrow \boldsymbol{\theta}^* \quad \text{as } N \rightarrow \infty \quad (\text{w.p.1}) \quad [14]$$

with:

$$\boldsymbol{\theta}^* \stackrel{\Delta}{=} \arg \min_{\boldsymbol{\theta}} E\{f(e_k(\boldsymbol{\theta}))\} \quad [15]$$

with $E\{\cdot\}$ indicating statistical expectation and w.p.1 with probability one (consistency property). Furthermore, provided that the sequence $\{e_k(\boldsymbol{\theta}^*)\}$ is approximately white,

$$\sqrt{N} \cdot \left(\hat{\boldsymbol{\theta}}_N - \boldsymbol{\theta}^* \right) \xrightarrow{\text{dist}} \mathcal{N}(\mathbf{0}, \mathbf{P}) \quad \text{as } N \rightarrow \infty \quad [16]$$

with $\mathcal{N}(\cdot, \cdot)$ designating Gaussian distribution with the indicated mean and covariance. Expression [16] indicates that the estimator converges in distribution to a random vector with mean value $\boldsymbol{\theta}^*$ and covariance matrix \mathbf{P} . The latter is equal to:

$$\mathbf{P} = \lambda \cdot [E\{\boldsymbol{\Psi}_k \cdot \boldsymbol{\Psi}_k^T\}]^{-1} \quad [17]$$

with:

$$\lambda \stackrel{\Delta}{=} E\{e_k^2(\boldsymbol{\theta}^*)\} \quad \boldsymbol{\Psi}_k \stackrel{\Delta}{=} \left. \frac{d}{d\boldsymbol{\theta}} \hat{y}_k(\boldsymbol{\theta}) \right|_{\boldsymbol{\theta}=\boldsymbol{\theta}^*} \quad [18]$$

In estimating λ in eqn [18], the statistical expectation is replaced by the sample mean.

2. The quadratic Prediction Error (Least Squares) criterion of eqns [10]–[11] may be written as follows in the frequency domain:

$$V_N(\boldsymbol{\theta}) = \frac{dt}{2\pi} \times \int_{-\pi/dt}^{\pi/dt} \frac{1}{2} \left| \frac{Y(i\omega)}{X(i\omega)} - G(i\omega, \boldsymbol{\theta}) \right|^2 \cdot \left| \frac{X(i\omega)}{H(i\omega, \boldsymbol{\theta})} \right|^2 \cdot d\omega \quad [19]$$

where ω represents frequency in rads per time unit, i the imaginary unit, $| \cdot |$ complex magnitude, and $X(i\omega)$, $Y(i\omega)$ the Fourier transforms (z -transforms evaluated on the unit circle) of the excitation and noise-corrupted response signals, respectively. Recognizing

$$\hat{G}(i\omega) \triangleq Y(i\omega)/X(i\omega) \quad [20]$$

as the ‘customary’ nonparametric (also called ‘empirical’) estimate of $G(i\omega)$ in the frequency domain, the quadratic Prediction Error criterion may be viewed as a criterion for the ‘fitting’ of $\hat{G}(i\omega)$ to the parametrized frequency response $G(i\omega, \boldsymbol{\theta})$, weighted (at each frequency) by $|X(i\omega)/H(i\omega, \boldsymbol{\theta})|^2$.

3. The selection $f(\cdot) = -\ln f_e(\cdot)$, with $f_e(\cdot)$ indicating the probability density of $e_k(\boldsymbol{\theta})$, leads to Maximum Likelihood estimation. The Maximum Likelihood estimator is asymptotically ($N \rightarrow \infty$) optimal as it achieves a minimal covariance matrix \mathbf{P} (asymptotic statistical efficiency). It is also worth noting that in the Gaussian case the quadratic (equations [10]–[11]) prediction error estimator coincides with the Maximum Likelihood estimator, being thus asymptotically efficient.

Least Squares-related Methods

Least Squares related methods constitute useful alternatives to Prediction Error identification, aiming at overcoming some of its limitations at the expense of potentially reduced accuracy. Three such methods are presented: the Prony method, the Two-Stage Least Squares (2SLS) method, and the Linear Multistage (LMS) method.

The Prony method The Prony method uses free or impulse response vibration data $\{y_k\}$ ($k = 0, 1, \dots, N-1$) to identify a complex exponential model of the form [4].

Let λ_l ($l = 1, 2, \dots, n$) designate the discrete model poles and $C(\lambda)$ the n th order polynomial having them as its roots (characteristic polynomial). Hence:

$$C(\lambda_l) \triangleq \lambda_l^n + \sum_{i=0}^{n-1} c_i \lambda_l^i = 0 \quad (c_n \equiv 1) \quad [21]$$

Next consider the quantity:

$$\begin{aligned} y_{k+n} + \sum_{i=0}^{n-1} c_i \cdot y_{k+i} &= \sum_{i=0}^n c_i \cdot \overbrace{\sum_{l=1}^n A_l \cdot \lambda_l^{k+i}}^{y_{k+i}} \\ &= \underbrace{\left\{ \sum_{i=0}^n c_i \cdot \lambda_l^i \right\}}_{=0} \cdot \left\{ \sum_{l=1}^n A_l \cdot \lambda_l^k \right\} = 0 \end{aligned} \quad [22]$$

where the model expression [4] with $e_k(\boldsymbol{\theta}) \equiv 0$ (deterministic case) and $\lambda_l = e^{\mu_l dt}$, along with [21], were used. The resulting homogeneous difference equation implied by [22] may be rewritten as:

$$y_k = \boldsymbol{\Phi}_k^T \cdot \mathbf{c} \quad [23]$$

with:

$$\begin{aligned} \boldsymbol{\Phi}_k^T &\triangleq [-y_{k-1} - y_{k-2} \dots - y_{k-n}]^T \\ \mathbf{c} &\triangleq [c_{n-1} \ c_{n-2} \ \dots \ c_0]^T \end{aligned}$$

Eqn [23] may be successively written for $k = n, n+1, \dots, N-1$ to form an overdetermined (assuming $N > 2n$) system of equations in the parameter vector \mathbf{c} , which may then be estimated via the Linear Least Squares estimator:

$$\hat{\mathbf{c}} = \left(\frac{1}{N} \sum_{k=n}^{N-1} \boldsymbol{\phi}_k \cdot \boldsymbol{\phi}_k^T \right)^{-1} \cdot \left(\frac{1}{N} \sum_{k=n}^{N-1} \boldsymbol{\phi}_k \cdot \mathbf{y}_k \right) \quad [24]$$

with $\tilde{N} \triangleq N - n$. Once the coefficients of the characteristic polynomial $C(\lambda)$ are available, its roots (poles) λ_l ($l = 1, 2, \dots, n$) may be readily obtained.

For the estimation of the modal amplitudes A_l ($l = 1, 2, \dots, n$), the Prony model (eqn [4]) is rewritten as:

$$y_k = \boldsymbol{\varphi}_k^T \cdot \mathbf{a} + e_k(\mathbf{a}) \quad [25]$$

where $\boldsymbol{\varphi}_k \triangleq [\lambda_1^k \ \lambda_2^k \ \dots \ \lambda_n^k]^T$ and $\mathbf{a} \triangleq [A_1 \ A_2 \ \dots \ A_n]^T$. Writing [25] for $k = 0, 1, 2, \dots, N-1$ defines a set of overdetermined equations in the modal amplitude vector \mathbf{a} , which may also be estimated via Linear Least Squares:

$$\hat{\mathbf{a}} = \left(\frac{1}{N} \sum_{k=0}^{N-1} \boldsymbol{\varphi}_k \cdot \boldsymbol{\varphi}_k^T \right)^{-1} \cdot \left(\frac{1}{N} \sum_{k=0}^{N-1} \boldsymbol{\varphi}_k \cdot \mathbf{y}_k \right) \quad [26]$$

When used in connection with impulse response data, the Prony method is known as the Complex Exponential method. The method's strong point is simplicity, whereas its main limitations are the assumed noise-free (deterministic) setting and the transient nature of the data which may limit the number of samples used in identification.

The Two-Stage Least Squares (2SLS) method The 2SLS method uses any type of excitation and forced response data to identify an ARMAX model of the form [6]. The method is based on the observation that the nonlinearity of the ARMAX predictor at time k , in terms of the parameter vector $\boldsymbol{\theta}$, would be overcome if the past (at times $k-1, \dots, k-nc$) model-based prediction errors were known. According to the method, these are approximately estimated via an ARX model of sufficiently high orders (ma, mb) (which constitute the method's design parameters):

$$A_{ma}(z, \boldsymbol{\theta}_m) \cdot Y(z) = B_{mb}(z, \boldsymbol{\theta}_m) \cdot X(z) + E(z, \boldsymbol{\theta}_m) \quad [27]$$

in which $\boldsymbol{\theta}_m \stackrel{\Delta}{=} [\text{coef } A_{ma}, \text{coef } B_{mb}]^T$. Comparing this with the ARMAX model form [6], it is evident that the $A_{ma}(z)$ and $B_{mb}(z)$ polynomials attempt to approximate the transfer functions $A(z)/C(z)$ and $B(z)/C(z)$, respectively; a fact dictating high orders ma, mb , especially when the true MA polynomial has zeros close to the unit circle. The estimation of the ARX model [27] is accomplished via Linear Least Squares, from which the prediction error sequence $\{e_k(\hat{\boldsymbol{\theta}}_m)\} (k=0, 1, 2, \dots, N-1)$ is obtained (stage 1).

Using the sequence $\{e_k(\hat{\boldsymbol{\theta}}_m)\}$, the ARMAX model form [6] is approximated as:

$$\begin{aligned} y_k + \sum_{i=1}^{na} a_i \cdot y_{k-i} &= \sum_{i=0}^{nb} b_i \cdot x_{k-i} + e_k(\boldsymbol{\theta}) \\ &+ \sum_{i=1}^{nc} c_i \cdot e_{k-i}(\hat{\boldsymbol{\theta}}_m) \\ \Rightarrow y_k &= \Phi_k^T \cdot \boldsymbol{\theta} + e_k(\boldsymbol{\theta}) \end{aligned} \quad [28]$$

with:

$$\begin{aligned} \Phi_k &\stackrel{\Delta}{=} \left[-y_{k-1} \dots -y_{k-na} \mid x_k \dots x_{k-nb} \mid e_{k-1}(\hat{\boldsymbol{\theta}}_m) \right. \\ &\quad \left. \dots e_{k-nc}(\hat{\boldsymbol{\theta}}_m) \right]^T \\ \boldsymbol{\theta} &\stackrel{\Delta}{=} \left[a_1 \dots a_{na} \mid b_0 \dots b_{nb} \mid c_1 \dots c_{nc} \right]^T \end{aligned}$$

and the parameter vector $\boldsymbol{\theta}$ is estimated via Linear Least Squares (stage 2). The 2SLS method is simple and computationally efficient, but also suboptimal (statistically inefficient).

The Linear Multi Stage method The LMS method also identifies an ARMAX model of the form [6] based upon any type of excitation and forced response data. The method starts (stage 1) with the estimation (via Linear Least Squares) of an ARX model of the form [27] of sufficiently high orders (ma, mb ; method's design parameters). It, nevertheless, subsequently relies only upon the estimated $A_{ma}(z)$ polynomial and not the prediction error sequence. Indeed, as already noted, the $A_{ma}(z)$ polynomial in [27] approximates the transfer function $A(z)/C(z)$ of the ARMAX model [6], hence:

$$\begin{aligned} \hat{A}_{ma}(z) \cdot C(z) &\approx A(z) \\ \Rightarrow \sum_{k=0}^j c_k \cdot (\hat{a}_{ma})_{j-k} &\approx a_j \quad (j=1, 2, \dots) \end{aligned} \quad [29]$$

where $(a_{ma})_0 = a_0 = c_0 = 1$, $a_j = 0$ for $j > na$, and $c_k = 0$ for $k > nc$. The c_k 's ($k=1, 2, \dots, nc$) are then linearly estimated from nc of the above equations (those corresponding to $j=na+1, \dots, na+nc$; stage 2).

Following the initial estimation of $C(z)$, the ARMAX model form [6] is approximated as (division by the estimate $\hat{C}(z)$):

$$A(z, \boldsymbol{\vartheta}) \cdot Y^F(z, \hat{\boldsymbol{c}}) = B(z, \boldsymbol{\vartheta}) \cdot X^F(z, \hat{\boldsymbol{c}}) + E(z, \boldsymbol{\vartheta}, \hat{\boldsymbol{c}}) \quad [30]$$

where:

$$\begin{aligned} Y^F(z, \hat{\boldsymbol{c}}) &\stackrel{\Delta}{=} \hat{C}^{-1}(z) \cdot Y(z) \\ X^F(z, \hat{\boldsymbol{c}}) &\stackrel{\Delta}{=} \hat{C}^{-1}(z) \cdot X(z) \end{aligned}$$

In [30] $\boldsymbol{\vartheta} \stackrel{\Delta}{=} [\text{coef } A, \text{coef } B]^T$ and $\boldsymbol{c} \stackrel{\Delta}{=} [\text{coef } C]^T$. The parameter vector $\boldsymbol{\vartheta}$ is then estimated based upon the ARX model [30] and Linear Least Squares (stage 3). The MA parameter vector \boldsymbol{c} is finally linearly reestimated from the first nc of equations [29] (those corresponding to $j=1 \dots nc$; stage 4). Notice that the method's last two stages may be iterated, with the ARMAX model attaining the minimal value of the criterion of eqns [10]–[11] selected as best.

The LMS maintains computational efficiency but, unlike the 2SLS, avoids the sensitive estimation of the

model-based prediction error sequence. Moreover, model and algorithmic stability (depending upon the AR and MA polynomials, respectively) may be warranted via available guaranteed stability versions.

Correlation Methods

Correlation methods are based on the observation that the prediction error $e_k(\boldsymbol{\theta})$ of a good model, being part of an uncorrelated sequence, should be uncorrelated with the past data $\{x_{k-1}, y_{k-1}, x_{k-2}, y_{k-2} \dots\} = \mathcal{Z}_0^{k-1}$. A feasible approach for the estimation of the parameter vector $\boldsymbol{\theta}$ then is to select a vector sequence $\{\zeta_k\}$ (sequence of correlation vectors), derived from \mathcal{Z}_0^{k-1} , and demand that ζ_k be uncorrelated with $e_k(\boldsymbol{\theta})$, that is:

$$E\{\zeta_k \cdot e_k(\boldsymbol{\theta})\} = \mathbf{0} \quad [31]$$

or, substituting the sample mean for statistical expectation:

$$\frac{1}{N} \sum_{k=0}^{N-1} \zeta_k \cdot e_k(\boldsymbol{\theta}) \approx \mathbf{0} \quad [32]$$

The parameter vector $\boldsymbol{\theta}$ may thus be estimated as the vector satisfying [32]. The approach may be generalized by allowing the correlation vector to depend upon $\boldsymbol{\theta}$ as well. Also note that the dimensionality of the correlation vector needs to be at least equal to that of $\boldsymbol{\theta}$. A commonly used correlation method is presented next.

An Instrumental Variable (IV) method This method estimates a system of the form:

$$A(z) \cdot Y(z) = B(z) \cdot X(z) + N(z) \quad [33]$$

with $N(z)$ designating the z -transform of a zero-mean, generally autocorrelated, noise sequence $\{n_k\}$, via an ARX-like model of the form (the term ARX-like signifies that the sequence $\{e_k(\boldsymbol{\theta})\}$ is not uncorrelated):

$$\begin{aligned} A(z, \boldsymbol{\theta}) \cdot Y(z) &= B(z, \boldsymbol{\theta}) \cdot X(z) + E(z, \boldsymbol{\theta}) \\ &\Rightarrow y_k = \Phi_k^T \cdot \boldsymbol{\theta} + e_k(\boldsymbol{\theta}) \end{aligned} \quad [34]$$

where:

$$\Phi_k = [-y_{k-1} \dots -y_{k-na} : x_k \dots x_{k-nb}]^T$$

$$\boldsymbol{\theta} = [a_1 \dots a_{na} : b_0 \dots b_{nb}]^T$$

Substituting [34] into the general criterion [32] yields:

$$\begin{aligned} \frac{1}{N} \sum_{k=0}^{N-1} \zeta_k \cdot (y_k - \Phi_k^T \cdot \boldsymbol{\theta}) &= \mathbf{0} \\ \Rightarrow \hat{\boldsymbol{\theta}} &= \left(\frac{1}{N} \sum_{k=0}^{N-1} \zeta_k \cdot \Phi_k^T \right)^{-1} \cdot \left(\frac{1}{N} \sum_{k=0}^{N-1} \zeta_k \cdot y_k \right) \end{aligned} \quad [35]$$

The selection of the correlation vector ζ_k (presently instrumental variable vector) must be such that it is sufficiently well correlated with Φ_k but not influenced by the noise sequence $\{n_k\}$. Given an initial estimate, say $\hat{\boldsymbol{\theta}}_0$, of the ARX-like model [34], a reasonable way of generating the elements of ζ_k (referred to as instruments) is:

$$\zeta_k = [-y_{k-1}^m(\hat{\boldsymbol{\theta}}_0) \dots -y_{k-na}^m(\hat{\boldsymbol{\theta}}_0) : x_k \dots x_{k-nb}]^T \quad [36]$$

with $y_k^m(\hat{\boldsymbol{\theta}}_0)$ representing the corresponding model output, that is (see also Figure 3):

$$A(z, \hat{\boldsymbol{\theta}}_0) \cdot Y^m(z, \hat{\boldsymbol{\theta}}_0) = B(z, \hat{\boldsymbol{\theta}}_0) \cdot X(z) \quad [37]$$

This leads to the following iterative Instrumental Variable method: (1) obtain an initial Linear Least Squares estimate $\hat{\boldsymbol{\theta}}_0$ of the ARX-like parameter vector via expression [13]; (2) compute the sequence of instrumental variable vectors via expressions [36] and [37]; (3) obtain the Instrumental Variable estimator for $\boldsymbol{\theta}$ via expression [35]; and (4) go to the second step and iterate until the sequence of obtained estimates $\hat{\boldsymbol{\theta}}$ converges. A problem with this method is that the initial estimate $\hat{\boldsymbol{\theta}}_0$ is, due to the autocorrelation of the noise sequence $\{n_k\}$, inconsistent (asymptotically biased), and several iterations may be needed for (potential) convergence of the iterative procedure.

Subspace Methods

Subspace methods are based upon the state space model form and linear operations. In vibrating system identification the most commonly used such method is the Eigensystem Realization Algorithm (ERA).

The Eigensystem Realization Algorithm (ERA) This method utilizes a deterministic state space model form (eqn [9] with $e_k(\boldsymbol{\theta}) \equiv \mathbf{0}$) and impulse vibration response data. Let $\{\mathbf{Y}_0, \mathbf{Y}_1, \dots, \mathbf{Y}_{N-1}\}$ designate the system's observed Markov parameters, with each \mathbf{Y}_k ($p \times r$) (r, p, n indicating the dimensionality of the input, output, and state vectors, respectively) being of the form:

$$\mathbf{Y}_k \stackrel{\Delta}{=} [y_k^1 \ y_k^2 \ \dots \ y_k^r] \quad [38]$$

with \mathbf{y}_k^i ($p \times 1$) indicating the response vector (at time k) due to an impulse excitation applied at the i th input. Next, form the generalized $\alpha \cdot p \times \beta \cdot r$ Hankel matrix as:

$$\mathbf{H}[k-1] = \begin{bmatrix} \mathbf{Y}_k & \mathbf{Y}_{k+1} & \dots & \mathbf{Y}_{k+\beta-1} \\ \mathbf{Y}_{k+1} & \mathbf{Y}_{k+2} & \dots & \mathbf{Y}_{k+\beta} \\ \vdots & \vdots & & \vdots \\ \mathbf{Y}_{k+\alpha-1} & \mathbf{Y}_{k+\alpha} & \dots & \mathbf{Y}_{k+\alpha+\beta-2} \end{bmatrix} \quad [39]$$

which is of rank n , provided that $\alpha \geq n$, $\beta \geq n$ (α, β constitute the method's design parameters; their proper selection may require a number of trials).

The singular value decomposition of $\mathbf{H}[0]$ gives ($\alpha p \geq \beta r$):

$$\mathbf{H}[0] = \mathbf{R} \cdot \Sigma \cdot \mathbf{S}^T \quad [40]$$

where \mathbf{R} ($\alpha \cdot p \times \alpha \cdot p$), \mathbf{S} ($\beta \cdot r \times \beta \cdot r$) are orthonormal matrices ($\mathbf{R}^T \mathbf{R} = \mathbf{I}_{\alpha p}$, $\mathbf{S}^T \mathbf{S} = \mathbf{I}_{\beta r}$, with \mathbf{I} representing the identity matrix of the indicated dimensionality). The columns of \mathbf{R} and \mathbf{S} are the left and right singular vectors. The matrix Σ ($\alpha \cdot p \times \beta \cdot r$) contains the system's singular values σ_i . Theoretically, an n th-order system has exactly n nonzero singular values, say $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n > 0$. Thus the Σ , \mathbf{R} , \mathbf{S} matrices may be partitioned as:

$$\Sigma = \begin{bmatrix} \Sigma_n & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad \mathbf{R} = [\mathbf{R}_n \quad \bar{\mathbf{R}}] \quad \mathbf{S} = [\mathbf{S}_n \quad \bar{\mathbf{S}}] \quad [41]$$

with $\Sigma_n \triangleq \text{diag}(\sigma_1, \sigma_2 \dots \sigma_n)$ ($\text{diag}(\cdot)$ designating diagonal matrix with the indicated elements), and \mathbf{R}_n , \mathbf{S}_n being composed of the corresponding n columns of \mathbf{R} , \mathbf{S} , respectively.

The state space matrices may then be estimated as:

$$\hat{\mathbf{A}} = \Sigma_n^{-1/2} \cdot \mathbf{R}_n^T \cdot \mathbf{H}[1] \cdot \mathbf{S}_n \cdot \Sigma_n^{-1/2} \quad [42]$$

$$\hat{\mathbf{B}} = \Sigma_n^{1/2} \cdot \mathbf{S}_n^T \cdot \mathbf{E}_r \quad [43]$$

$$\hat{\mathbf{C}} = \mathbf{E}_p^T \cdot \mathbf{R}_n \cdot \Sigma_n^{1/2} \quad [44]$$

while $\hat{\mathbf{D}} = \mathbf{Y}_0$. In the above $\mathbf{E}_p^T \triangleq [\mathbf{I}_p \mathbf{0}_p \dots \mathbf{0}_p]$, $\mathbf{E}_r^T \triangleq [\mathbf{I}_r \mathbf{0}_r \dots \mathbf{0}_r]$, with $\mathbf{0}_i$ representing a null $i \times i$ matrix.

The discrete-time eigenvalues (system poles) are estimated from the characteristic equation:

$$\det[\lambda \mathbf{I}_n - \hat{\mathbf{A}}] = 0 \quad [45]$$

following the solution of which the $(\mathbf{A}, \mathbf{B}, \mathbf{C})$ matrices may be transformed to modal coordinates as $(\Lambda, \Psi^{-1}\mathbf{B}, \mathbf{C})$, with $\Lambda \triangleq \text{diag}(\lambda_1, \dots \lambda_n)$ and $\Psi \triangleq [\Psi_1 \Psi_2 \dots \Psi_n]$ designating the corresponding eigenvector matrix. The matrix $\Psi^{-1}\mathbf{B}$ provides the initial modal amplitudes (modal participation factors) and the matrix $\mathbf{C}\Psi$ the mode shapes at the sensor points.

The determination of the true structural modes (among a higher number of modes generally identified) is based upon the modal amplitude coherence (MAC). The value of the MAC for the l th eigenvalue ($l = 1, 2, \dots, n$) is defined as the magnitude of the normalized dot product between the vectors $\bar{\mathbf{q}}_l$ and $\hat{\mathbf{q}}_l$:

$$MAC_l = \frac{|\bar{\mathbf{q}}_l^* \cdot \hat{\mathbf{q}}_l|}{(|\bar{\mathbf{q}}_l^* \cdot \bar{\mathbf{q}}_l| \cdot |\hat{\mathbf{q}}_l^* \cdot \hat{\mathbf{q}}_l|)^{1/2}} \quad [46]$$

with $*$ indicating complex conjugate transposition. In the above $\bar{\mathbf{q}}_l$ ($\beta \cdot r \times 1$) is obtained by transposing the l th row of the controllability matrix:

$$\bar{\mathbf{Q}}_{\text{ctr}} = \Psi^{-1} \cdot \Sigma_n^{1/2} \cdot \mathbf{S}_n^T \quad [47]$$

whereas $\hat{\mathbf{q}}_l$ ($\beta \cdot r \times 1$) is obtained as:

$$\hat{\mathbf{q}}_l = \left[\mathbf{b}_l^T \quad \lambda_l \cdot \mathbf{b}_l^T \quad \lambda_l^2 \cdot \mathbf{b}_l^T \quad \dots \quad \lambda_l^{\beta-1} \cdot \mathbf{b}_l^T \right]^T \quad [48]$$

with \mathbf{b}_l ($r \times 1$) being the transposed l th row of the matrix $\Psi^{-1}\mathbf{B}$. MAC values are obviously confined in the interval $[0, 1]$. Eigenvalues (and thus corresponding modes) with values close to unity are classified as structural; otherwise as extraneous (false).

The ERA is numerically robust, but limited to impulse (or free) response data under deterministic (noise-free) conditions. Other types of data may be accommodated via an additional stage aiming at the estimation of the system's impulse response, while the presence of noise may distort the estimates and make exact order (nonzero singular value) determination difficult.

Remarks on the Methods

Despite the lack of detailed and systematic comparisons of the various identification methods with different types of vibrating systems, a few general remarks may be made. Prediction Error methods are generally considered most accurate, provided that problems related to local minima and algorithmic instabilities may be accommodated for. Least squares related and subspace methods are generally suboptimal, although their accuracy need not be far from optimality. In case of large-size (several

degree-of-freedom) problems, these may be the only viable approaches. Algorithmic and model stability may then become crucial, and schemes such as the guaranteed stability versions of the LMS method practically necessary. Correlation methods may be useful, but they may also have convergence problems and not achieve adequate accuracy.

A good strategy in practice is to use a combined procedure, in which identification (within a selected model class) is first based upon a least squares related, correlation, or subspace method, with subsequent refinement based upon a Prediction Error method. Also useful in practice (especially in low noise cases) is to identify simple ARX models via Linear Least Squares before turning to more appropriate models, such as ARMAX, output error, or state space.

Deterministic methods (such as Linear Least Squares, the Prony method, or the ERA) achieve acceptable accuracy in low noise cases. When the noise is nonnegligible, their performance generally deteriorates. In such a case significant model order overdetermination is commonly used, but the distinction of actual structural modes may become difficult. The use of stochastic methods is, then, recommended. An additional point deserving attention, especially for large-size (several degree-of-freedom) problems, is the difficulty that may be encountered with methods based on free/impulse response measurements (such as the Prony method or the ERA). This stems from the limited number of available signal samples which, in turn, limits the number of model parameters that may be estimated with acceptable accuracy.

Commercial software specifically designed for the parametric identification of vibrating systems appears limited. The MATLAB-based Structural Dynamics Toolbox by the Scientific Software Group includes some parametric identification tools. The ARTeMIS Extractor by Structural Vibration Solutions focuses on the output-only case. There is, nevertheless, a number of general-purpose packages. These include the MATLAB System Identification Toolbox by MathWorks, the MATRIXx (Xmath) System Identification (SID) module by Integrated Systems, and the ADAPTx Automated System Identification Software by Adapts. The MATLAB Frequency Domain System Identification Toolbox is also available for frequency domain based identification.

Model Order Selection, Validation, and Modal Parameter Extraction

Model Order Selection

Model order selection, which is theoretically related to the determination of the actual number of struc-

tural degrees of freedom, is crucial for successful identification. In reality the two issues are decoupled, as significant order overdetermination is generally necessary for accurate identification. This is especially so for deterministic methods, which rely more heavily on order overdetermination in counteracting the effects of otherwise unaccounted noise.

Identification accuracy may be evaluated in terms of quality criteria of the form:

$$V_N^1 \triangleq \frac{1}{N} \sum_{k=0}^{N-1} (y_k - \hat{y}_k(\hat{\Theta}))^2 \quad [49]$$

$$V_N^2 \triangleq \frac{1}{N} \sum_{k=0}^{N-1} (y_k - y_k^m(\hat{\Theta}))^2 \quad [50]$$

in which $\hat{y}_k(\hat{\Theta})$ represents the estimated model-based one-step-ahead prediction for time k , and $y_k^m(\hat{\Theta})$ the model response (Figure 3). Both V_N^1 and V_N^2 generally decrease with increasing model order, and although they should theoretically reach a plateau as soon as the model order coincides with that of the true system, their decreasing pattern typically continues.

In order to overcome this difficulty and enable proper model order selection, a number of statistical criteria that penalize model complexity (order) as a counteraction to a decreasing quality criterion, have been introduced. Among them, well known are the Akaike Information Criterion (AIC) and the Bayesian information criterion (BIC):

$$\text{AIC} \triangleq N \cdot \ln [V_N^1(\hat{\Theta})] + 2 \cdot \dim \Theta \quad [51]$$

$$\text{BIC} \triangleq \ln [V_N^1(\hat{\Theta})] + \dim \Theta \times \frac{\ln N}{N} \quad [52]$$

the minimization of which indicates the optimal model order (dimensionality of the parameter vector Θ). In these expressions $\dim(\cdot)$ stands for dimensionality of the indicated vector and $\ln(\cdot)$ for natural logarithm. Note that these criteria may only be applied to those stochastic methods that lead to an uncorrelated prediction error (residual) sequence $\{e_k(\hat{\Theta})\}$ (thus, not to the Instrumental Variable method).

An alternative approach to model order selection is based on rank determination for an appropriate matrix, the rank of which coincides with the system order. An example of this is the Hankel matrix $H[0]$ (eqn [40]) in the ERA. In practice, however, exact rank determination is often difficult due to lack of an obvious threshold.

Model order selection based upon the estimation data set Z_0^{N-1} should be considered tentative, with final selection following successful model validation.

Model Validation

A basic validation procedure is based upon the posterior examination of the assumptions behind the identification method used. In stochastic methods such assumptions concern the sequence of estimated prediction errors $\{e_k(\hat{\theta})\}$, which should be (the Instrumental Variable method excluded) uncorrelated (white) and also uncorrelated with past values of the excitation.

An additional, as well as essential, validation procedure is based upon the cross-validation principle, and presumes the availability of an additional data set, referred to as the validation set. To accommodate this need, the available data are often split into estimation and validation sets, with the former used exclusively for estimation and the latter for validation. The behavior of the identified model is then examined within the validation set and model quality criteria, such as those of eqns [49] and [50], are computed. This could be done for a variety of models (and model forms), with the model behaving best selected as final.

Modal Parameter Extraction

Once an estimated model has been validated, its structural transfer function is used for modal parameter extraction. The global modal parameters are obtained as:

$$\omega_{nl} = \frac{1}{dt} \sqrt{\left(\frac{\ln(\lambda_l \cdot \lambda_l^*)}{2} \right)^2 + \left(\cos^{-1}\left(\frac{\lambda_l + \lambda_l^*}{2\sqrt{\lambda_l \cdot \lambda_l^*}}\right) \right)^2} \quad [53]$$

$$\zeta_l = \sqrt{\frac{[\ln(\lambda_l \cdot \lambda_l^*)]^2}{[\ln(\lambda_l \cdot \lambda_l^*)]^2 + 4 \cdot \left(\cos^{-1}\left(\frac{\lambda_l + \lambda_l^*}{2\sqrt{\lambda_l \cdot \lambda_l^*}}\right) \right)^2}} \quad [54]$$

with ω_{nl} representing the l th natural frequency in rads per time unit, ζ_l the corresponding damping ratio, (λ_l, λ_l^*) the l th discrete complex conjugate eigenvalue pair, dt the sampling period, and $\ln(\cdot)$ the natural logarithm.

Mode shape determination is more complicated, requiring the selection of a particular discrete-to-continuous model transformation. The simplest such transformation is based upon the impulse

invariance principle, with the l th mode shape Φ_l being then obtained as:

$$\Phi_l = \begin{bmatrix} 1 & \frac{R_{i2l}}{R_{i1l}} & \dots & \frac{R_{iql}}{R_{i1l}} \end{bmatrix}^T \quad [55]$$

with q representing the estimated number of structural degrees of freedom and R_{ijl} the ij th element of the l th ($l = 1, 2, \dots, q$) residue matrix \mathbf{R}_l of the estimated receptance transfer matrix $\mathbf{G}(z)$. The rest of the residue matrices are complex conjugates of the foregoing.

The distinction of structural modes A major issue in modal parameter extraction is the distinction of structural from extraneous modes, the latter being a result of the generally significant model order over-determination that is necessary for accurate identification (overdetermination is generally higher for deterministic methods). The approaches used for this purpose include the Modal Amplitude Coherence (MAC), dispersion analysis, and frequency stabilization diagrams.

The Modal Amplitude Coherence has been already discussed within the context of ERA. The dispersion analysis methodology assesses the vibration energy associated with each mode in each identified structural transfer function (each element of $\mathbf{G}(z)$). Modes characterized by negligible dispersion (that is, contribution to the vibration energy of the transfer function response) consistently for all transfer functions in $\mathbf{G}(z)$ may be considered extraneous (or too weak to be safely identified). Mathematically, the condition for accepting an identified mode may be expressed as:

$$\|\Delta_l\| = \|\Delta_{ijl}\| > \varepsilon \quad [56]$$

with Δ_{ijl} representing the dispersion of mode l in the ij th transfer function, $\|\cdot\|$ matrix norm, and ε a selected threshold. Note that $\Delta_{ijl} \triangleq |E_{ijl}|/E_{ij}$, with E_{ij} representing the energy of the i th vibration response due to the j th excitation, and E_{ijl} that part of E_{ij} that is associated with mode l .

Frequency stabilization diagrams represent the evolution of estimated natural frequencies with increasing model order. Their basis for structural mode distinction lies with the expectation that structural frequencies will tend to stabilize (remain invariant) as the order increases, whereas extraneous frequencies will change ‘randomly’ within the considered frequency range. Stabilization diagrams may indeed be useful, although the expected pattern is often distorted by phenomena such as frequency

splitting and stabilization of extraneous (noise) frequencies. In all cases, the distinction of extraneous modes may be facilitated by simultaneous examination of their associated damping ratios.

Example

Parametric identification results for a lightly damped scale aircraft skeleton structure based upon mimo experimental data ($r = 2$ random force excitations, $p = 3$ vibration acceleration responses) are presented for the frequency range of 5–75 Hz. Signal preprocessing includes signal band-pass filtering (in the aforementioned range), subsampling at $f_s \approx 205$ Hz, signal scaling, and sample mean removal. Each resulting signal is $N = 2048$ samples long.

p -dimensional ARX(na, nb) and ARMAX(na, nb, nc) models (with $A(z)$, $B(z)$, and $C(z)$ presently being polynomial matrices), which simultaneously accommodate all measured signals, are fitted to the data set. Identification is based upon the multivariate (mimo) Linear Least Squares method (ARX models) and a guaranteed stability version of the multivariate LMS method (ARMAX models). Values of the BIC criterion are, for various estimated models, presented in Figure 4. Minima are achieved for $na = 12$ (ARX case) and $na = 5$ (ARMAX case; notice that the criterion continues to decrease in this case). It is interesting to observe that these models are significantly overdetermined ($na = 5$ is theoretically adequate as the structure is characterized by seven modes within the considered frequency range), and also that the ARMAX models achieve uniformly better BIC values than their ARX counterparts despite the former's increased parametric complexity penalized by the BIC (see eqn [52]).

A frequency stabilization diagram is presented in Figure 5 for ARMAX (k, k, nc) models with $k \in [5, 16]$ and nc optimally preselected. The seven structural modes (at about 6, 16, 36, two closely spaced at about 39, 44 and 61 Hz) are stabilized, and may be

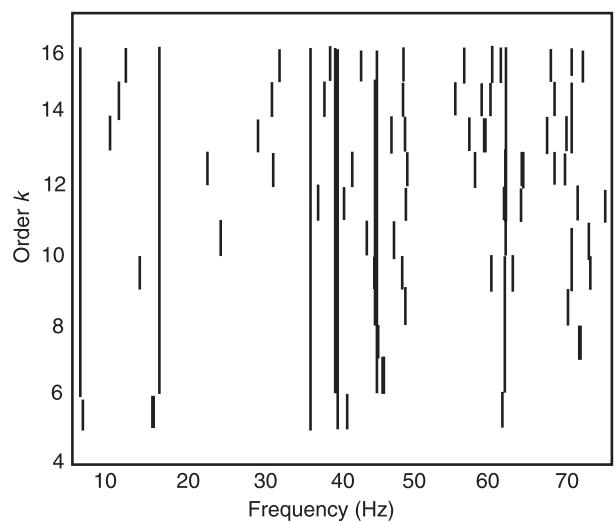

Figure 5 Frequency stabilization diagram: ARMAX (k, k, nc) models.

distinguished. It should be noted that this rather ‘nice’ behavior of the stabilization diagram is partly due to the adequate capturing of the noise by the ARMAX models. Similar results are obtained by dispersion analysis. Based upon them, the ARX(12,12) and ARMAX(11,11,14) models are selected.

Model validation is partly considered in Figure 6, where the first measured response is compared to the ARMAX-based response. The estimates, by both the ARX and ARMAX methods, of the magnitude of the frequency response function of the transfer function $G_{11}(z)$ relating the first excitation to the first response, are presented in Figure 7. The two estimates are in very good agreement, clearly depicting six of the structural modes (one is evident in the neighborhood of the two closely spaced modes at ~ 39 Hz). In this case, owing to the low level of noise, the ARX and ARMAX results are similar; the ARMAX method mainly offers a slightly reduced model order. A comparison with classical nonparametric frequency domain identification (vector spectral analysis via

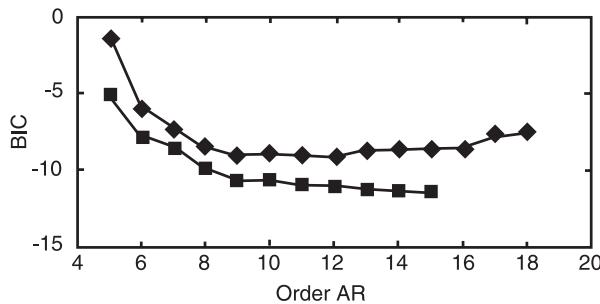

Figure 4 BIC versus AR order. Diamonds, ARX models; squares, ARMAX models.

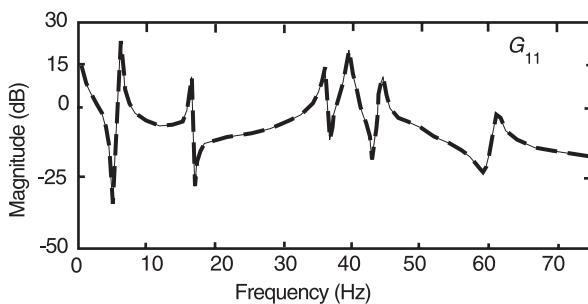

Figure 7 Estimated frequency response magnitude. Continuous line, ARX model; dashed line, ARMAX model.

the Blackman–Tukey method using 512 sample long records and Hamming windowing) is made in Figure 8, in which the corresponding estimate of the frequency response magnitude of $G_{11}(z)$ is presented. The advantages of parametric methods in such a case, where the number of data samples is limited, are evident.

Nomenclature

x_k	sampled force excitation
y_k	sampled noise-corrupted vibration response
n_k	sampled stochastic noise
w_k	sampled white noise (optimal prediction error)
$\hat{y}_{k/k-1}$	optimal one-step-ahead prediction of y_k
n	system order
na	order of the $A(z)$ polynomial
nb	order of the $B(z)$ polynomial
nc	order of the $C(z)$ polynomial
$E\{\cdot\}$	statistical expectation
N	number of data samples (per signal)
$G(z)$	structural transfer function
$H(z)$	noise transfer function
k	discrete time corresponding to continuous time $k \cdot dt$ ($k = 0, 1 \dots N-1$)
t	continuous time
dt	sampling period
z	z -transform variable
s	Laplace transform variable
Θ	model parameter vector
$\hat{y}_k(\Theta)$	model-based one-step-ahead prediction of y_k
$y_k^m(\Theta)$	model response
$e_k(\Theta)$	model-based prediction error

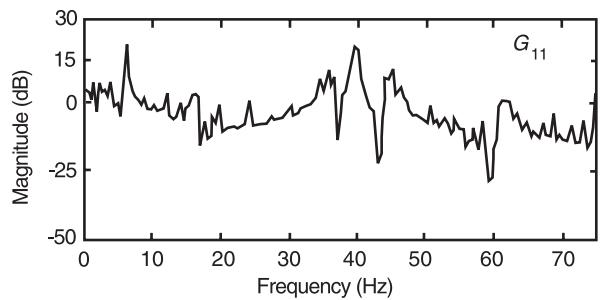

Figure 8 Estimated frequency response magnitude. Vector spectral analysis via the Blackman–Tukey method.

$G(z, \Theta)$	model of the structural transfer function
$H(z, \Theta)$	model of the noise transfer function
λ_l	l th discrete pole
μ_l	l th continuous pole
ω	frequency in rads per time unit
ω_{nl}	l th natural frequency in rads per time unit
ζ_l	l th damping ratio
ϕ_l	l th mode shape

doi:10.1006/rwvb.2001.0097

Many problems in physics, science and engineering science can be described schematically in the block diagram form shown in Figure 1. For example, the vector differential equation governing the motion of a linear vibrating system is given by:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f}(t) \quad [1]$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping and stiffness matrices and $\mathbf{f}(t)$ is the vector of the external force. The block diagram takes for this case the form shown in Figure 2.

Problems where the system and the input are given, and the output is to be determined, are classified as direct problems. Inverse problems are those where the system is to be found based on the knowledge of the input and the output.

The algebraic eigenvalue problem plays an important role in vibration analysis. The eigenvalue

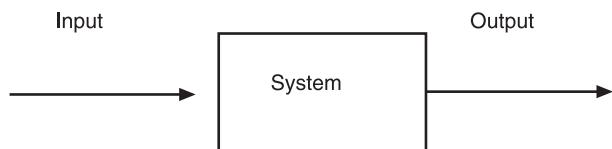

Figure 1 Input-output relation.

problem associated with eqn [1] is to determine the poles s_i and their associated modes $\mathbf{v}_i \neq 0$ that satisfy:

$$(s_i^2 \mathbf{M} + s_i \mathbf{C} + \mathbf{K}) \mathbf{v}_i = \mathbf{0} \quad [2]$$

Problems of reconstructing physical parameters appearing in the matrices \mathbf{M} , \mathbf{C} , and \mathbf{K} based on partial knowledge of the poles and modes of the system are called inverse vibration problems .

The Classical Problem

Perhaps the most celebrated inverse problem in vibration is that of reconstructing, using spectral data, a simply connected n -degree-of-freedom mass-spring system, such as that shown in Figure 3A. The eigenvalue problem associated with this system may be written in the form:

$$(\mathbf{K} - \lambda \mathbf{M}) \mathbf{v} = \mathbf{0} \quad \lambda = -s^2 \quad [3]$$

where \mathbf{K} is a tridiagonal symmetric matrix:

$$\mathbf{K} = \begin{bmatrix} k_1 & -k_1 & & & \\ -k_1 & k_1 + k_2 & -k_2 & & \\ & -k_2 & k_2 + k_3 & -k_3 & \\ & & \ddots & \ddots & \ddots \\ & & & -k_{n-1} & k_{n-1} + k_n \end{bmatrix} \quad [4]$$

and \mathbf{M} is diagonal:

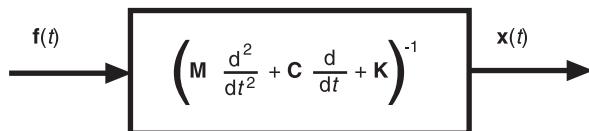

Figure 2 Block diagram for vibrating system.

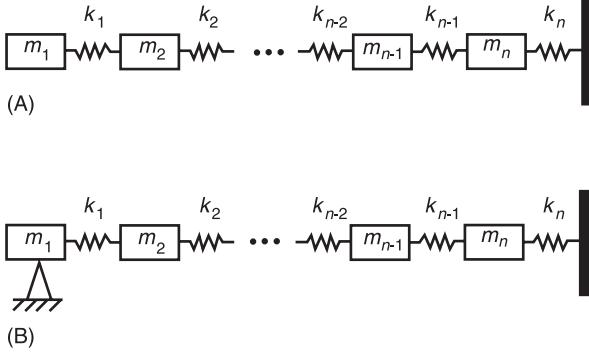

Figure 3 Mass-spring system: (A) fixed-free, and (B) fixed-fixed configuration.

$$\mathbf{M} = \text{diag} \{m_1 \ m_2 \ m_3 \ \cdots \ m_n\} \quad [5]$$

This problem has n distinct positive eigenvalues which may be ordered in the form:

$$\lambda_1 < \lambda_2 < \lambda_3 < \cdots < \lambda_n \quad [6]$$

If the mass m_1 is attached to the ground via a rigid support, as shown in **Figure 3B**, then the constrained system has $n - 1$ degrees-of-freedom with the eigenvalue problem:

$$(\hat{\mathbf{K}} - \mu \hat{\mathbf{M}}) \hat{\mathbf{v}} = \mathbf{0} \quad [7]$$

where $\hat{\mathbf{K}}$ is an $(n - 1) \times (n - 1)$ tridiagonal symmetric matrix determined by omitting the first row and column of \mathbf{K} :

$$\hat{\mathbf{K}} = \begin{bmatrix} k_1 + k_2 & -k_2 & & \\ -k_2 & k_2 + k_3 & -k_3 & \\ & \ddots & \ddots & \ddots \\ & & -k_{n-1} & k_{n-1} + k_n \end{bmatrix} \quad [8]$$

and similarly $\hat{\mathbf{M}}$ is a diagonal matrix obtained by removing the first row and column of \mathbf{M} :

$$\hat{\mathbf{M}} = \text{diag} \{m_2 \ m_3 \ \cdots \ m_n\} \quad [9]$$

The distinct real positive eigenvalues μ_i of this system

may be numbered in an increasing order:

$$\mu_1 < \mu_2 < \cdots < \mu_{n-1} \quad [10]$$

Knowing the total mass:

$$m_T = \sum_{i=1}^n m_i \quad [11]$$

and the two sets of eigenvalues, eqns [6] and [10], the masses $m_i > 0$ and the springs $k_i > 0$, $i = 1, 2, \dots, n$, can be determined uniquely, provided that the interlacing property:

$$\lambda_1 < \mu_1 < \lambda_2 < \mu_2 < \lambda_3 < \cdots < \mu_{n-1} < \lambda_n \quad [12]$$

holds.

In order to show how the physical parameters of the system may be determined from the given data a matrix \mathbf{A} is defined such that:

$$\mathbf{A} = \mathbf{M}^{-1/2} \mathbf{K} \mathbf{M}^{-1/2} \quad [13]$$

where:

$$\mathbf{M}^{-1/2} = \text{diag} \left\{ \frac{1}{\sqrt{(m_1)}} \frac{1}{\sqrt{(m_2)}} \ \cdots \ \frac{1}{\sqrt{(m_n)}} \right\} \quad [14]$$

The matrix \mathbf{A} is symmetric tridiagonal:

$$\mathbf{A} = \begin{bmatrix} \alpha_1 & \beta_1 & & & \\ \beta_1 & \alpha_2 & \beta_2 & & \\ & \beta_2 & \alpha_3 & \beta_3 & \\ & & \ddots & \ddots & \ddots \\ & & & \beta_{n-1} & \alpha_n \end{bmatrix} \quad [15]$$

and being congruently equivalent to the matrix pencil $\mathbf{K} - \lambda \mathbf{M}$ it has the eigenvalues given in eqn [6]. Moreover, a matrix $\hat{\mathbf{A}}$ which is formed by removing the first row and column of \mathbf{A} , i.e.:

$$\hat{\mathbf{A}} = \begin{bmatrix} \alpha_2 & \beta_2 & & & \\ \beta_2 & \alpha_3 & \beta_3 & & \\ & \ddots & \ddots & \ddots & \\ & & \beta_{n-1} & \alpha_n \end{bmatrix} \quad [16]$$

has the eigenvalues given in eqn [10].

Denote the spectral decomposition of \mathbf{A} by:

$$\mathbf{AV} = \mathbf{V}\Lambda \quad [17]$$

where $\mathbf{V} = [v_{ij}]$ is orthogonal:

$$\mathbf{V}^T \mathbf{V} = \mathbf{I} \quad [18]$$

and:

$$\mathbf{\Lambda} = \text{diag}\{\lambda_1 \ \ \lambda_2 \ \ \cdots \ \ \lambda_n\} \quad [19]$$

Then the j th element of the first row of \mathbf{V} can be determined by the eigenvalue–eigenvector relation:

$$v_{1j}^2 = \frac{\prod_{i=1}^{n-1} (\lambda_j - \mu_i)}{\prod_{\substack{i=1 \\ i \neq j}}^n (\lambda_j - \lambda_i)} \quad [20]$$

The first row of eqn [17] gives the following set of equations:

$$\begin{aligned} \alpha_1 v_{11} + \beta_1 v_{21} &= \lambda_1 v_{11} \\ \alpha_1 v_{12} + \beta_1 v_{22} &= \lambda_2 v_{12} \\ &\vdots \\ \alpha_1 v_{1n} + \beta_1 v_{2n} &= \lambda_n v_{1n} \end{aligned} \quad [21]$$

by virtue of eqn [15]. Multiplying the i th equation of eqn [21] by v_{1i} yields:

$$\begin{aligned} \alpha_1 v_{11}^2 + \beta_1 v_{11} v_{21} &= \lambda_1 v_{11}^2 \\ \alpha_1 v_{12}^2 + \beta_1 v_{12} v_{22} &= \lambda_2 v_{12}^2 \\ &\vdots \\ \alpha_1 v_{1n}^2 + \beta_1 v_{1n} v_{2n} &= \lambda_n v_{1n}^2 \end{aligned} \quad [22]$$

Adding these equations gives:

$$\alpha_1 = \sum_{i=1}^n \lambda_i v_{1i}^2 \quad [23]$$

since $\sum_{i=1}^n v_{1i}^2 = 1$ and $\sum_{i=1}^n v_{1i} v_{2i} = 0$ by virtue of the orthogonal relation given in eqn [18]. So α_1 is determined by the given data via eqns [20] and [23].

It also follows from eqn [21] that:

$$\begin{aligned} (\alpha_1 - \lambda_1)^2 v_{11}^2 &= \beta_1^2 v_{21}^2 \\ (\alpha_1 - \lambda_2)^2 v_{12}^2 &= \beta_1^2 v_{22}^2 \\ &\vdots \\ (\alpha_1 - \lambda_n)^2 v_{1n}^2 &= \beta_1^2 v_{2n}^2 \end{aligned} \quad [24]$$

Hence adding the equations in eqn [24] and using the orthogonal relation $\sum_{i=1}^n v_{2i}^2 = 1$ gives:

$$\beta_1 = -\sqrt{\left(\sum_{i=1}^n (\alpha_1 - \lambda_i)^2 v_{1i}^2 \right)} \quad [25]$$

which determines β_1 .

Knowing α_1 and β_1 the second row of the eigenvector matrix \mathbf{V} can be obtained by eqn [21]. The other elements of \mathbf{A} , α_j and β_j , may then be determined successively for $j = 2, 3 \dots n$ by following a similar process in which α_j and β_j are determined from the set of equations:

$$\begin{aligned} \beta_{j-1} v_{j-1,1} + \alpha_j v_{j1} + \beta_j v_{j+1,1} &= \lambda_1 v_{j1} \\ \beta_{j-1} v_{j-1,2} + \alpha_j v_{j2} + \beta_j v_{j+1,2} &= \lambda_2 v_{j2} \\ &\vdots \\ \beta_{j-1} v_{j-1,n} + \alpha_j v_{jn} + \beta_j v_{j+1,n} &= \lambda_n v_{jn} \end{aligned} \quad [26]$$

describing the elements of the j th row of eqn [17] with $\beta_n = v_{n+1,1} = 0$. The interlacing property (eqn [12]) ensures that the diagonal elements of \mathbf{A} are all positive and that $\beta_j < 0$ for $j = 1, 2, \dots, n-1$.

After reconstructing \mathbf{A} the mass and stiffness matrices can be evaluated as follows. Multiplying eqn [13] by $\mathbf{M}^{1/2} \mathbf{p}$, where:

$$\mathbf{p} = \frac{\sqrt{(m_n)}}{k_n} \begin{pmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix} \quad [27]$$

gives:

$$\mathbf{AM}^{1/2} \mathbf{p} = \mathbf{M}^{-1/2} \mathbf{K} \mathbf{p} \quad [28]$$

Or, by virtue of eqns [4], [14] and [27]:

$$\mathbf{Ay} = \mathbf{e}_n \quad [29]$$

where:

$$\mathbf{y} = \frac{\sqrt{(m_n)}}{k_n} \begin{pmatrix} \sqrt{(m_1)} \\ \sqrt{(m_2)} \\ \vdots \\ \sqrt{(m_n)} \end{pmatrix} \quad [30]$$

and \mathbf{e}_n is the n th unit vector $\mathbf{e}_n = (0 \dots 0 \ 1)^T$. Knowing \mathbf{A} the vector \mathbf{y} can be determined from eqn [29]. Then:

$$\mathbf{y}^T \mathbf{y} = \frac{m_n}{k_n^2} \sum_{i=1}^n m_i = \frac{m_n m_T}{k_n^2} \quad [31]$$

implies that:

$$\frac{\sqrt{(m_n)}}{k_n} = \sqrt{\left(\frac{\mathbf{y}^T \mathbf{y}}{m_T}\right)} \quad [32]$$

and hence the masses m_i , $i = 1, 2 \dots n$, are determined by eqns [30] and [32]. Knowing \mathbf{M} and \mathbf{A} the stiffness matrix is found by:

$$\mathbf{K} = \mathbf{M}^{1/2} \mathbf{A} \mathbf{M}^{1/2} \quad [33]$$

which completes the reconstruction of the system.

Other Problems

One other problem that has attracted much attention is the problem of reconstructing the physical parameters m_i , k_i and d_i of a mass–spring–rod system, such as that shown in Figure 4. The parameters are essentially constructed from three sets of spectral data, e.g. fixed–free, fixed–fixed and fixed–simply supported configurations. This problem is associated with the reconstruction of a five-diagonal symmetric matrix. The conditions ensuring the reconstruction of a realizable system with positive parameters have been found by Gladwell and they are more involved than the simple interlacing properties.

There are several variations of the classical problem of reconstructing the mass–spring system from spectral data. Instead of fixing the left mass of Figure 3A a mass or spring may be attached to the free end. If a damper is attached to the free end, as shown in Figure 5, then m_i , k_i , and c can be reconstructed apart from a scale factor by knowing only the $2n$ (complex) poles of the damped system. This interesting result is due to K. Veselic.

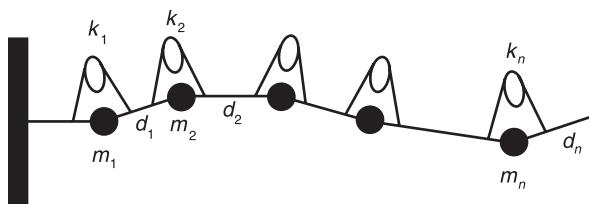

Figure 4 Mass–spring–rod system.

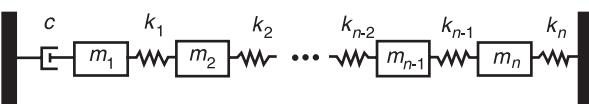

Figure 5 Vecelic's system.

Inverse mode problems are those where the reconstruction of the system is based on eigenvector and eigenvalue data. For example, the mass–spring system of Figure 3A may be reconstructed from two mode-shapes, one eigenvalue, and the total mass of the system. Similarly the mass–spring–rod system of Figure 4 may be reconstructed from three eigenvectors, two eigenvalues and the total mass.

The problems mentioned so far are all finite-dimensional systems. In analogy the physical parameters of distributed parameter systems may be reconstructed from spectral and modal data. For example, the axial rigidity and density functions of a nonuniform axially vibrating rod are determined by two sets of spectral data associated with the fixed–free and fixed–fixed configurations. Alternatively two eigenfunctions, an eigenvalue and the total mass determine the rigidity and density of the rod. Many of the inverse problems associated with finite dimensional systems may be regarded as a certain discrete version of a distributed parameter problem. It should be noted, however, that since the asymptotic behavior of eigenvalues of a distributed parameter system is different from that of its related discrete model, there is no reliable way to reconstruct the physical parameters of a distributed parameter system by considering a related discrete system.

Concluding remarks

The problem of reconstructing the mass–spring system from two spectral sets and the total mass studied above is fully solved in the following sense: (1) there exists a unique realizable system, with positive masses and springs, that fits the prescribed data whenever the interlacing property eqn [12] holds, (2) there is no realizable system when the spectral data violate eqn [12], and (3) direct methods for reconstructing the system do exist. Only a few other inverse problems in vibration have been posed and fully solved in this sense. For many other inverse problems the spectral data do not allow the unique reconstruction of a realistic system. For some problems there exists a continuous family of solutions. In other problems there is a finite number of systems satisfying the given data. The necessary and sufficient conditions which allow the construction of a realistic system are not always known. For some problems there is no direct method of solution and iterative methods are used instead. Many iterative methods do not always converge.

This suggests that the subject is still in its development phase. It started with Gantmakher and Krein in 1950 with a problem similar to reconstructing the mass–spring system from spectral data. This was

highlighted by Gladwell in his monograph *Inverse Problems in Vibration* describing the state-of-the-art of knowledge, including his own major contribution in the field. It is most probable that related research will continue to be carried out in the future developing the subject further.

Nomenclature

$f(t)$	vector of the external force
m	mass
V	eigenvector matrix
μ	eigenvalue

Introduction

This article describes structural dynamics model reduction based on Krylov vectors and Lanczos vectors. Finite element models of large or geometrically complicated structures may attain tens of thousands of degrees of freedom, or even many more. For dynamic response analyses and for control design applications it is not computationally feasible to solve such large systems of equations. Therefore, model order reduction plays an indispensable role in such analyses. Model reduction of a structural dynamics system is usually performed by the Rayleigh–Ritz method, which transforms the large-order matrix system differential equation into one of smaller order by using a projection subspace. It is indisputable that the choice of projection subspace is very important to the accuracy and computational efficiency of the reduced model. Classically, the subspace of undamped normal modes has been used for projection because it has a clear physical meaning, because it simultaneously diagonalizes both the mass matrix and the stiffness matrix, and because it preserves the system's undamped natural frequencies. This approach is called mode superposition, or the mode displacement method. However, with regard to the accuracy of a system's computed response to time-dependent excitation, various numerical studies have shown that preservation of the system natural frequencies is not necessarily the primary concern. This is particularly true if there are concentrated time-dependent loads, or if, as is usually the case, stresses are to be computed from displacements. Although mode displacement solutions may be improved by the addition of pseudostatic correction terms in a computational approach called the mode acceleration

method, the methods discussed in this article produce accurate solutions in a more straightforward and efficient manner.

The Krylov vectors and Lanczos vectors discussed in this article are special types of derived Ritz vectors. Professor Ed Wilson, the originator of the method, refers to these special Ritz vectors as load-dependent Ritz vectors. The first Ritz vector (or block of vectors) corresponds to the static deflection shape(s) of the structure due to the applied load distribution(s). Inverse iteration and Gram–Schmidt orthogonalization are employed to compute additional vectors. Krylov–Lanczos model reduction methods have been found to be particularly effective in solving dynamic response problems, like response of building structures to earthquake loading. While closely related to the powerful and popular Lanczos eigensolvers, the Krylov–Lanczos procedures discussed here do not employ an eigenvector subspace; they avoid the computational expense of obtaining converged eigenvectors, and, at the same time, provide a more suitable subspace for model reduction. Thus, compared to a ‘classical’ mode superposition solution, the computational effort for dynamic response analysis of large structures may be reduced by a factor of three or more without compromising accuracy.

Physical Meaning of Krylov Vectors and Lanczos Vectors

The finite element model of an undamped structure may be described by:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{F}\mathbf{u}(t) \quad [1]$$

where $\mathbf{x} \in R^n$ is the displacement vector, $\mathbf{u} \in R^l$ is the input force vector, \mathbf{M} and \mathbf{K} are the system mass and stiffness matrices, and \mathbf{F} is the force distribution matrix. Model reduction of a structural dynamics system is usually performed by the Rayleigh–Ritz method, which employs a projection transformation of the form:

$$\mathbf{x} = \mathbf{T}\bar{\mathbf{x}}, \quad \bar{\mathbf{x}} \in R^r \quad [2]$$

and transforms the large-order system equation into a reduced-order model that has the form:

$$\ddot{\mathbf{M}}\ddot{\mathbf{x}} + \ddot{\mathbf{K}}\ddot{\mathbf{x}} = \ddot{\mathbf{F}}\ddot{\mathbf{u}} \quad [3]$$

In the classical Ritz transformation, the reduced system matrices and the original system matrices are related by the following expressions:

$$\ddot{\mathbf{M}} = \mathbf{T}^T \mathbf{M} \mathbf{T}, \quad \ddot{\mathbf{K}} = \mathbf{T}^T \mathbf{K} \mathbf{T}, \quad \ddot{\mathbf{F}} = \mathbf{T}^T \mathbf{F} \quad [4]$$

The choice of the projection matrix, \mathbf{T} , governs the accuracy of the reduced system. In this chapter, Krylov vectors and Lanczos vectors are used for model reduction.

Krylov Vectors and Krylov Modes

It is well known that the modes of free vibration of an n degree-of-freedom (n -DOF) finite element model of an undamped structure satisfy the algebraic eigenproblem:

$$\mathbf{K}\phi_i = \lambda_i \mathbf{M}\phi_i \quad i = 1, 2, \dots, n \quad [5]$$

where $\lambda_i (\equiv \omega_i^2)$ and ϕ_i are the i th eigenvalue and i th eigenvector, respectively. However, Krylov vectors and Lanczos vectors are not as well known as are eigenvectors. Note that eqn [5] is essentially an equilibrium equation relating elastic restoring forces $\mathbf{K}\phi$ to inertia forces $\omega^2 \mathbf{M}\phi$, and recall that a similar equation, namely:

$$\mathbf{K}\psi_{j+1} = \mathbf{M}\psi_j \quad [6]$$

is the basis for the inverse iteration method for computing eigenvalues and eigenvectors, assuming that \mathbf{K} is nonsingular. The vector ψ in eqn [6] converges to the fundamental mode (eigenvector) or, with suitable orthogonalization with respect to lower-frequency modes, to a higher-frequency mode.

Eqn [6] states that, given a vector ψ_j , a new vector ψ_{j+1} may be generated by solving for the static deflection produced by the inertia forces associated with ψ_j , that is (symbolically):

$$\psi_{j+1} = \mathbf{K}^{-1} \mathbf{M} \psi_j \quad [7]$$

Eqn [7] provides a basis for defining a Krylov vector subspace. Given a starting vector ψ_{K1} , the vectors ψ_{Kj} are said to form a Krylov subspace of order r , $1 \leq r \leq n$, given by:

$$\begin{aligned} \Psi_K &\equiv [\psi_{K1} \ \psi_{K2} \ \psi_{K3} \ \dots \ \psi_{Kr}] \\ &= [\psi_{K1}, [\mathbf{K}^{-1} \mathbf{M}] \psi_{K1}, [\mathbf{K}^{-1} \mathbf{M}]^2 \psi_{K1} \dots [\mathbf{K}^{-1} \mathbf{M}]^{(r-1)} \psi_{K1}] \end{aligned} \quad [8]$$

To illustrate Krylov vectors, the Krylov sequence of eqn [8] will be obtained for the four degree-of-freedom (4-DOF) consistent-mass finite element model of the cantilever beam shown in Figure 1.

Figure 2 illustrates the four Krylov vectors generated from a starting vector that is the static deflection due to a unit force at DOF 1. In Figure 2 the elements of the Krylov vectors determine the nodal displacements and rotations; standard cubic shape functions are used to determine the beam's deflection shape between nodes. The resulting Ritz functions will be referred to as Krylov modes.

Lanczos Vectors and Lanczos Modes

Lanczos vectors differ from the Krylov vectors defined in eqn [8] in that each Lanczos vector is made orthogonal to the previous two Lanczos vectors. It can be shown that this makes the present Lanczos vector (theoretically) orthogonal to *all* prior vectors. The following algorithm may be used to compute Lanczos vectors for an undamped structure. The reader should consult literature listed in the Further Reading section for other algorithms which

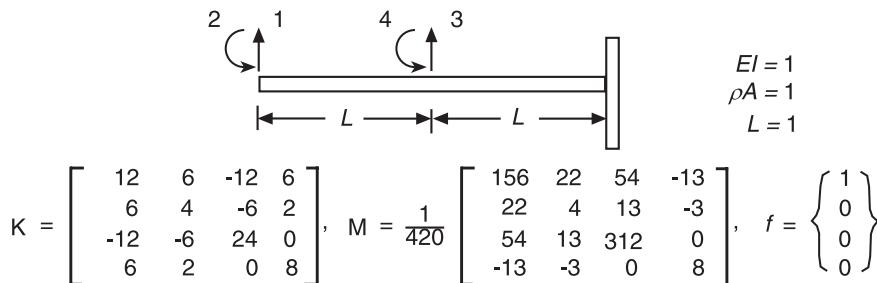

Figure 1 Four-DOF cantilever beam model.

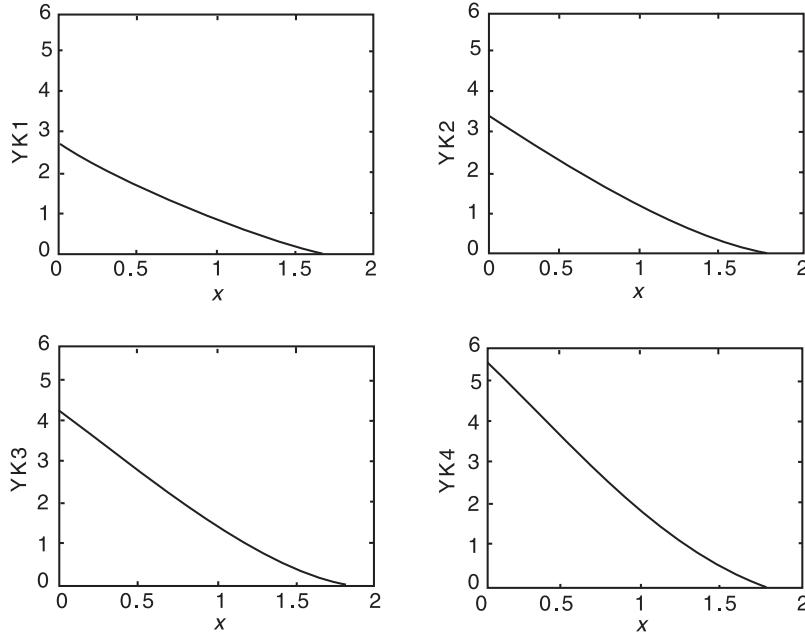

Figure 2 Four Krylov modes for the four-DOF cantilever beam.

may differ, in some details, from this algorithm. Such an alternative algorithm is described in the section on block Lanczos algorithms, below.

Algorithm 1: undamped structure; single load vector

1. *Starting vector:* As the starting vector, select the static deflection of the structure due to the load distribution vector, f . That is, solve the equation:

$$\mathbf{K}q_1 = f \quad [a]$$

for the static deflection q_1 . Mass normalize this to form the starting Lanczos vector:

$$\psi_{L1} = \frac{1}{\beta_1} q_1 \quad [b]$$

where the normalizing factor β_1 is determined by:

$$\beta_1 = \sqrt{q_1^T \mathbf{M} q_1} \quad [c]$$

2. *Second Lanczos vector:* The second Lanczos vector is obtained by first solving for the static deflection of the structure subjected to inertia loading due to the first vector's deflection. In addition, there is a Gram–Schmidt orthogonalization step that removes the starting vector component. First, solve the equation:

$$\mathbf{K}\tilde{q}_2 = \mathbf{M}\psi_{L1} \quad [d]$$

for the static deflection \tilde{q}_2 . Then, use the Gram–Schmidt procedure to remove the ψ_{L1} -component of this iterate:

$$q_2 = \tilde{q}_2 - \alpha_1 \psi_{L1} \quad [e]$$

where:

$$\alpha_1 = \psi_{L1}^T \mathbf{M} \tilde{q}_2 \quad [f]$$

Finally, mass normalize the vector q_2 to form the second Lanczos vector:

$$\psi_{L2} = \frac{1}{\beta_2} q_2 \quad [g]$$

where the normalizing factor β_2 is determined by:

$$\beta_2 = \sqrt{q_2^T \mathbf{M} q_2} \quad [h]$$

3. *General Lanczos vector:* The general Lanczos vector, ψ_{Lj} , $j = 3, 4, \dots$ is obtained by the following steps. First, solve the equation:

$$\mathbf{K}\tilde{q}_{(j+1)} = \mathbf{M}\psi_{Lj} \quad [i]$$

for the static deflection $\tilde{q}_{(j+1)}$. Use the Gram-Schmidt procedure to remove both the ψ_{L_j} -component and the $\psi_{L(j-1)}$ -component of this iterate:

$$q_{(j+1)} = \tilde{q}_{(j+1)} - \alpha_j \psi_{L_j} - \beta_j \psi_{L(j-1)} \quad [j]$$

where:

$$\alpha_j = \psi_{L_j}^T \mathbf{M} \tilde{q}_{(j+1)} \quad [k]$$

and:

$$\beta_j = \psi_{L(j-1)}^T \mathbf{M} \tilde{q}_{(j+1)} \quad [l]$$

which can be shown to be just the preceding normalizing factor. Finally, mass normalize the vector $q_{(j+1)}$ to form the $(j+1)$ -st Lanczos vector:

$$\psi_{L(j+1)} = \frac{1}{\beta_{(j+1)}} q_{(j+1)} \quad [m]$$

where the normalizing factor $\beta_{(j+1)}$ is determined by:

$$\beta_{(j+1)} = \sqrt{\psi_{L(j+1)}^T \mathbf{M} \psi_{L(j+1)}} \quad [n]$$

Figure 3 shows the four Lanczos modes for the cantilever beam shown in **Figure 1**. The starting vector for these is the same starting vector that was used for the set of Krylov modes.

Lanczos Coordinate Coupling; Tridiagonal Lanczos Matrix

The distinguishing feature of Lanczos algorithms is that, while one of the system matrices is diagonalized, the other system matrix is converted to tridiagonal form. Let Ψ_{Lr} contain the first r Lanczos vectors as columns, that is, let:

$$\Psi_{Lr} \equiv [\psi_{L1} \ \psi_{L2} \ \psi_{L3} \ \dots \ \psi_{Lr}] \quad [9]$$

and let the matrix \mathbf{L}_r , the corresponding tridiagonal matrix containing coefficients α_i and β_i , be:

$$\mathbf{L}_r = \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \dots & 0 & 0 \\ \beta_2 & \alpha_2 & \beta_3 & \dots & 0 & 0 \\ 0 & \beta_3 & \alpha_3 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & \alpha_{r-1} & \beta_r \\ 0 & 0 & 0 & \dots & \beta_r & \alpha_r \end{bmatrix} \quad [10]$$

which can be expressed directly in matrix form as:

$$\mathbf{L}_r = \Psi_{Lr}^T \mathbf{M} \mathbf{K}^{-1} \mathbf{M} \Psi_{Lr} \quad [11]$$

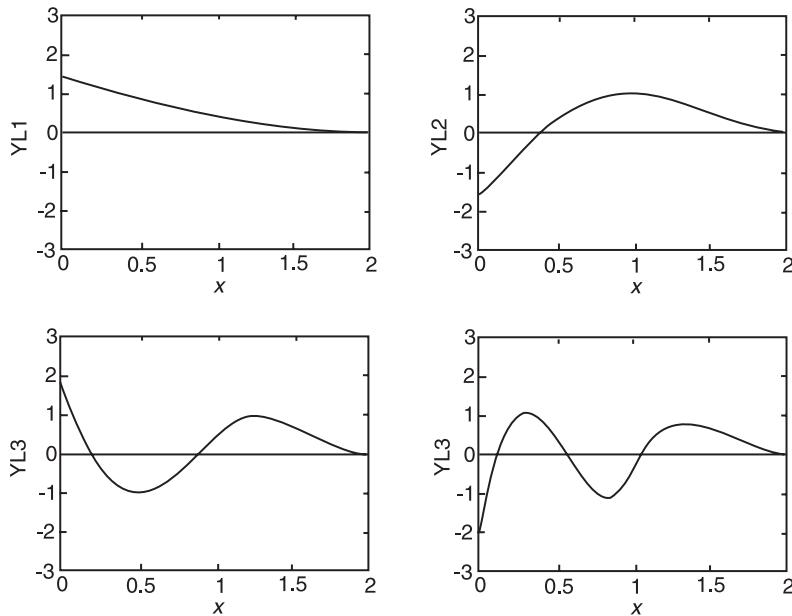

Figure 3 Four Lanczos modes for the four-DOF cantilever beam.

Because of the presence of the extra $\mathbf{K}^{-1}\mathbf{M}$ factor in eqn [11], this is not a standard Ritz transformation. However, with the Ritz-type coordinate transformation:

$$\mathbf{x} = \Psi_{\text{Lr}}\bar{\mathbf{x}}_r \quad [12]$$

eqn [1] can be shown to reduce to the following form:

$$\begin{aligned} \Psi_{\text{Lr}}^T \mathbf{M} \mathbf{K}^{-1} \mathbf{M} \Psi_{\text{Lr}} \ddot{\bar{\mathbf{x}}}_r(t) + \Psi_{\text{Lr}}^T \mathbf{M} \Psi_{\text{Lr}} \bar{\mathbf{x}}_r(t) \\ = \Psi_{\text{Lr}}^T \mathbf{M} \mathbf{K}^{-1} \mathbf{f} u(t) \end{aligned} \quad [13]$$

which reduces to the simple form:

$$L_r \ddot{\bar{\mathbf{x}}}_r(t) + \bar{\mathbf{x}}_r(t) = [\beta_1 \ 0 \ \dots]^T u(t) \quad [14]$$

Note that the transformed mass matrix is the tridiagonal matrix of orthogonalization coefficients, while the transformed stiffness matrix is just the unit matrix. Also note that the only nonzero forcing term acts on the first Lanczos coordinate; the remaining coordinates are only coupled through the off-diagonal terms of the transformed mass matrix in eqn [14].

Some Properties of Lanczos Vectors

1. *Efficiency*: The efficiency of Krylov–Lanczos reduced-order models stems from the fact that the starting vector, or starting block of vectors, can be selected to span the static deflection of the structure under the given load patterns, while the higher-order terms in the sequence express the effects of inertia loads due to previous vectors in the sequence.
2. *Normalization and orthogonality*: Unlike the Krylov vectors in eqn [8], each Lanczos vector is mass orthonormalized. In ‘exact arithmetic’, when the ψ_{L_j} -component and the $\psi_{\text{L}_{(j-1)}}$ -component have been removed from $\tilde{\mathbf{q}}_{(j+1)}$ (step j of Algorithm 1), the new Lanczos vector $\psi_{\text{L}_{(j+1)}}$ can be shown to be mass orthogonal to all previous Lanczos vectors. In practice, reorthogonalization with respect to all prior vectors may be necessary at some steps. Such computational details are discussed in the literature.
3. *Tridiagonality*: Although the coordinate transformation given in eqn [13] and based on the Lanczos vectors obtained through the use of Algorithm 1 is not a standard Ritz transformation (eqns [2]–[4]), other Lanczos algorithms do employ the standard Ritz transformation to obtain the transformed equation in the simple form of eqn [14], as will be demonstrated below. Even though the transformed equations are not completely uncoupled,

as they would be if the transformation were based on eigenvectors, advantage can still be taken of the sparseness of the tridiagonal transformed mass matrix when eqn [14] is solved for dynamic response.

4. *Reduced-order models*: If Krylov vectors or Lanczos vectors are determined for an n -DOF model, but the sequence is truncated at $r < n$, the resulting subspace forms a reduced-order model of the original n -DOF system. Truncation criteria for determining an appropriate subspace order r have been presented by some authors.
5. *Block Krylov and block Lanczos algorithms*: The Krylov and Lanczos sequences can be defined for blocks of vectors, as demonstrated below.

A Block-Lanczos Algorithm for Model Reduction of Undamped Structural Systems

A *block-Lanczos algorithm* for an undamped structural dynamics system in input–output form will now be presented. The block format permits the force distribution matrix \mathbf{F} to have more than one column. The output equation is included here to permit reduced-order modeling of the system output along with reduced-order modeling of the structure itself. Therefore, the system is described by the following system equation of motion and output equation:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{F}u(t) \quad \mathbf{y} = \mathbf{V}\mathbf{x} + \mathbf{W}\dot{\mathbf{x}} \quad [15]$$

where $\mathbf{x} \in \mathbb{R}^n$ is the displacement vector, $\mathbf{u} \in \mathbb{R}^l$ is the input force vector, $\mathbf{y} \in \mathbb{R}^m$ is the output measurement vector, \mathbf{M} and \mathbf{K} are the system mass and stiffness matrices, \mathbf{F} is the force distribution matrix, and \mathbf{V} and \mathbf{W} are the velocity and displacement sensor distribution matrices. The output equation is of particular interest in applications to control the flexible structures. The reduced system equation takes the form:

$$\overline{\mathbf{M}}\ddot{\bar{\mathbf{x}}} + \overline{\mathbf{K}}\bar{\mathbf{x}} = \overline{\mathbf{F}}u(t) \quad \bar{\mathbf{y}} = \overline{\mathbf{V}}\bar{\mathbf{x}} + \overline{\mathbf{W}}\dot{\bar{\mathbf{x}}} \quad [16]$$

with the reduced system coordinate $\bar{\mathbf{x}}$ and the original system coordinate \mathbf{x} related by eqn [2]. The reduced system matrices and the original system matrices are related by:

$$\begin{aligned} \overline{\mathbf{M}} &= \mathbf{T}^T \mathbf{M} \mathbf{T}, & \overline{\mathbf{K}} &= \mathbf{T}^T \mathbf{K} \mathbf{T}, & \overline{\mathbf{F}} &= \mathbf{T}^T \mathbf{F}, \\ \overline{\mathbf{V}} &= \mathbf{V} \mathbf{T}, & \overline{\mathbf{W}} &= \mathbf{W} \mathbf{T} \end{aligned} \quad [17]$$

The choice of the projection matrix, \mathbf{T} , governs the accuracy of the reduced system.

If the projection matrix \mathbf{T} is formed by the set of Krylov vectors defined in eqn [18], then the reduced system has certain parameter-matching properties, which ensures that the Krylov model will faithfully represent low-frequency motion:

$$\text{span}\{\mathbf{T}\} = \text{span}\{\mathbf{T}_F \mathbf{T}_V \mathbf{T}_W\} \quad [18]$$

The blocks of Krylov vectors contained in \mathbf{T}_F can be generated by applying the simple iteration formula:

$$\mathbf{Q}_1 = \mathbf{K}^{-1}\mathbf{F}, \quad \mathbf{Q}_{i+1} = \mathbf{K}^{-1}\mathbf{M}\mathbf{Q}_i \quad [19]$$

As noted above, Krylov vectors have a clear physical interpretation. The first block of Krylov vectors, $\mathbf{K}^{-1}\mathbf{F}$, is the system's static deflection due to the force distribution matrix, \mathbf{F} . The matrix \mathbf{Q}_{i+1} can be interpreted as the matrix of static deflection vectors produced by the inertia force vectors associated with respective columns of \mathbf{Q}_i . If only the dynamic response simulation is concerned, the projection matrix \mathbf{T} is simply \mathbf{T}_F . From an input-output point of view, \mathbf{T}_V , \mathbf{T}_W , and \mathbf{T}_F are equally important. So, to construct a reduced-order model for control applications, where the input-output property is important, the following block Lanczos algorithm for generating the projection matrix \mathbf{T} is given.

Algorithm 2: Undamped structural system with output equation; multiple load vectors

1. Form the starting block of vectors:

- (a) $\mathbf{Q}_0 = \mathbf{0}$
- (b) $\mathbf{R}_0 = \mathbf{K}^{-1}\tilde{\mathbf{F}}$, $\tilde{\mathbf{F}}$ = linearly-independent portion of $[\mathbf{F}\mathbf{V}^T\mathbf{W}^T]$
- (c) $\mathbf{R}_0^T \mathbf{K} \mathbf{R}_0 = \mathbf{U}_0 \Sigma_0 \mathbf{U}_0^T$ (singular-value decomposition)
- (d) $\mathbf{Q}_1 = \mathbf{R}_0 \mathbf{U}_0 \Sigma_0^{-1/2}$ (normalization)

2. For $j = 1, 2, \dots, k - 1$, repeat:

- (e) $\bar{\mathbf{R}}_j = \mathbf{K}^{-1}\mathbf{M}\mathbf{Q}_j$
- (f) $\mathbf{R}_j = \bar{\mathbf{R}}_j - \mathbf{Q}_j \mathbf{A}_j - \mathbf{Q}_{(j-1)} \mathbf{B}_j$
(orthogonalization)
- (g) $\mathbf{A}_j = \mathbf{Q}_j^T \mathbf{K} \bar{\mathbf{R}}_j$, $\mathbf{B}_j = \mathbf{U}_{(j-1)} \Sigma_{(j-1)}^{1/2}$
- (h) $\mathbf{R}_j^T \mathbf{K} \mathbf{R}_j = \mathbf{U}_j \Sigma_j \mathbf{U}_j^T$ (singular-value decomposition)
- (i) $\mathbf{Q}_{(j+1)} = \mathbf{R}_j \mathbf{B}_{(j+1)}^{-T} = \mathbf{R}_j \mathbf{U}_j \Sigma_j^{-1/2}$ (normalization)

3. Form the k -block projection matrix:

$$\mathbf{T} = [\mathbf{Q}_1 \mathbf{Q}_2 \dots \mathbf{Q}_k]$$

In the above algorithm the \mathbf{K} matrix is used as the normalization weighting matrix; in eqn [8] the \mathbf{M} matrix is used. By using \mathbf{K} as the normalization

weighting matrix, the generated Lanczos vectors orthonormalize the \mathbf{K} matrix and block-tridiagonalize the \mathbf{M} matrix. Therefore, the standard Ritz method can be employed to transform the system's dynamic equation into the following form:

$$\mathbf{T}^T \mathbf{M} \mathbf{T} \ddot{\mathbf{x}} + \mathbf{T}^T \mathbf{K} \mathbf{T} \bar{\mathbf{x}} = \mathbf{T}^T \mathbf{F} \mathbf{u} \quad [20]$$

where the transformed mass matrix $\mathbf{T}^T \mathbf{M} \mathbf{T}$ is block tridiagonal.

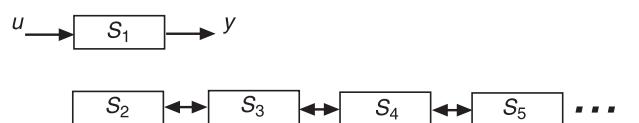

The vectors generated by Algorithm 2 lie in a Krylov subspace, because they are generated by the Krylov iteration formula in step (e). The algorithm is called a Lanczos algorithm because of the three-term orthogonalization scheme used in step (f). Remarks about the numerical details of Algorithm 2 and the properties of the resulting reduced-order model are discussed elsewhere in the literature.

Due to the choice of starting block of vectors in Algorithm 2, the \mathbf{K} -orthogonalization, and the three-term recurrence, the transformed system equation in the Lanczos coordinates has a mass matrix in block-tridiagonal form, a stiffness matrix equal to the identity matrix, and force distribution and measurement distribution matrices with nonzero elements only in the first block of each. The form of the transformed system equation is:

$$\begin{bmatrix} \times & \times & & & \\ \times & \times & \times & & \\ . & . & . & & \\ & . & . & . & \\ & . & . & . & \\ & & \times & \times & \times \\ & & & \times & \times \end{bmatrix} \ddot{\mathbf{x}} + \bar{\mathbf{x}} = \begin{bmatrix} \times \\ 0 \\ . \\ . \\ . \\ 0 \\ 0 \end{bmatrix} \mathbf{u} \quad [21]$$

$$\mathbf{y} = [\times \ 0 \ 0 \ \dots \ 0] \bar{\mathbf{x}} + [\times \ 0 \ 0 \ \dots \ 0] \dot{\mathbf{x}}$$

where \times denotes the location of nonzero elements. This special form reflects the structure of a tandem system (Figure 4), in which only subsystem S_1 is directly controlled and measured while the remaining subsystems, $S_i, i = 2, 3, \dots$ are excited through chained dynamic coupling. This form of the transformed system equation and output equation has a major advantage in control applications.

Other Applications of Krylov Vectors and Lanczos Vectors

In addition to the two algorithms presented in this article, various authors have presented other algorithms for undamped structures. Some of these algorithms are currently available in structural dynamics finite element codes. Some of the other applications that may be found in the literature are listed below.

1. *Dynamic response of damped, linear structure:* Several authors have presented Krylov–Lanczos algorithms for analyzing the dynamic response of damped linear systems. The simplest version is for systems that have proportional viscous damping, and employs Ritz vectors for the corresponding undamped system. Iteration steps have been employed to extend this approach to handle nonproportional damping cases. In the case of nonproportional damping, Krylov–Lanczos algorithms have been proposed that are based on a transformation of the equations of motion from second-order form to first-order form. For general linear viscous damping, both one-sided and two-sided unsymmetric block-Lanczos algorithms have been presented. It has been demonstrated that much greater accuracy can be achieved than by a simple use of Ritz vectors computed for the undamped structure.
2. *Dynamic response of linear structures with nonlinear elements:* Load-dependent Ritz vectors have been used to calculate the nonlinear dynamic response of structures that have localized energy dissipation devices or that develop plastic hinges, and have also been employed for the iterative solution of other nonlinear response problems.
3. *Component mode synthesis of linear structures:* A popular approach to solving large structural dynamics problems is to divide the structure into smaller substructures and apply one of the methods of component mode synthesis. The classical component mode synthesis methods employ both normal modes of free vibration of the separate components and also various derived Ritz vectors (e.g., constraint modes or attachment modes) that improve the accuracy of dynamic response solutions. It has been shown that it is unnecessary to use component normal modes of free vibration; Krylov modes or Lanczos modes can be substituted for component normal modes without degradation of accuracy.

Along similar lines, Lanczos modes have been employed to model the flexibility of components of multibody systems, where the governing equations are nonlinear.

4. *Feedback control design for flexible structures:* By including the output equation as well as the equation of motion, as illustrated above, it is possible to obtain reduced-order models that are very attractive for use in control system design. The benefit that accrues from the use of Lanczos vectors for model reduction is the special sparse form of the resulting Lanczos model, as illustrated in Figure 4, especially the sparseness of the transformed input and output distribution matrices.
5. *System identification; damage detection:* Experimental modal analysis, the standard procedure for using vibration testing to obtain an experimental model of a structure, usually seeks to obtain a ‘modal model’ of the structure; that is, to obtain natural frequencies, damping factors, and mode shapes (either real normal modes or complex modes). A few authors have recently proposed that vibration test data can also be used to generate a Krylov-mode or Lanczos-mode representation. Recent work has involved use of these Krylov–Lanczos vectors to assess structural damage.

Acknowledgment

The author expresses his deep indebtedness to his former student, Dr Tsu-Jeng Su, whose creativity and thorough knowledge of linear systems theory led to pioneering work in the application of Krylov–Lanczos methods to the control of flexible structures.

Nomenclature

f	load distribution vector
F	force distribution matrix
q_1, q_2	static deflections
T	projection matrix
V	velocity sensor distribution matrix
W	displacement sensor distribution
β_1, β_2	normalizing factors

LASER BASED MEASUREMENTS

doi:10.1006/rwvb.2001.0152

In recent years the techniques for the measurement and analysis of mechanical vibrations have been widely investigated because of their relevance in a large number of industrial applications. Important results have been achieved in the field of noncontact sensors by using innovative electrooptic methodologies and, in particular, those based on laser techniques.

Among the different laser-based techniques for vibration measurement (such as holography, electronic speckle pattern interferometry (ESPI), shearography, etc.), laser Doppler vibrometry (LDV) is one of the most investigated and used, mainly because of its flexibility and applicability in a wide range of testing situations.

Nonintrusive measurement techniques are advantageous with respect to traditional ones, based on the use of accelerometers, since they allow one to avoid errors due to mass loading effects, especially when testing light or small structures or highly damped nonlinear materials (like rubber); moreover, they often drastically reduce testing time and help perform remote measurements.

LDV is an interferometric technique for vibration measurements on solid bodies. This method deter-

mines the instantaneous velocity by observing the Doppler effect induced on a laser beam diffused by the object surface.

The initial studies on LDV sensors were presented in the late 1960s, and the first commercial system was introduced by DISA during the 1970s. This instrument was based on an optical heterodyne detection of Doppler shift and it was very similar to those which are available in the market at present; however, its limited sensitivity allowed measurements on only very diffusive surfaces.

During the 1980s several researches were performed in order to increase the performances of these sensors: fibre optic systems were used to improve handiness and compactness, while different alternative solutions were studied to realize specific signal analysis strategies.

It was only in the early 1990s that commercial sensors, typically fully-bulk optic systems, with the capabilities of working with higher sensitivity and signal-to-noise ratio were presented. Typical performances of actual systems are high accuracy for remote measurements (accuracy 1–2.5% root mean square of reading at a distance larger than 30 m), bandwidth up to 200 kHz, velocity range of $\pm 10 \text{ m s}^{-1}$, resolution of about 8 nm in displacement and $0.5 \mu\text{m s}^{-1}$ in velocity and reduced testing time. Due to the high optical sensitivity of the last generation of sensors, the measured surface does not need to be specifically treated or prepared in advance.

The combination of an interferometer with two moving mirrors driven by galvanometric actuators makes it possible to direct the laser beam to the desired measurement points. Such an instrument, named the scanning laser Doppler vibrometer (SLDV), can quickly perform a series of velocity measurements on a grid of points over the structure under test. This particular capability, together with its noncontact nature, makes SLDV technology suited for situations where the use of accelerometers is difficult, as in the case of rotating structures. Besides, if a high number of measurements has to be taken on different points, it would be necessary to arrange an array of contact transducers, which is time-consuming and costly. In contrast, the SLDV is able to provide both spatial information and time dependence of the vibration, whereas other full-field optical techniques, including ESPI and double-pulse laser holography, supply only spatial information and have no means to control the time dependence. In addition, SLDV provides automatically calibrated velocity amplitude and phase information at each measurement point.

These new laser-based techniques have proved to be of paramount importance for overcoming problems related to vibration measurements, such as frequency range, spatial resolution, electromagnetic interference sensitivity, and for allowing measurements in harsh conditions, such as high-temperature surfaces and noisy environments, or when hard-to-reach, small, or weak objects are analyzed.

Because of their high accuracy, they are often used as a primary reference for the calibration of other sensors, like accelerometers. In addition, these techniques are effectively used in structural dynamic testing, biological and clinical diagnostics, fluid-structure interaction, online monitoring of industrial plants, acoustics, and fault detection, to cite only a few. Furthermore, the coupling of laser vibrometers and scanning systems seems to open up new possibilities, e.g., in the field of measurements in tracking mode on moving objects.

Laser Doppler Vibrometry Technique

The Doppler Effect

The laser Doppler vibrometer is a noncontact velocity transducer, based on the analysis of the Doppler effect on a laser beam emerging from a solid surface.

When a coherent radiation of frequency f (Figure 1A), emitted by a source S , interacts with a reflecting or diffusing moving surface P at velocity v , the radiation observed by O is affected by a Doppler shift Δf_D proportional to the surface velocity.

If, as usual (Figure 1B), the position of the source and of the observer are coincident (back-scatter configuration), such a frequency shift is given by:

$$\Delta f_D = \frac{2v}{\lambda} \cos \theta \quad [1]$$

The corresponding phase shift is given by:

$$\Delta\phi = \frac{4\pi d}{\lambda} \cos \theta \quad [2]$$

where $d(t) = \int_0^t v(\tau) d\tau$ is the displacement of the target surface.

In general, if the target moves at a speed $v(t)$ varying in time, the phase (and frequency) difference becomes time-dependent.

The Laser Doppler Vibrometer

If a He-Ne ($\lambda = 632.8$ nm) laser is used for the measurement of a velocity of 1 m s^{-1} , the frequency $f = 4.7 \times 10^{14} \text{ Hz}$ is shifted $3.16 \times 10^6 \text{ Hz}$. A dynamic range of about 6.7×10^{-9} (164 dB) is required for detection. Under the same conditions, the phase shift observed for a displacement of $1 \mu\text{m}$ is about 6.321π .

The interferometric approach can be used in order to measure such a relatively small frequency shift and to have a reference in the phase assessment. Usually a laser beam is split in two, with one beam acting as a stationary reference (reference beam) while the other

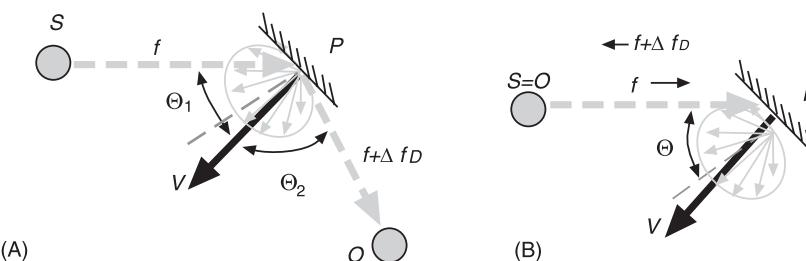

Figure 1 The Doppler effect on a scattering surface.

beam is directed to a vibrating surface (measuring beam).

If the intensity of the resulting field is measured using a photodiode with square-law response and with heterodyning efficiency ε (which is a parameter taking into account degradation of the AC current for optical distortions and misalignment and depends on intensities, coherence, and polarization, as discussed in the following paragraphs), the output signal is:

$$\begin{aligned} I(t) &\propto A_m^2 + A_r^2 + 2\varepsilon A_m A_r \cos\left(2\pi \frac{2\nu(t)}{\lambda} \cos \theta t\right) \\ &= A_m^2 + A_r^2 + 2\varepsilon A_m A_r \cos\left(\frac{4\pi d(t)}{\lambda} \cos \theta\right) \end{aligned} \quad [3]$$

where A_m, A_r are the amplitudes of electric field of light (measurement and reference). The third addendum is the only one related to displacement or velocity, therefore with an AC coupling the other components are eliminated.

When observing eqn [3] it is possible to note that the AC part of the $I(t)$ function is odd with respect to velocity and therefore the same intensity corresponds to velocities with opposite direction. Such ambiguity in the direction assessment can be eliminated in different ways depending on the optical and electronic set-up (see below).

In order to extract the information on the required component of velocity, different interferometers and different demodulation techniques can be used depending on specific requirements and applications. A review of the main instruments based on such phenomena is reported.

Basic Interferometer Configurations

The so-called single-point vibrometer, the first developed and the most diffused vibrometer, is basically an axial vibrometer, i.e., an instrument which is able to measure displacement and velocity in the direction of its optical axis.

Different interferometer configurations can be employed in such an instrument. In particular, the most widely used are the Michelson and the Mach-Zehnder interferometers.

In Figures 2 and 3 a scheme of the different interferometers is shown.

The basic interferometer design is that of Michelson. A linearly polarized laser (usually a He-Ne oriented at 45°) beam is split by a polarizing beam-splitter, PBS2. Both reflected and transmitted beams are back-reflected along the same paths by a mirror (reference beam) and by a reflecting or scattering surface (measurement beam) on the target.

Along the optical path both beams encounter twice (before and after reflection/diffusion) a $\lambda/4$ plate. Therefore, due to the orthogonal polarization obtained, the beam splitter BS1 deviates both beams at the photodiodes where interference occurs.

If the target is moving, the optical path is continuously changing and dark and bright fringes appear to the observer.

In the Mach-Zehnder interferometer the same effect is obtained with a different optical arrangement. The first polarizing beam-splitter (PBS1) splits light (linear 45° polarized) from the source and reflected and transmitted beams run parallel to each other. A lens collects the measurement beam, interacting with the scattering surface on the target. A $\lambda/4$ plate rotates the polarization plane 90° and then the

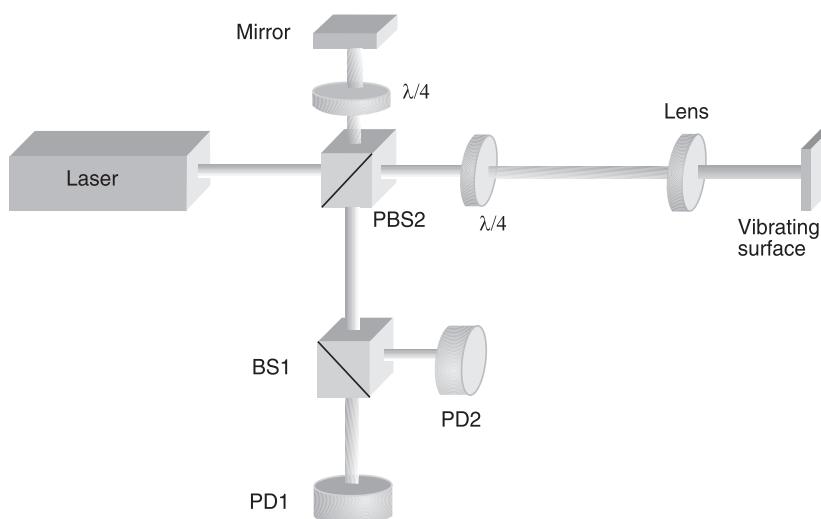

Figure 2 Scheme of a single-point vibrometer based on a Michelson interferometer.

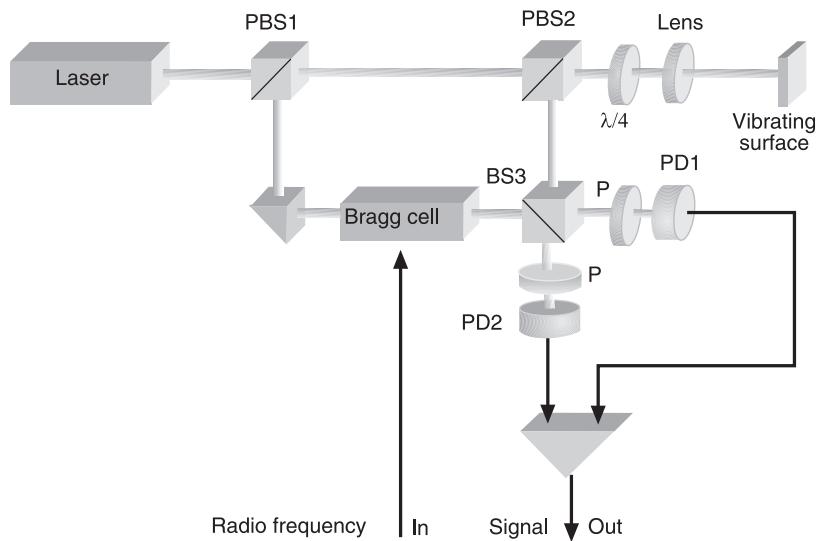

Figure 3 Scheme of a single-point vibrometer based on a Mach-Zehnder interferometer.

beam is deviated by the polarizing beam-splitters PBS2. On BS3, the measurement beam interacts with the reference beam, shifted by the Bragg cell, and it is observed by photodiodes PD1 and PD2.

In each case the observer can be composed by a single photodiode or by two photodiodes which are optically coupled by a beam-splitter (as shown in Figure 3). Thus it is possible to obtain two signals, corresponding to the destructive and constructive interference.

Such a solution can be used for different purposes. In particular, the Mach-Zehnder interferometer usually allows there to be two opposite signals for each interference condition. In fact, the different number of reflections in the optical path to PD1 and PD2 induces coupling of laser beams with different phases, and therefore a destructive interference on PD1 and a constructive interference on PD2 at the same time. Noises are usually not sensitive to such a phenomenon and have the same phase in both photodiodes. The difference between such signals presents a good improvement of the signal-to-noise ratio, due to common-mode noises rejection.

Frequency Shifting Devices for Direction Ambiguity Elimination and Signal-processing Scheme

As previously shown, due to the interferometer design and the sensitivity of photodiodes to light intensity, the resultant signal from photodiodes is not sensitive to the direction of the target velocity vector, and it does not allow a complete analysis of the target velocity history.

The direction ambiguity can be eliminated in different ways. An electronic approach is used with Michelson schemes, where the signal from photodiodes is at a frequency of Δf_D , fluctuating from zero to the maximum modulus of the velocity. In this case two carriers multiply sinusoidal and cosinusoidal signals (with a frequency f_{Shift}) from PD1 and PD2. The carriers, with a frequency f_c depending on the frequency range to be analyzed, are shifted 90° from each other, in order to obtain a sine and a cosine. The sum of such signals gives a modulated signal frequency, which is sensitive to velocity direction. The signal is then demodulated to obtain the velocity information.

The classical solution is the introduction of an additional modulation of the laser beam in the measurement or reference path. In fact, a modulation frequency modifies the total frequency seen by the detector, adding a virtual velocity, to:

$$\Delta f_{\text{TOT}} = \Delta f_{\text{Shift}} + \Delta f_D = \Delta f_{\text{Shift}} + \frac{2v}{\lambda} \quad [4]$$

The resultant frequency signal depends on the velocity direction and, in particular:

$$\begin{aligned} \Delta f_{\text{TOT}} &> \Delta f_{\text{Shift}} \text{ if } v > 0 \\ \Delta f_{\text{TOT}} &< \Delta f_{\text{Shift}} \text{ if } v < 0 \end{aligned} \quad [5]$$

Such a shift can be obtained in different ways. The most interesting seems to be acoustooptic modulators – the most used solution – and, in particular, Bragg cells.

The signal obtained from a photodiode can be processed in different ways in order to extract the information from the interference signal.

Depending on the optical arrangement of the interferometer, a heterodyne or homodyne signal is obtained. In addition the analysis strategies can be devoted to velocity or displacement assessment.

The choice between the two approaches depends on the kind of information requested and induces important effects on signal quality.

The heterodyne interference is realized when the frequency shift technique is applied to obtain velocity ambiguity resolution, as in the Mach-Zehnder. In that case, the signal from photodiodes is at frequency $f_{\text{Shift}} + f_{\text{Doppler}}$, which is usually in the range of 40 MHz.

The demodulation of such a radiofrequency signal can be performed using the same technology developed in signal transmission. For this reason radio-based chips are frequently used for this purpose, but for vibration application a more complex technique seems to be required. Therefore this demodulation is realized basically as a down-mixing of interference signal with the reference signal driving the Bragg cell. Such a signal, with a sensitivity and linearity which are optimized in several ranges of decoding, is then filtered depending on the frequency range chosen, in order to obtain the velocity signal. To this basic structure, usually smarter filtering strategies (such as amplifiers, signal conditioners, tracking filters, Butterworth filters, etc.) are added, in order to improve the signal-to-noise ratio.

In addition, the signal analysis can be devoted to displacement assessment. When a displacement d of the target surface occurs, a path length variation $2d$ in the arm of the interferometer corresponds, and the interference signal presents a phase shift (see eqn [2]), given by:

$$\Delta\phi = \frac{4\pi d}{\lambda} = 2\pi N \quad [6]$$

For a direct evaluation of surface displacement it is sufficient to count the number N of fringes, i.e., of constructive and destructive interference, each one corresponding to a displacement of half of the wavelength λ . Digital counters usually perform this purpose.

Scanning Laser Doppler Vibrometer

The SLDV was invented in 1981, while modifying a laser Doppler sensor. An SLDV is basically a sensor equipped with a scanning device and data acquisition and processing system, where the sensor is a laser Doppler single-point vibrometer, as previously discussed.

The peculiar part of a SLDV is the scanning system that directs the laser beam by means of two moving mirrors. By adding coordinate control using scanning mirrors, a single-point vibrometer sensor can be used to scan across a surface, gathering multipoint data from large vibrating objects. A possible arrangement, which can be used to carry out the scanning, is shown in Figure 4.

To aim the measuring beam at specified locations, two voltages have to be applied to the galvanometric controllers (motors), so that the scanning mirrors rotate at the desired angles. This is only accurately obtained if the spatial relationship between the test structure and the SLDV system is precisely determined. In order to define uniquely a position on the test object, calibration must be performed by directing the laser spot to specified calibration points. This operation makes it necessary to use a computer in order to perform the scanning control automatically, which dramatically reduces the time required for the measurement tests.

One of the features, which turned out to be extremely helpful in calibration and application of the SLDV, was an integral video camera. This solution allows the operator to monitor the location of the laser beam on the test item (Figure 5) and to overlay the measured results on an image of the test item. This solution is adopted by most manufacturers of laser Doppler vibrometers. Different arrangements can be designed.

In-plane Vibrometer

The in-plane vibrometer measures the velocity component perpendicular to its optical axis and therefore

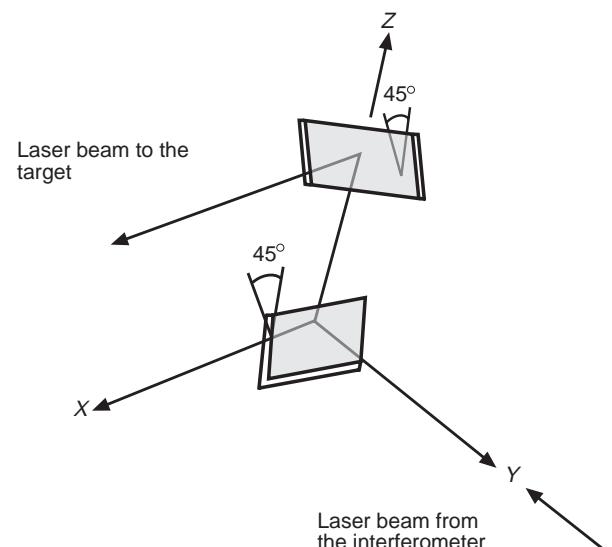

Figure 4 Scheme of a possible layout of a scanning system.

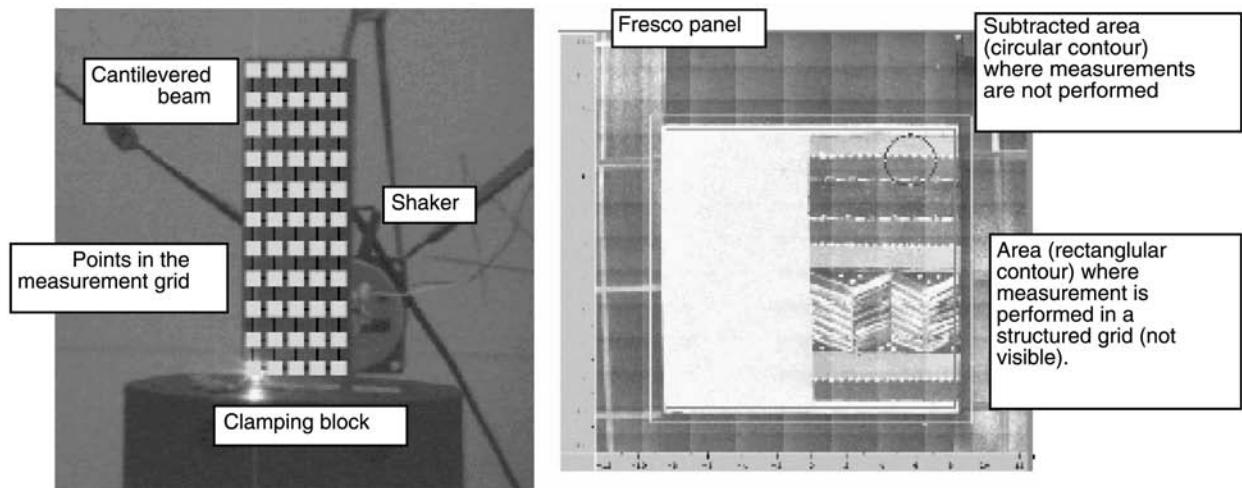

Figure 5 The measurement area in two different scanning laser Doppler vibrometer (SLDV) systems.

can be utilized to determine experimentally in-plane or tangential vibrations. Its functioning is based on the interaction between the surface roughness and the interference fringes area formed in correspondence with the intersection of two laser beams (Figure 6). The determination of the velocity value occurs by Doppler effect in the scattered light, which is collected by the optics to the photodetector.

If λ is the laser wavelength and θ is the angle between the two beams, the relation between the in-plane velocity v and the measured Doppler shift Δf_D is:

$$v = \frac{\lambda/2}{\sin(\theta/2)} \Delta f_D \quad [7]$$

The measurement volume usually has an ellipsoidal shape and consists of the interference fringe area where an optical heterodyne phenomenon is produced. The introduction of a Bragg cell induces an optical frequency shift in one beam. The nonstationary fringe pattern obtained allows one to eliminate direction ambiguity. Usually a laser diode (670–690 nm, 25 mW), stabilized in temperature by a

Peltier cell, is used in a back-scattering configuration. A tension signal proportional to velocity is obtained through a frequency–voltage converter.

Typical performances are a bandwidth from 0 to 10 kHz and a velocity range up to 100 m s^{-1} DC. The typical calibration accuracy is about $\pm 0.5\%$.

Rotational Vibrometer

Rotational vibrometers permit the measurement of rotational speed and the analysis of torsional vibrations, also under operational conditions, with a simple and noncontact set-up. They are based on the design shown in Figure 7 to measure the angular velocity optically.

In general, each point on the perimeter of a rotating part of any shape has a tangential velocity v_t depending on the rotational radius R and on the angular velocity ω . As shown below, it is possible to determine the angular velocity ω by measuring two parallel translational velocity components (Figure 7).

Two interferometers with parallel measurement beams with separation d are used and the velocity components v_A and v_B in the direction of beams are acquired. The following formula is obtained for the Doppler frequency shift in rotational vibrometers:

$$\begin{aligned} f_D &= f_{DA} + f_{DB} = \frac{2v_A}{\lambda} + \frac{2v_B}{\lambda} \\ &= \frac{2}{\lambda} \omega (r_A \cos \varphi_A + r_B \cos \varphi_B) = \frac{2}{\lambda} \omega d \end{aligned} \quad [8]$$

which therefore only depends on the vibrometer constructive parameters (d and λ) and on the angular velocity ω .

It is evident that an additional translational motion in the direction of measurement beams, overlapping

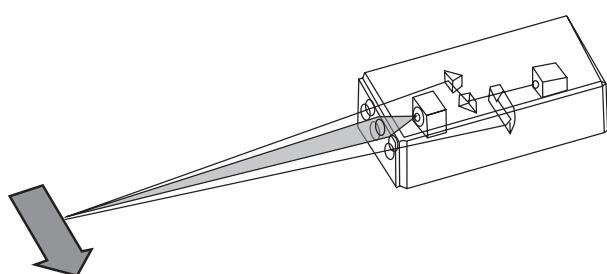

Figure 6 Optical scheme of the in-plane vibrometer.

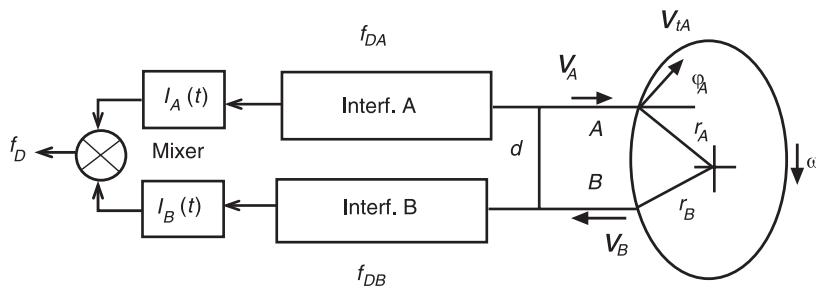

Figure 7 Scheme of the rotational vibrometer measurement principle.

both velocities v_A and v_B , has no influence on the resulting Doppler frequency. Also a vertical translation, as a motion perpendicular to the measurement beams, cannot create a measurement effect and therefore this technique seems to be basically insensitive to translational movements. It appears also to be insensitive to bending motions of the rotating object not in the plane of beams, as long as such motions do not add different velocities at the two measurement points. The only measurement requirement is that the laser beam plane must be perpendicular to the system's rotation axis. If this does not happen, only the component $\omega \cos \beta$ of the angular velocity is measured, where β is the angle between the beam plane and the shaft axis. No particular surface preparation is usually required.

Typical velocity range is from -7000 to $11\,000$ rpm up to 1000 rad s $^{-1}$. The frequency range in vibrational angle measurement is from 1 Hz to 10 kHz. The typical calibration accuracy is about $\pm 0.5\%$.

Surface Characteristic Effects: The Speckle Noise

One of the most important problems and noise sources in every kind of laser Doppler vibrometer is the effect of the speckle. The speckle is the interference image generated when a beam of coherent light interacts with a rough surface. Waves constituting the beam are diffused by the surface and interfere, generating a distribution of light intensity found by dark and bright zones, due to destructive and constructive interference. The superposition of the interference pattern with the desired light signal, containing the Doppler frequency, introduces uncertainty in the demodulation procedure, where the velocity information is carried out. The consequence of speckle noise is represented by momentarily signal drop-out (spikes) typical in a LDV output (Figure 8).

In general, interfering inputs due to speckle are caused by in-plane velocity components of the measurand surface: the change in the local roughness

shape induces a sort of motion in the speckle pattern. There are many cases of technical interest, where it is necessary to measure the orthogonal vibration component of a surface, which is also moving tangentially (e.g., flexural vibrations of shaft and rotating disks) and therefore the study of speckle phenomena becomes important.

Interesting results in this field can be achieved using tracking filters. A tracking filter works by analyzing the instantaneous phase of the radiofrequency signal and generating a sinusoidal waveform according to the original one. The effect obtained is similar to a low-pass filter, but with a more effective result and better agreement with the input signal.

Also on the demodulated signal (i.e., the vibration velocity signal) it is possible to apply different algorithms for drop-out elimination, like the tracking filter itself; however, usually a band-pass or low-pass filter is applied. Such a simple filter allows better control of a performed test, as it is easy to set, and introduces more predictable signal-processing effect.

Applications

Due to the sensitivity, accuracy, and versatility of LDVs, different systems based on this principle are now in widespread use for a broad range of applications. In fact, these systems were applied not only in mechanics, the traditional field of application of vibration measurement techniques, but also where other techniques demonstrate important limits.

An example of those fields is represented by damage detection methods, where promising results have been found in the analysis of delaminations in frescos and composite materials. Damages in such structures are very localized and do not modify global modal properties of the object, inducing only local vibration modes: therefore, it is critical to investigate both cases by contact techniques, such as accelerometers, since they are very light, highly damped, and delicate, with important modes up to 100 kHz.

In addition, the portability of LDV systems offers a unique possibility of in-field tests, without complex

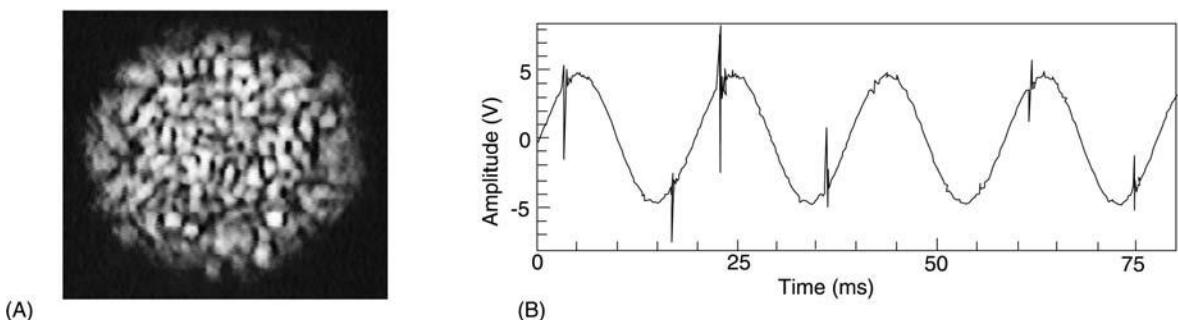

Figure 8 (A) Speckle pattern and (B) drop-out induced by optical noises in a sinusoidal velocity signal.

and costly installations, and makes it possible to operate directly where the structure is usually working or installed.

A large number of applications in the field of system identification of light or very small structures have been developed, thanks to the noncontact nature of LDV measurements. It is well known that the effects of mass loading due to accelerometers is often also significant in large or rigid structures. When mass or dimension of the measurand is comparable to those of the transducer, this effect becomes important. Interesting results have been found in the characterization of hard disk drives or in the study of tire vibrations.

The capability of SLDV to measure, quickly and in an automatic way, the velocity at a very large number of points is very useful in updating methods of the finite element model, in particular for the analysis of the high-frequency range. Furthermore, the recent availability of systems which are able to plot the measurement points on a geometrical spatially defined three-dimensional grid for modal analysis has extended this possibility. However, it has also stressed the need for accuracy when determining the relative position and orientation between laser head and test structure.

Boundary element models or superimposition methods were applied, starting from high-density data (amplitude and phase information of vibration pattern), given by SLDV in order to predict the acoustic emission of vibrating surfaces.

The versatility and ease of installation and control allow Doppler systems to be used in several industrial applications and quality control systems. In the car industry LDV has been proposed to analyze the behavior of mechanical and structural components, such as a window lift system. In quality control, laser Doppler sensors have been employed at the bench for automatic testing and selection of washing machines at the end of the production line. Data obtained during operating conditions have been analyzed using neural network algorithms.

Another interesting application is vibration measurement across a flame (e.g., in the inner surface of a burner). This is a typical case where noncontact measurement techniques are the only possible solution. In fact, because of the high temperature, conventional techniques (e.g., accelerometers, strain gauges, etc.) cannot be applied without damaging the instruments; the same restriction applies to non-contact devices which must be placed close to the measured surface (e.g., eddy current proximity sensors, etc.). Among the different noncontact remote optical measurement techniques, LDVs may be usefully employed for this application, but interactions between laser beam and flame must be carefully considered.

Finally, a field which is demonstrating an increasing interest in laser Doppler techniques is biomedical engineering, in particular for vibration measurement and analysis of different human body parts or conditions. The problems of vibration transmission from the grip of tractors or power tools to the human hand-arm system were analyzed in real case studies. Other researchers investigated problems related to bit-and-teeth structure, stressed when high rotational velocity drills or ultrasound devices are used in a dentist practice, or as a tool for evaluating degree of tooth mobility. Middle-ear ossicles and tympanic membrane vibrations in sound simulation have also been studied using laser techniques.

Other Non-Doppler Measurement Techniques

Interesting performances have also been facilitated by laser-based optical non-Doppler sensors, like optical proximity sensors and triangulation sensors.

The former, usually made up of a bundle of optic fibres from which light is emitted and received, can potentially be employed to measure vibration displacement, since they are able to detect micrometric movements to a frequency of 50 kHz. One

problem in their practical use is the need for static calibration on the surface, which will reflect the sensor's light.

Triangulation devices are displacement sensors, which cost about one-tenth of a vibrometer, with both static and dynamic performances within a range of interest for vibration analysis of mechanical systems. The triangulation sensor is based on a simple geometrical principle. A class II laser source, usually with a wavelength of 670 nm, is focused on the target surface, in points A' or A of Figure 9, depending on the target distance. The spot diameter is usually about 140–230 μm .

A position-sensing detector collects the light difused by the target. Triangulation relation directly correlates the position of the spot centroid in the position-sensing detector with the distance z . The value of the distance z between the sensor and the target can be obtained by:

$$z = \frac{(OC \cdot BO \cdot \cos \gamma)}{B'B + BO \cdot \sin \gamma} \quad [9]$$

where $B'B$ is the measured quantity and γ is defined as in Figure 9.

The typical bandwidth is from static displacement to about 60 kHz, with a range varying from ± 0.25 to ± 100 mm depending on the sensor configuration, resolution from 0.1 to 60 μm and linearity error from 2 to 600 μm .

In addition such a sensor uses laser not as a coherent source of radiation, but simply as a collimated light. Such a condition allows one to reduce the sensitivity of the sensor to noises related to phase decorrelation of the light, like the speckle effects.

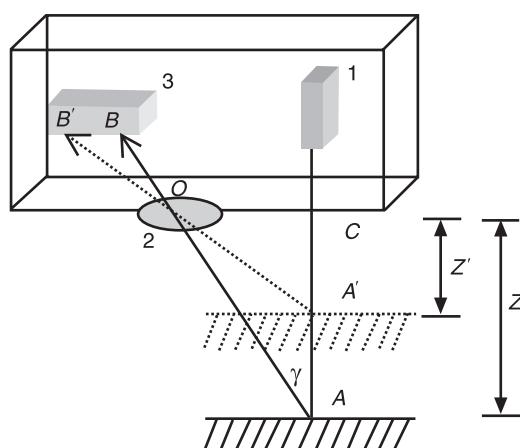

Figure 9 Elements of geometric optics for the assessment of z in a triangulation sensor: 1, laser source; 2, optics; 3, position-sensing detector.

Therefore the sensor works accurately to measure axial vibration when a tangential motion is also present: vibration measurement of a translating object with Eulerian approach becomes easier. Furthermore, triangulation is most robust to optical troubles and it is easier for the user to assess uncertainty sources.

The main problem is related to the reduced versatility of the sensor, mainly due to the fixed distance at which the sensor should work. Furthermore, since this instrument measures displacement, this quantity has reduced amplitude in the high-frequency range.

Full-field Measurement Techniques

In the field of optical techniques for vibration analysis, good alternatives to laser vibrometers, and in particular to SLDV, are two other techniques based on interferometric effect: the laser holography and ESPI.

Such techniques offer some advantages with respect to other solutions, due to their whole-field capability, i.e., the possibility to obtain noncontact information at several points at the same time. This offers an interesting opportunity to obtain static or dynamic information on the behavior of every point of the structure in a fast way. In addition, the whole-field approach gives a direct image of the vibration in test conditions (i.e., the mode shapes).

Depending on different techniques, the particular optical configuration may be different.

The measurement chain for holographic interferometry is shown in Figure 10A.

A pulsed laser source is used to generate a laser beam divided in two parts by a beam-splitter. The measurement arm illuminates the object, while the second arm is directly sent on the recording plate, usually composed of photographic or thermoplastic film.

The recording plate also receives the light difused by the investigated object. Therefore, an interference image is generated on the plate, containing the information relative to the three-dimensional shape of the object. This information is received as each light wavefront, diffused by the different portions of the object surface, reaches the plate by a different optical path length and thus with a different phase. The phase depends on the spatial positions of the diffusing portions and, as a consequence, on the three-dimensional shape.

In order to extract the three-dimensional shape from the impressed plate, another step is required using the experimental set-up shown in Figure 10B. Here the holographic image is reconstructed by diffraction, illuminating the plate with just the reference beam. In this case the interference image, previously recorded on the plate, acts as a diffraction grid, where

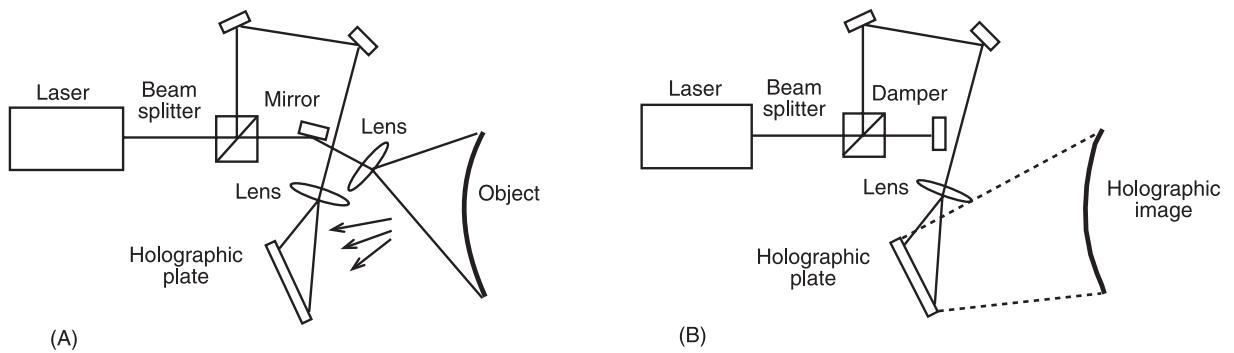

Figure 10 Scheme of system for holographic image recording (A) and reproduction (B).

the grid dimensions depend on the interference pattern. The holographic image, reconstructed where the test object was previously positioned, can be acquired using a video camera and digitally transferred to a PC.

The above measurement chain can be used for both static (shape), quasistatic (deformation) and dynamic (vibration) measurements. Two or more consecutive images of the vibrating object are recorded on the plate, where they interfere, creating a pattern which is in proportion to the variation of the object shape between the two pulses, which in practice is the mode shape. A time delay between pulses is set according to the frequency of the mode of interest, when the object must be sinusoidally excited.

Further to the multiexposure technique, time-averaging techniques can also be employed, using a longer illumination time. In this case, the result is an average of the displacement amplitude at the different points of the vibrating structure.

In order to obtain a full-field technique that is more practical, i.e. based on digital recording devices with a relatively low resolution, the ESPI has been developed in the last 10 years.

In Figure 11 the optical arrangement of an ESPI system is shown. In the measurement chain a couple of beam-splitters are used. The first one allows one to split the beam into two arms: the measurement one, which is expanded by a lens in order to illuminate the target object, and a reference one. The reference beam is reflected by a mirror, moved by a piezo-actuator for the control of the phase, and interferes in the second beam-splitter with the light scattered by the target surface and collected by an objective. The low-aperture objective is needed to generate the speckle pattern, which can be observed by a low-resolution camera.

This set-up allows one to acquire directly the image obtained by interference between the speckle pattern and the reference wave.

A reference image is first acquired, digitized, and stored. The subsequent images of the vibrating object are acquired at different phase values and digitally

compared, by subtraction, with the first one. Contiguous points, characterized by the same displacements, produce loci of black speckles that appear as fringes and can easily be observed as isodisplacement lines of the operational mode shape (as shown in Figure 11).

In order to improve the visibility of fringes, the phase shift method can be applied. The phase of the reference wave can be controlled by a mirror driven by a piezoelectric actuator, in such a way as to superimpose a phase shift of π to the subsequent acquired images. Subtracting the images, the common mode noise and the background light are rejected and the signal-to-noise ratio of the measurement is substantially improved. This technique can be used, together with traditional methods for signal enhancement (e.g., averaging a significant number of measurements), in order to obtain better results, in particular for automatic postprocessing based on image analysis.

This kind of system is affected by the same optical problems of laser interferometry as speckle effect, due to additional in-plane motions and surface scattering capability. However, main limits seem to be due to the need for single-frequency excitation, which reduces the in-field applicability for the measurement of operational deflection shapes, and for knowledge of the amplitude of vibration in a reference point, in order to have quantitative results.

In addition, the technological limits of employed electronics should be considered, e.g., concerning spatial resolution, but scientific improvements in this field seem to be very quick and promising.

Finally, it is interesting to compare these performances with those offered by SLDV. In fact, while the full-field techniques are based on a contemporary analysis of the whole structure, the SLDV, which is based on sequential measurements on each point of the target, allows one to improve both spatial resolution and frequency band with nonsinusoidal excitation, as in traditional modal analysis or in operating conditions. Therefore, when it is possible to excite

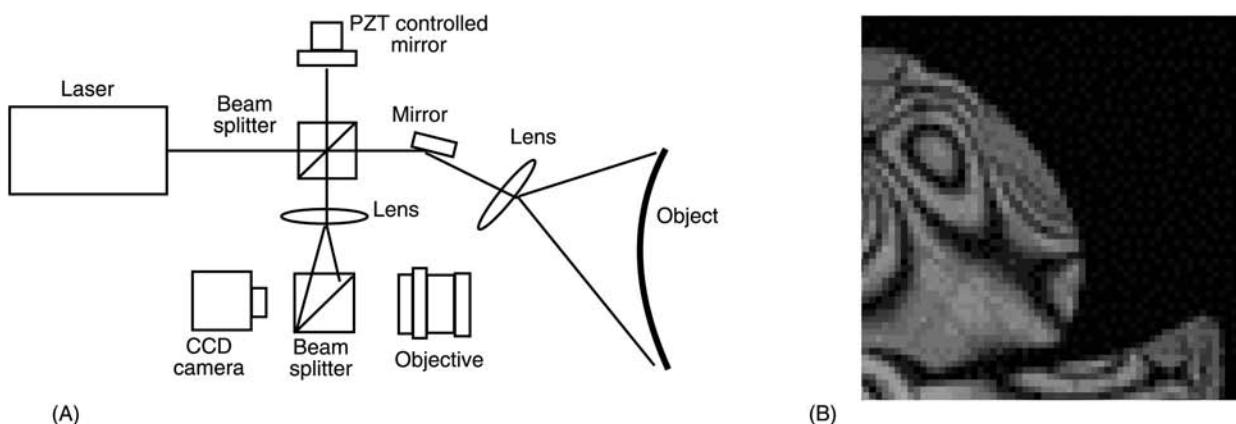

Figure 11 (A) Scheme of electronic speckle pattern interferometry (ESPI) system and (B) an example of a mode shape described by isodisplacement lines.

stationary or repeatable vibrations on the structure (as frequently happens), SLDV allows higher performances.

In contrast, in some practical problems, as in the vibration analysis for disk brake squeeze, it is quite difficult to obtain stationary and repeatable conditions or to have a reference signal for synchronous and nonsynchronous phenomena. In such cases, the whole-field techniques offer a more natural and convenient approach, obtaining direct information of the relative amplitude and phase of vibration at different points of the analyzed structure.

Nomenclature

A	amplitude
f	frequency
v	velocity
Δf_D	Doppler shift
ε	efficiency
λ	wavelength
ω	angular velocity

doi:10.1006/rwvb.2001.0003

Solving linear systems of equations is at the heart of most computational analysis methods. In order to compute a solution accurately and fast, the method for solving those systems must be chosen according to:

- the properties of the matrix operator (i.e., symmetry, definite positiveness, singularity and sparsity)
- the size of the system (from a few unknowns up to several millions)
- the numerical conditioning of the system of equations
- its capability to efficiently handle multiple right-hand sides
- the burden of its implementation
- its ability to run on vector or parallel computers.

Although a large variety of problems encountered in practice involve symmetric definite matrices, some

important cases require the solution of singular systems (e.g., analysis of floating structures), nondefinite systems (harmonic analysis or constrained systems) and nonsymmetric systems (coupled problems and nonlinear systems).

In what follows, we will assume that all matrices are real in order to outline the basic ideas in a simple manner. Nevertheless, the concepts described here can be extended to complex matrices.

Solving Nonsingular Linear Systems

Solution methods are usually classified as iterative or direct methods. Direct solvers (i.e., factorization techniques) yield an exact solution (that is up to the round-off errors due to the finite precision of computers) after a predictable number of operations. Iterative methods typically involve an evaluation of the action of the system matrix on trial vectors (matrix-vector multiplication) and yield an approximate solution whose accuracy improves as the number of iterations grows. The latter methods were devised to handle large systems at a time when powerful computers did not exist and thus, when factorization of large matrices was not an option.

Iterative schemes usually do not exhibit good robustness when applied to real-life problems. Therefore, direct solution methods have been widely favored in engineering codes. In this text, only direct methods will be discussed. Nevertheless, the reader should be aware that iterative or semi-iterative techniques have regained tremendous popularity, thanks to recent innovative algorithmic developments, to their lower storage space requirement and finally because of their natural ability to exploit efficiently vectorial and multiprocessing capabilities of modern supercomputers.

We assume that the number n of unknowns is equal to the number of equations in the system so that the linear system takes the general form:

$$\mathbf{Ax} = \mathbf{b} \text{ or } \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \\ a_{n1} & \dots & & a_{nn} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{bmatrix} \quad [1]$$

We further assume that the square matrix \mathbf{A} is non-singular, which implies that a unique solution exists for \mathbf{x} . The case where \mathbf{A} is square but singular, or rectangular will be discussed later.

Nonsymmetric Systems: the LU Factorization

The most natural method that comes to mind for solving a system as in eqn [1] consists in recasting the first equation as:

$$x_1 = \frac{1}{a_{11}}(b_1 - a_{12}x_2 - \dots - a_{1n}x_n) \quad [2]$$

so that x_1 can be eliminated from all subsequent equations by substitution of eqn [2]. Repeating the process for x_2 in the second equation and so on leads to a sequence of transformed equations, the last of which yields x_n . Substituting back the value of x_n into the transformed equation $n - 1$ then yields x_{n-1} and substituting further into the transformed equations yields $x_{n-2} \dots x_1$ recursively. This procedure can also be understood as building linear combinations of the original equations so as to bring matrix \mathbf{A} to an upper triangle form as follows.

Assuming that $x_1 \dots x_{k-1}$ have already been eliminated, the operator of the transformed system is as in Figure 1. Step k then consists in transforming equations $k + 1 \dots n$ by adding a linear combination of equation k so as to zero the coefficients of x_k . Hence, if \mathbf{U} and $\tilde{\mathbf{b}}$ are initially set to \mathbf{A} and \mathbf{b} , respectively, every row i below k becomes:

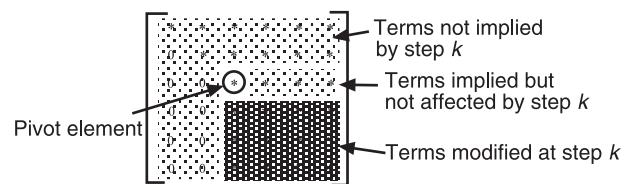

Figure 1 Gauss elimination: transforming \mathbf{A} into an upper triangular form \mathbf{U} .

$$u_{ij} \leftarrow u_{ij} - l_{ik}u_{kj} \quad i, j = k + 1, \dots, n \quad [3]$$

$$\tilde{b}_i \leftarrow \tilde{b}_i - l_{ik}\tilde{b}_k \quad [4]$$

where:

$$l_{ik} = \frac{u_{ik}}{u_{kk}} \quad [5]$$

in order to zero u_{ik} , $i = k + 1 \dots n$. After $n - 1$ steps, \mathbf{U} is an upper triangular matrix. The solution is then found by backward substitution first for x_n , then for x_{n-1} and so on:

$$x_i = \frac{1}{u_{ii}} \left(\tilde{b}_i - \sum_{j=i+1}^n u_{ij}x_j \right) \quad i = n, n-1, \dots, 1 \quad [6]$$

The algorithm described above is known as a Gaussian elimination and can be viewed as transforming \mathbf{A} into a product of a lower triangular matrix \mathbf{L} and the upper triangular matrix \mathbf{U} , i.e.:

$$\mathbf{A} = \mathbf{LU} \quad [7]$$

where, according to eqn [3], \mathbf{L} has a unit diagonal ($l_{ii} = 1$) and its lower triangular coefficients are l_{ik} directly obtained from the elimination process. The direct solution procedure can thus be summarized as follows:

- Factorize $\mathbf{A} = \mathbf{LU}$, eqns [3] and [5], so that the system is

$$\mathbf{L}\mathbf{U}\mathbf{x} = \mathbf{L}\tilde{\mathbf{b}} = \mathbf{b} \quad \text{where we define } \tilde{\mathbf{b}} = \mathbf{U}\mathbf{x} \quad [8]$$

- Solve successively the triangular systems

$$\mathbf{L}\tilde{\mathbf{b}} = \mathbf{b} \quad [9]$$

$$\mathbf{U}\mathbf{x} = \tilde{\mathbf{b}} \quad [10]$$

Solving eqn [9] corresponds to transforming the right-hand side as in eqn [4] and is called forward substitution whereas solving eqn [10] is a backward substitution as defined by eqn [6].

The factorization of the matrix requires of the order of $2n^3/3$ operations, while the forward and backward factorizations each involve of the order of n^2 operations. If the system must be solved for multiple right-hand sides, the factorization only needs to be performed once, and one forward and backward substitution must be performed for every right-hand side.

Example

$$\mathbf{A} = \begin{bmatrix} 1 & 2 & 3 \\ 1 & 1 & 2 \\ 1 & 0 & -1 \end{bmatrix} \xrightarrow{k=1} \underbrace{\begin{bmatrix} 1 & 2 & 3 \\ 0 & -1 & -1 \\ 0 & -2 & -4 \end{bmatrix}}_{L_1} \quad \Rightarrow \quad \xrightarrow{k=2} \underbrace{\begin{bmatrix} 1 & 2 & 3 \\ 0 & -1 & -1 \\ 0 & 0 & -2 \end{bmatrix}}_{L_2}$$

$$\Rightarrow \mathbf{LU} = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 2 & 1 \end{bmatrix} \begin{bmatrix} 1 & 2 & 3 \\ 0 & -1 & -1 \\ 0 & 0 & -2 \end{bmatrix}$$

Remarks At step k of the elimination, the diagonal element u_{kk} is called a pivot (Figure 1) and must be nonzero in eqn [5]. In order to have a nonzero pivot and to ensure numerical stability of the elimination, it is required to apply permutations on the rows and columns so to bring on the diagonal k the element of highest modulus of the submatrix yet to be triangularized. This procedure is called pivoting. The factorization is then expressed as:

$$\mathbf{P}_1 \mathbf{A} \mathbf{P}_2 = \mathbf{LU} \quad [11]$$

where \mathbf{P}_1 and \mathbf{P}_2 are permutation operators related to the pivoting of the rows and columns, respectively. If only the rows are reordered, the procedure is known as partial pivoting. Since permutation matrices are identity matrices with reordered rows:

$$\begin{aligned} \det(\mathbf{A}) &= \pm \det(\mathbf{P}_1 \mathbf{A} \mathbf{P}_2) = \pm \det(\mathbf{L}) \det(\mathbf{U}) \\ &= \pm \det(\mathbf{U}) = \pm \prod_{k=1}^n u_{kk} \end{aligned}$$

Therefore one is guaranteed to find a nonzero pivot if pivoting is applied and if \mathbf{A} is nonsingular.

In order to minimize memory requirements, the initial matrix \mathbf{A} is usually overwritten by the coefficients of \mathbf{U} and \mathbf{L} , it being understood that the unit diagonal of \mathbf{L} need not be stored.

The elimination algorithm can be rearranged in several different ways. In particular, rewriting eqn [1] in the block partitioned form:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \end{bmatrix} \quad [12]$$

one can use the first set of equations to eliminate the set of unknowns \mathbf{x}_1 in a way similar to eqn [2], i.e.:

$$\mathbf{x}_1 = \mathbf{A}_{11}^{-1}(\mathbf{b}_1 - \mathbf{A}_{12}\mathbf{x}_2) \quad [13]$$

where \mathbf{A}_{11} is assumed to be nonsingular. Substituting eqn [13] into the partitioned form eqn [12] yields the block triangular form:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ 0 & \mathbf{A}_{22} - \mathbf{A}_{21}\mathbf{A}_{11}^{-1}\mathbf{A}_{12} \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 - \mathbf{A}_{21}\mathbf{A}_{11}^{-1}\mathbf{b}_1 \end{bmatrix} \quad [14]$$

This last equation should be compared to \mathbf{U} in Figure 1. The lower diagonal block $\mathbf{A}_{22}^* = \mathbf{A}_{22} - \mathbf{A}_{21}\mathbf{A}_{11}^{-1}\mathbf{A}_{12}$ is the matrix \mathbf{A} when the unknowns \mathbf{x}_1 have been condensed out. If \mathbf{A} is a stiffness matrix, \mathbf{A}_{22}^* represents the stiffness operator coupling the variables \mathbf{x}_2 when \mathbf{x}_1 are left free. To mathematicians, \mathbf{A}_{22}^* is known as the Schur complement of \mathbf{A} for \mathbf{x}_2 . The blocks $\mathbf{A}_{11}^{-1}\mathbf{A}_{12}$ and $\mathbf{A}_{11}^{-1}\mathbf{b}_1$ in eqn [14] can be computed by factorizing \mathbf{A}_{11} and performing forward and backward substitutions for \mathbf{A}_{12} and \mathbf{b}_1 . The factorization of \mathbf{A} is then completed by factorizing \mathbf{A}_{22}^* . Applying this idea successively to several blocks, one can device the block LU factorization which involves mainly matrix-matrix operations and thereby renders the factorization more efficient on vector and parallel computers.

Symmetric Systems: LDL^T and Cholesky Factorization

When the system matrix is symmetric, its reduction to a triangular form can be organized so as to require only half the number of operation of the LU factorization. \mathbf{A} is then factorized into the symmetric form:

$$\mathbf{A} = \mathbf{LDL}^T$$

or:

$$\begin{aligned} & \begin{bmatrix} a_{11} & a_{21} & a_{31} & \dots \\ a_{21} & a_{22} & a_{32} & \\ a_{31} & a_{32} & a_{33} & \\ \vdots & & \ddots & \\ d_{11} & d_{11}l_{21} & d_{11}l_{31} & \dots \\ & d_{22} & d_{22}l_{32} & \\ 0 & & & \ddots \end{bmatrix} = \begin{bmatrix} 1 & & 0 \\ l_{21} & 1 & \\ l_{31} & l_{32} & 1 \\ \vdots & & \ddots \end{bmatrix} \\ & \times \begin{bmatrix} d_{11} & & & \\ & d_{22} & & \\ & & d_{33} & \\ & & & \ddots \end{bmatrix} \end{aligned} \quad [15]$$

where \mathbf{L} is a lower triangular matrix with unit diagonal and \mathbf{D} is diagonal. Obviously, comparing eqn [15] to the LU factorization, the upper triangular matrix \mathbf{U} is expressed as \mathbf{DL}^T in the symmetric case. The solution \mathbf{x} of eqn [1] is then found as for the LU factorization, i.e., by forward and backward substitution similar to eqns [9] and [10].

At step k of the LDL^T factorization (eqn [15]), the first $k - 1$ rows of \mathbf{L} and \mathbf{D} are known. The coefficients of \mathbf{L} on row k are recursively computed by successively identifying $a_{k1}, a_{k2} \dots a_{kk-1}$ to the right-hand side in eqn [15], and d_{kk} is then found by identifying the diagonal a_{kk} , i.e.:

step k

$$\begin{aligned} a_{kj} &= d_{jj}l_{kj} + \sum_{s=1}^{j-1} l_{ks}d_{ss}l_{js} \quad j = 1, \dots, k-1 \\ \Rightarrow l_{kj} &= \frac{1}{d_{jj}} \left(a_{kj} - \sum_{s=1}^{j-1} l_{ks}d_{ss}l_{js} \right) \end{aligned} \quad [16]$$

$$\begin{aligned} a_{kk} &= d_{kk} + \sum_{s=1}^{k-1} d_{ss}l_{ks}^2 \\ \Rightarrow d_{kk} &= a_{kk} - \sum_{s=1}^{k-1} d_{ss}l_{ks}^2 \end{aligned} \quad [17]$$

In order to reduce the number of multiplications, we can write eqns [16] and (17) in terms of the temporary variables $\tilde{l}_{kj} = d_{jj}l_{kj}$, namely:

$$\tilde{l}_{kj} = a_{kj} - \sum_{s=1}^{j-1} \tilde{l}_{ks}l_{js} \quad j = 1, \dots, k-1 \quad [18]$$

$$d_{kk} = a_{kk} - \sum_{s=1}^{k-1} \tilde{l}_{ks}l_{ks} \quad [19]$$

One can therefore determine first \tilde{l}_{kj} and, after step k , determine l_{kj} by:

$$l_{kj} = \frac{\tilde{l}_{kj}}{d_{jj}} \quad j = 1, \dots, k-1 \quad [20]$$

In this form the LDL^T factorization uses approximately half the number of operations of the LU factorization, that is $n^3/3$ operations.

Remarks As for the LU factorization, the elimination process can break down if d_{kk} becomes zero: to avoid this and to ensure numerical stability, pivoting should be applied. For the matrix to remain symmetric after pivoting, the same permutation must be applied to the row and to the columns of \mathbf{A} .

Since $\det(\mathbf{A}) = \det(\mathbf{L})\det(\mathbf{D})\det(\mathbf{L}) = \det(\mathbf{D}) = \prod_{k=1}^n d_{kk}$, all diagonal terms d_{kk} are strictly positive if \mathbf{A} is a positive definite matrix. Symmetric positive definite systems are very common, since they typically derive from quadratic energy functions which are positive and symmetric due to the very underlying physical principles. In that case, the factorization of \mathbf{A} can also be given as:

$$\mathbf{A} = \mathbf{LDL}^T = \mathbf{LD}^{1/2}\mathbf{D}^{1/2}\mathbf{L}^T = \mathbf{CC}^T \quad [21]$$

which is known as the Cholesky factorization. The Cholesky algorithm is similar to the LDL^T factorization and requires the same number of operations, but it involves computing square roots of the pivots. Note that when \mathbf{A} is positive definite, all pivots are guaranteed to be strictly positive, so that in that particular case pivoting is not compulsory.

In practice, only half of \mathbf{A} is stored (e.g., its lower triangular part) and \mathbf{A} can be overwritten by \mathbf{L} and the diagonal of \mathbf{D} , so that solving the system barely requires any additional memory.

As for the LU factorization, the LDL^T and Cholesky factorization algorithms can be re-organized in several ways. For instance the frontal method is a very popular variant for solving finite element problems.

Sparse Matrices

Discretization methods using functions defined over the entire computational domain to approximate the solution such as in the Rayleigh–Ritz or the boundary element approaches usually lead to small but full (or dense) matrices. When performing detailed analyses, the more versatile finite element or finite volume methods with fine meshes are preferred. In that case, the number of unknowns can be very large, but since the shape or flux functions are local, the connectivity between unknowns is limited to neighboring nodes so

that the system matrix is sparse. Special storage and solution techniques must then be applied in order to take advantage of sparsity.

To avoid storing zeros of a sparse matrix, one can store the index $[i, j]$ of its nonzero entries together with their values. This is the basic principle of sparse storage schemes. Special variants of the factorization algorithms sometimes called sparse solvers have been developed first, in a symbolic factorization step, the matrix coefficients that will be modified are determined, then the factorization is performed. Unfortunately, when a sparse matrix is factorized, many zero entries become nonzeros (called fill-ins) and the sparsity of the matrix is destroyed.

Renumbering schemes are usually applied to the system of equations, i.e., permutation of rows (reordering of the equations) and/or columns (renumbering of the unknowns) is performed in order to form a cluster of nonzero terms along the diagonal of the matrix (Figure 2). Since the factorization of the matrix corresponds to building linear combinations with previous rows, it will not introduce fill-ins above the first nonzero entry in a column so that the sparsity of the renumbered matrix will not be significantly altered during factorization.

When renumbering a symmetric matrix, the same permutation is applied to its columns and to its rows in order to preserve the symmetry. The two most commonly used renumbering schemes are Sloan's algorithm (heuristics to regroup degrees-of-freedom that are neighbors in the mesh) and the reverse Cuthill MacNeal (RCM) technique based on the minimization of the topological distance between degrees-of-freedom in the graph of the mesh connectivity.

The nonzero entries of the renumbered matrix being close to the diagonal, one can store all the entries between the skyline and the diagonal. This leads to the skyline storage technique as illustrated in Figure 2 for a symmetric matrix: the elements of the

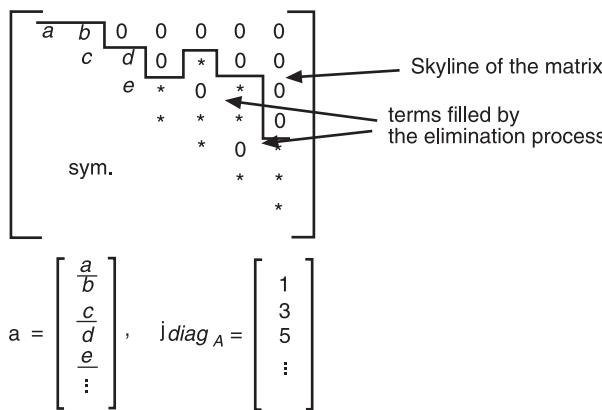

Figure 2 Skyline storage of a symmetric matrix.

columns between the skyline and the diagonal are stored in the one-dimensional array a while pointers for the position of the diagonal terms in a are stored separately in j_{diagA} . Obviously, the skyline of the matrix remains unchanged when factorization is applied without pivoting. Calling b the maximum height of a column under the skyline of a symmetric matrix (commonly called the band), the number of operations required for its factorization is of the order of nb^2 operations.

Singular Systems: Nullspace, Solutions and Generalized Inverse

Singular operators are not rare in vibration analysis. For instance, the stiffness matrix of a structure having rigid-body modes is singular, namely there exists displacement modes creating no deformation energy (e.g., translations and rotations of an aircraft in flight or a satellite in orbit). We will first define the nullspace of a singular matrix and then discuss the conditions under which a solution exists for a singular system. The concept of the generalized inverse is then introduced.

Let us consider the general case of a rectangular matrix \mathbf{A} of dimension $m \times n$, i.e., a system of m equations with n unknowns.

Singular Matrix and Nullspace

The set of all p independent solutions \mathbf{r}_s of:

$$\mathbf{A}\mathbf{r}_s = 0 \quad s = 1, \dots, p \quad [22]$$

forms the nullspace of \mathbf{A} . For a stiffness matrix, \mathbf{r}_s represent the rigid-body modes if not enough boundary conditions exist to restrain the structure. Note that any linear combination of \mathbf{r}_s satisfies eqn [22]. One can also define the nullspace vectors $\tilde{\mathbf{r}}_r$ of the transpose of \mathbf{A} such that:

$$\mathbf{A}^T \tilde{\mathbf{r}}_r = 0 \quad \text{or} \quad \tilde{\mathbf{r}}_r^T \mathbf{A} = 0 \quad r = 1, \dots, \tilde{p} \quad [23]$$

If p nullspace vectors \mathbf{r}_s exist for \mathbf{A} of dimension $m \times n$, eqn [22] indicates that only $n - p$ columns are linearly independent. Hence, the rank of \mathbf{A} is $n - p$ and \mathbf{A} has $n - p$ linearly independent rows. From eqn [23], the number of linearly independent rows is also $m - \tilde{p}$ and thus $m - \tilde{p} = n - p$. In particular, if \mathbf{A} is square, $p = \tilde{p}$ and if furthermore \mathbf{A} is symmetric, the nullspace defined by \mathbf{r}_s is identical to the nullspace represented by $\tilde{\mathbf{r}}_r$.

Let us assume without loss of generality but only to simplify the notations that the system can be partitioned as:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \end{bmatrix} \quad [24]$$

where \mathbf{A}_{11} is a nonsingular square matrix of dimension equal to the rank of \mathbf{A} , i.e. \mathbf{A}_{11} is the largest nonsingular submatrix of \mathbf{A} . Since the p columns labeled 2 in eqn [24] are linearly dependent on the $n - p$ first ones, there exists a matrix \mathbf{W} of dimension $(n - p) \times p$ such that:

$$\begin{bmatrix} \mathbf{A}_{12} \\ \mathbf{A}_{22} \end{bmatrix} = \begin{bmatrix} \mathbf{A}_{11} \\ \mathbf{A}_{21} \end{bmatrix} \mathbf{W} \quad [25]$$

The first set of equations in eqn [25] yields:

$$\mathbf{W} = \mathbf{A}_{11}^{-1} \mathbf{A}_{12} \quad [26]$$

and, substituting in the second set of equations in eqn [25]:

$$\mathbf{A}_{22} - \mathbf{A}_{21} \mathbf{A}_{11}^{-1} \mathbf{A}_{12} = \mathbf{0} \quad [27]$$

The left-hand side of the expression above is the system operator when \mathbf{x}_1 has been eliminated from the equations as indicated by eqn [14]. Hence the Gaussian elimination (LU , LDL^T or Cholesky factorization) would break down after $n - p$ steps since the lower diagonal block of dimension $\tilde{p} \times p$ is then zero. This is in fact an indication that the inverse of \mathbf{A} does not exist. If \mathbf{A} is a stiffness matrix, $\mathbf{A}_{22} - \mathbf{A}_{21} \mathbf{A}_{11}^{-1} \mathbf{A}_{12}$ is the condensed stiffness and the structure cannot be properly fixed if the degrees-of-freedom \mathbf{x}_2 are not restrained or, in other words, \mathbf{x}_2 defines a set of fixations that renders the structure statically determined. From eqn [25] we can write:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} = \begin{bmatrix} -\mathbf{W} \\ \mathbf{I}_{p \times p} \end{bmatrix} = \mathbf{0} \quad [28]$$

where $\mathbf{I}_{p \times p}$ is the identity matrix of dimension p . Hence, the nullspace of \mathbf{A} can be represented by:

$$\mathbf{R} = [\mathbf{r}_1 \dots \mathbf{r}_{\tilde{p}}] = \begin{bmatrix} -(\mathbf{A}_{11}^{-1} \mathbf{A}_{12}) \\ \mathbf{I}_{p \times p} \end{bmatrix} \quad [29]$$

In the same manner, the linear dependency of the rows of \mathbf{A} can be expressed by defining a matrix $\tilde{\mathbf{W}}$ of dimension $(m - \tilde{p}) \times \tilde{p}$ such that:

$$[\mathbf{A}_{21} \quad \mathbf{A}_{22}] = \tilde{\mathbf{W}}^T [\mathbf{A}_{11} \quad \mathbf{A}_{12}] \quad [30]$$

or:

$$\begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix}^T \begin{bmatrix} -\tilde{\mathbf{W}} \\ \mathbf{I}_{\tilde{p} \times \tilde{p}} \end{bmatrix} = \mathbf{0} \quad [31]$$

yielding:

$$\tilde{\mathbf{R}} = [\tilde{\mathbf{r}}_1 \dots \tilde{\mathbf{r}}_{\tilde{p}}] = \begin{bmatrix} -\tilde{\mathbf{W}} \\ \mathbf{I}_{\tilde{p} \times \tilde{p}} \end{bmatrix} = \begin{bmatrix} -(\mathbf{A}_{11}^{-T} \mathbf{A}_{21}^T) \\ \mathbf{I}_{\tilde{p} \times \tilde{p}} \end{bmatrix} \quad [32]$$

Solution of Singular and Rectangular Systems

If the matrix operator of a system is square but singular or if the matrix is rectangular, the inverse of \mathbf{A} cannot be defined. Nevertheless solutions to the system may exist. Indeed, let us assume that \mathbf{b}_1 and \mathbf{b}_2 exhibit the same linear dependency as the rows of \mathbf{A} , namely according to eqn [30]:

$$\mathbf{b}_2 = \tilde{\mathbf{W}}^T \mathbf{b}_1 \quad [33]$$

The set of equations associated with the linearly dependent rows $[\mathbf{A}_{21} \mathbf{A}_{22}]$ are then redundant and the system $\mathbf{Ax} = \mathbf{b}$ contains only $m - \tilde{p}$ independent equations for which an infinite number of solutions exist.

Taking account of eqn [32], relation [33] is found to be equivalent to $\tilde{\mathbf{R}}^T \mathbf{b} = \mathbf{0}$. Thus, it can be shown that a solution to the system $\mathbf{Ax} = \mathbf{b}$ exists if and only if \mathbf{b} is orthogonal to the nullspace of \mathbf{A}^T .

If \mathbf{A} is a stiffness matrix, this shows that a static solution exists if and only if the applied forces are self-equilibrated with respect to the rigid-body modes. If we define the image (or range) of \mathbf{A} as the set of \mathbf{Ay} for any vector \mathbf{y} , it can be equivalently stated that a solution to the system $\mathbf{Ax} = \mathbf{b}$ exists if and only if \mathbf{b} belongs to the image of \mathbf{A} . Indeed, by definition, if \mathbf{b} belongs to the image of \mathbf{A} , there exists \mathbf{y} such that:

$$\mathbf{Ax} = \mathbf{b} = \mathbf{Ay} \quad [34]$$

and \mathbf{y} is obviously a solution for \mathbf{x} .

Besides, if a solution \mathbf{x} exists while there exists a nullspace \mathbf{R} , this solution is clearly not unique since:

$$\mathbf{A} \left(\mathbf{x} + \sum_{s=1}^{\tilde{p}} \alpha_s \mathbf{r}_s \right) = \mathbf{Ax} = \mathbf{b} \quad [35]$$

for any linear combination α_s of the nullspace vectors. Hence the component of the solution lying in the nullspace is undetermined. In the context of structural mechanics, this means that if the forces are self-equilibrated, a static solution exists but the rigid-body displacements are arbitrary.

A Family of Generalized Inverses

Since, under the conditions described above, solutions \mathbf{x} exist for singular systems, we can define an operator \mathbf{A}^+ , called generalized inverse or pseudoinverse such that a solution \mathbf{x} is expressed as:

$$\mathbf{x} = \mathbf{A}^+ \mathbf{b} \quad [36]$$

Substituting the solution in the system equations, we obtain:

$$\mathbf{A}\mathbf{A}^+ \mathbf{b} = \mathbf{b} \quad [37]$$

and since \mathbf{b} is in the image of \mathbf{A} if a solution exists:

$$\mathbf{A}\mathbf{A}^+ \mathbf{A}\mathbf{y} = \mathbf{A}\mathbf{y} \quad [38]$$

Hence, the generalized inverse \mathbf{A}^+ of \mathbf{A} can also be defined as an operator satisfying:

$$\mathbf{A}\mathbf{A}^+ \mathbf{A} = \mathbf{A} \quad [39]$$

which stipulates that the image of \mathbf{A} is unchanged by the operator $\mathbf{A}\mathbf{A}^+$. For singular or rectangular systems, $\mathbf{A}\mathbf{A}^+$ is not the identity but has the same effect as an identity matrix when applied to the image of \mathbf{A} . Obviously, if \mathbf{A} is square and nonsingular, $\mathbf{A}^+ = \mathbf{A}^{-1}$.

Let us point out that unless \mathbf{A} is square and nonsingular, the generalized inverse satisfying eqn [39] is not unique. Indeed, calling \mathbf{R} and $\tilde{\mathbf{R}}$ the nullspace of \mathbf{A} and \mathbf{A}^T respectively as defined earlier, and calling \mathbf{A}^+ a generalized inverse satisfying eqn [39], then

$$\tilde{\mathbf{A}}^+ = \mathbf{A}^+ + \mathbf{B}\tilde{\mathbf{R}}^T + \mathbf{R}\mathbf{C} \quad [40]$$

also satisfies eqn [39] for any \mathbf{B} and \mathbf{C} . Eqn [40] thus defines a family of generalized inverses. The solution obtained with $\tilde{\mathbf{A}}^+$ in eqn [40] is:

$$\mathbf{x} = \mathbf{A}^+ \mathbf{b} + \mathbf{B}\tilde{\mathbf{R}}^T(\mathbf{A}\mathbf{y}) + \mathbf{R}\mathbf{C}\mathbf{b} = \mathbf{A}^+ \mathbf{b} + \mathbf{R}\mathbf{C}\mathbf{b} \quad [41]$$

which differs from the solution $\mathbf{A}^+ \mathbf{b}$ only by its rigid-body mode content.

Example Let us show that, using the block notation introduced in eqn [24], the matrix $\mathbf{A}^{[11]+}$ defined by

$$\mathbf{A}^{[11]+} = \begin{bmatrix} \mathbf{A}_{11}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad [42]$$

is a generalized inverse, \mathbf{A}_{11} being as before a square submatrix of maximum range, i.e., \mathbf{A}_{11} is formed by

any $n - p$ linearly independent columns and rows of \mathbf{A} .

To show that $\mathbf{A}^{[11]+}$ is a generalized inverse, we prove that it satisfies eqn [39] as follows:

$$\begin{aligned} \mathbf{A}\mathbf{A}^{[11]+}\mathbf{A} &= \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{A}_{11}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{21}\mathbf{A}_{11}^{-1}\mathbf{A}_{12} \end{bmatrix} \end{aligned} \quad [43]$$

and recalling from eqn [27] that $\mathbf{A}_{21}\mathbf{A}_{11}^{-1}\mathbf{A}_{12}$ is equal to \mathbf{A}_{22} concludes the proof. Another proof can be constructed by showing that $\mathbf{A}^{[11]+}\mathbf{b}$ is a solution of $\mathbf{Ax} = \mathbf{b}$ when $\tilde{\mathbf{R}}^T\mathbf{b} = \mathbf{0}$. This is left to the reader.

As will be discussed later, this particular generalized inverse is of the form obtained by classical factorization techniques since it is constructed by factorizing a full-rank submatrix of \mathbf{A} .

Singular Value Decomposition and the Moore–Penrose Generalized Inverse

Singular Value Decomposition (SVD)

It can be shown that any matrix \mathbf{A} with m rows and n columns can be decomposed as follows:

There exist \mathbf{U} , Σ and \mathbf{V} such that:

$$\mathbf{A} = \mathbf{U}\Sigma\mathbf{V}^T \quad [44]$$

where \mathbf{U} and \mathbf{V} are orthogonal matrices of dimension $m \times m$ and $n \times n$ such that:

$$\mathbf{U}^T\mathbf{U} = \mathbf{I}_{m \times m} \quad \text{and} \quad \mathbf{V}^T\mathbf{V} = \mathbf{I}_{n \times n} \quad [45]$$

and where Σ is a matrix of dimension $m \times n$ whose diagonal terms are the singular values:

$$\Sigma = \underbrace{\begin{bmatrix} \sigma_1 & & & \\ & \ddots & & \\ & & \sigma_r & \\ & & & \mathbf{0} \end{bmatrix}}_n \Bigg\}_m \quad [46]$$

$r = n - p$ being the rank of \mathbf{A} .

From eqns [45] and [46], it is clear that the last columns of \mathbf{U} and \mathbf{V} , respectively, store the nullspaces $\tilde{\mathbf{R}}$ and \mathbf{R} of \mathbf{A} .

In the particular case where \mathbf{A} is square and symmetric, the singular value decomposition (SVD) defined above is equivalent to the spectral expansion:

$$\mathbf{A} = [\mathbf{X} \quad \mathbf{R}] \begin{bmatrix} \Lambda & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \mathbf{X}^T \\ \mathbf{R}^T \end{bmatrix} = \mathbf{X} \Lambda \mathbf{X}^T$$

$$= \sum_{k=1}^{n-p} \lambda_k \mathbf{x}_k \mathbf{x}_k^T$$
[47]

where Λ is the diagonal matrix containing the non-zero eigenvalues λ_k and \mathbf{X} stores the corresponding eigenvectors \mathbf{x}_k . Comparing eqns [47] and [44], we see that the singular values of a symmetric matrix are its nonzero eigenvalues and $\mathbf{U} = \mathbf{V} = [\mathbf{X} \quad \mathbf{R}]$.

The Moore–Penrose Generalized Inverse

The generalized inverse of a matrix plays an important role in solving singular systems and we have shown how we can build one particular generalized inverse $\mathbf{A}^+ = \mathbf{A}^{[11]+}$. Choosing different linear independent rows and columns in \mathbf{A} to form $\mathbf{A}^{[11]+}$ in eqn [42] leads to a different generalized inverse, with a different nullspace content as shown by eqn [40].

Penrose showed in 1955 that only one generalized inverse, commonly denoted by \mathbf{A}^\dagger , satisfies the four relations:

$$\mathbf{A}\mathbf{A}^\dagger\mathbf{A} = \mathbf{A} \quad [48a]$$

$$\mathbf{A}^\dagger\mathbf{A}\mathbf{A}^\dagger = \mathbf{A}^\dagger \quad [48b]$$

$$(\mathbf{A}\mathbf{A}^\dagger)^T = \mathbf{A}\mathbf{A}^\dagger \quad [48c]$$

$$(\mathbf{A}^\dagger\mathbf{A})^T = \mathbf{A}^\dagger\mathbf{A} \quad [48d]$$

known as the Penrose equations. The unique generalized inverse \mathbf{A}^\dagger was also studied earlier by Moore and hence is known as the Moore–Penrose inverse.

The first Penrose equation [48a] is the condition introduced in the previous section to characterize the family of generalized inverses. The second Penrose equation [48b] stipulates that \mathbf{A} is a generalized inverse for \mathbf{A}^\dagger . Eqns [48c] and [48d] state that $\mathbf{A}\mathbf{A}^\dagger$ and $\mathbf{A}^\dagger\mathbf{A}$ are symmetric. Note that a generalized inverse $\mathbf{A}^{[11]+}$ constructed as in eqn [42] satisfies the first and second equation, but not the last two.

Recalling the singular value decomposition, eqn [44], and defining:

$$\boldsymbol{\Sigma}^\dagger = \underbrace{\begin{bmatrix} 1/\sigma_1 & & & \\ & \ddots & & \\ & & 1/\sigma_r & \\ 0 & & & 0 \end{bmatrix}}_m \Bigg\}^n \quad [49]$$

the Moore–Penrose inverse of a real matrix can be written as:

$$\mathbf{A}^\dagger = \mathbf{V} \sum^\dagger \mathbf{U}^T \quad [50]$$

Indeed, from eqns [44] and [45], it is straightforward to verify that eqn [50] satisfies the Penrose equations (eqn [48a] to [48d]). From eqn [50], we observe that the Moore–Penrose inverse is a generalized inverse such that if \mathbf{R} and $\tilde{\mathbf{R}}$ represent the nullspace of \mathbf{A} and \mathbf{A}^T respectively:

$$\mathbf{A}^\dagger \mathbf{R} = \mathbf{0} \quad \text{and} \quad \mathbf{A}^{\dagger T} \tilde{\mathbf{R}} = \mathbf{0} \quad [51]$$

Hence, the Moore–Penrose inverse \mathbf{A}^\dagger is characterized as having the same left and right nullspace as \mathbf{A}^T . Therefore, for any generalized inverse \mathbf{A}^+ , the Moore–Penrose inverse can be obtained as:

$$\mathbf{A}^\dagger = \mathbf{P} \mathbf{A}^+ \tilde{\mathbf{P}} \quad [52]$$

where \mathbf{P} and $\tilde{\mathbf{P}}$ are, respectively, the projectors onto the subspaces orthogonal to \mathbf{R} and $\tilde{\mathbf{R}}$, respectively:

$$\mathbf{P} = \mathbf{I} - \mathbf{R}(\mathbf{R}^T \mathbf{R})^{-1} \mathbf{R}^T \quad [53]$$

$$\tilde{\mathbf{P}} = \mathbf{I} - \tilde{\mathbf{R}}(\tilde{\mathbf{R}}^T \tilde{\mathbf{R}})^{-1} \tilde{\mathbf{R}}^T \quad [54]$$

Note that this corresponds to defining \mathbf{B} and \mathbf{C} in eqn [40] of the family of generalized inverse matrices such that eqn [51] is satisfied.

In the particular case where \mathbf{A} is symmetric, the SVD (eqn [50]) of the Moore–Penrose inverse becomes the classical spectral expansion:

$$\mathbf{A}^\dagger = \sum_{k=1}^{n-p} \frac{\mathbf{x}_k \mathbf{x}_k^T}{\lambda_k} = \mathbf{X} \Lambda^{-1} \mathbf{X}^T \quad [55]$$

Comparing with the spectral expansion (eqn [47]) of \mathbf{A} , we observe that \mathbf{A}^\dagger is a generalized inverse whose nullspace is equal to the nullspace of \mathbf{A} and whose non-zero eigenvalues are the inverse of the nonzero eigenvalues of \mathbf{A} , the associated eigenvectors being identical. It can be obtained from any generalized inverse as:

$$\mathbf{A}^\dagger = \mathbf{P} \mathbf{A}^+ \mathbf{P} \quad [56]$$

The role played by the Moore–Penrose inverse for the solution of linear systems and in vibration analysis in particular will be illustrated in the next sections.

Application of the Moore–Penrose Inverse

Least-squares solution When the right-hand side \mathbf{b} of $\mathbf{Ax} = \mathbf{b}$ is not in the image of \mathbf{A} no solution exists. In that case one can look for a solution such that the error $\mathbf{Ax} - \mathbf{b}$ is a minimum in the least squares sense, namely such that $(\mathbf{Ax} - \mathbf{b})^T(\mathbf{Ax} - \mathbf{b})$ is a minimum. \mathbf{x} is thus solution of:

$$\mathbf{A}^T \mathbf{Ax} = \mathbf{A}^T \mathbf{b} \quad [57]$$

Solving the least-squares equation (eqn [57]) by a factorization technique is not recommended if the numerical conditioning of \mathbf{A} is bad. Indeed, the condition number of $\mathbf{A}^T \mathbf{A}$ is the square of the condition number of \mathbf{A} . An alternative consists in computing the solution to eqn [57] by the Moore–Penrose inverse as $\mathbf{x} = \mathbf{A}^+ \mathbf{b}$. Indeed, using the first and third Penrose equations [48a, 48c]:

$$\begin{aligned} \mathbf{A}^T \mathbf{AA}^\dagger \mathbf{b} &= \mathbf{A}^T (\mathbf{AA}^\dagger)^T \mathbf{b} \\ &= (\mathbf{AA}^\dagger \mathbf{A})^T \mathbf{b} = \mathbf{A}^T \mathbf{b} \end{aligned} \quad [58]$$

If \mathbf{A} has no right nullspace (i.e., $\mathbf{R} = \mathbf{0}$), the solution $\mathbf{x} = \mathbf{A}^\dagger \mathbf{b}$ is the unique solution of the least-squares problem. But if there exists a nullspace \mathbf{R} , the solution is not unique. Nevertheless, because $\mathbf{x} = \mathbf{A}^\dagger \mathbf{b}$ is orthogonal to \mathbf{R} , it is the solution of the minimal Euclidean norm.

Inverse power iterations for singular symmetric matrices If an inverse iteration scheme is used to find the eigensolutions of a singular symmetric matrix \mathbf{A} , the Moore–Penrose generalized inverse can be used since its spectrum is closely related to the eigen-spectrum of \mathbf{A} as explained above. Indeed, applying a power iteration method on:

$$\frac{\mathbf{x}}{\lambda} = \mathbf{A}^\dagger \mathbf{x} \quad [59]$$

yields, according to eqn [55], the eigenvectors \mathbf{x}_k associated with the lowest non-zero eigenvalues λ_k . Therefore in practice, the inverse iteration is carried out using a generalized inverse and projector \mathbf{P} :

$$\mathbf{x}^{i+1} = \mathbf{P} \mathbf{A}^+ \mathbf{P} \mathbf{x}^i \quad [60]$$

Note that this can also be interpreted as performing an inverse iteration with any generalized inverse and applying orthogonal deflation with respect to the

nullspace \mathbf{R} . We observe that because $\mathbf{P} \mathbf{P} = \mathbf{P}$, the projection of \mathbf{x}^i is redundant.

Application of the Generalized Inverse in Vibration Analysis

We have already stressed the importance of the generalized inverse for solving static problems for structures with rigid-body modes. We now present two important applications of the Moore–Penrose inverse to computation methods in vibration analysis.

Computing Vibration Modes by Inverse Iteration in the Presence of Rigid-body Modes

Calling \mathbf{M} and \mathbf{K} , respectively, the symmetric mass and stiffness matrices, the nonzero vibration frequencies $\omega_{(k)}$ and modes $\mathbf{x}_{(k)}$ are nontrivial solutions of the eigenproblem:

$$\mathbf{Kx}_{(k)} = \omega_{(k)}^2 \mathbf{Mx}_{(k)} \quad k = 1, \dots, n-p \quad [61]$$

where n is the number of degrees-of-freedom and p is the number of rigid-body modes or zero energy modes $\mathbf{r}_{(r)}$ satisfying:

$$\mathbf{Kr}_{(r)} = \mathbf{0} \quad k = 1, \dots, p \quad [62]$$

It is common practice to avoid dealing with the singularity of \mathbf{K} by modifying the eigenproblem (eqn [61]) either by a shifting strategy or by introducing small additional springs to fix the structure in space. There is, however, another effective and maybe more natural way to apply inverse iteration based methods to floating structures as explained below.

If \mathbf{M} is nonsingular, there exists a Cholesky factorization such that $\mathbf{M} = \mathbf{C}_M \mathbf{C}_M^T$. Therefore the eigenproblem (eqn [61]) can be put in the standard form:

$$\mathbf{C}_M^{-1} \mathbf{KC}_M^{-T} \mathbf{y}_{(k)} = \omega_{(k)}^2 \mathbf{y}_{(k)} \quad [63]$$

where:

$$\mathbf{y}_{(k)} = \mathbf{C}_M^T \mathbf{x}$$

As explained earlier, the inverse iteration can be carried out based on the Moore–Penrose inverse of $\mathbf{C}_M^{-1} \mathbf{KC}_M^{-T}$ as follows:

$$\mathbf{x}^{i+1} = \mathbf{P} (\mathbf{C}_M^{-1} \mathbf{KC}_M^{-T})^+ \mathbf{P} \mathbf{x}^i \quad [64]$$

where:

$$\mathbf{P} = \mathbf{I} - \mathbf{V} (\mathbf{V}^T \mathbf{V})^{-1} \mathbf{V}^T$$

\mathbf{V} being the nullspace of $\mathbf{C}_M^{-1}\mathbf{K}\mathbf{C}_M^{-T}$. If \mathbf{R} stores the rigid-body modes ($\mathbf{KR} = \mathbf{0}$), the nullspace \mathbf{V} is represented by $\mathbf{V} = \mathbf{C}_M^T\mathbf{R}$. We also note that $(\mathbf{C}_M^{-1}\mathbf{K}\mathbf{C}_M^{-T})^+ = \mathbf{C}_M^T\mathbf{K}^+\mathbf{C}_M$. Therefore, substituting in eqn [64], the inverse iteration can be written as:

$$\begin{aligned} \mathbf{x}^{i+1} &= \mathbf{K}^\oplus \mathbf{M} \mathbf{x}^i \\ \text{where: } \mathbf{K}^\oplus &= \mathbf{P}_M^T \mathbf{K}^+ \mathbf{P}_M & [65] \\ \mathbf{P}_M &= \mathbf{I} - \mathbf{M} \mathbf{R} (\mathbf{R}^T \mathbf{M} \mathbf{R})^{-1} \mathbf{R}^T \end{aligned}$$

This last form of the inverse iteration is used in practice since it involves using only a generalized inverse of \mathbf{K} and the rigid-body modes.

Remarks The scheme described by eqn [65] iterates in a subspace orthogonal to \mathbf{R} in the metric of \mathbf{M} , which is exactly the space of the vibration modes of nonzero frequencies. Hence, eqn [65] can also be understood as an inverse iteration with deflation of the rigid-body modes. Therefore it can be shown that:

$$\mathbf{K}^\oplus = \sum_{s=1}^{n-p} \frac{\mathbf{x}_{(s)} \mathbf{x}_{(s)}^T}{\omega_{(s)}^2} \quad [66]$$

The similarity between the spectral expansion (eqn [66]) of \mathbf{K}^\oplus used in the inverse iteration and the spectral expansion (eqn [55]) of the Moore–Penrose inverse is noteworthy. However, \mathbf{K}^\oplus is not a Moore–Penrose inverse: its spectral expansion is in terms of eigenmodes of the free vibration problem (eqn [61]) and not in terms of the eigenvectors of \mathbf{K} itself.

As for eqn [60], the two projections are redundant because $\mathbf{P}_M \mathbf{M} \mathbf{P}_M^T = \mathbf{P}_M \mathbf{M} = \mathbf{M} \mathbf{P}_M^T$. Nevertheless, they are useful to prevent numerical errors which may cause rigid modes to reappear in the successive iterates.

The first projection ensures that the inertia forces $\mathbf{P}_M \mathbf{M} \mathbf{x}^i$ of iterate \mathbf{x}^i are self-equilibrated so that a static solution can be found by applying \mathbf{K}^+ . The second projection removes from the static solution obtained by \mathbf{K}^+ any component which does not lie in the space of the nonzero vibration modes.

Mode Acceleration Method in the Presence of Rigid-body Modes

The mode acceleration method is an improved mode superposition technique where the dynamic response computed by a truncated series of mode is corrected so that the solution exactly satisfies the quasistatic equilibrium.

Assuming, to simplify the presentation, that no damping is present, the dynamic equations are:

$$\mathbf{M} \ddot{\mathbf{x}} + \mathbf{K} \mathbf{x} = \mathbf{f}(t) \quad [67]$$

where $\ddot{\mathbf{x}}$ represents the second-order time-derivative of \mathbf{x} (i.e., the acceleration) and \mathbf{f} is an external force, a function of time. In the mode acceleration method, the contributions of the high-frequency modes to the inertia forces are neglected. The solution is thus obtained by truncating the modal expansion of the dynamic response so as to include only the q first vibration modes and by correcting the response with the quasistatic contribution of the remaining modes. In the presence of rigid-body modes, assuming that the modes have been orthonormalized with respect to the mass matrix, the dynamic response is approximated by:

$$\mathbf{x} = \sum_{r=1}^p \alpha_r(t) \mathbf{r}_{(r)} + \sum_{k=1}^q \eta_k(t) \mathbf{x}_{(k)} + \sum_{s=q+1}^{n-p} \mathbf{x}_{(s)} \frac{\mathbf{x}_{(s)}^T \mathbf{f}(t)}{\omega_{(s)}^2} \quad [68]$$

where $\alpha_r(t)$ and $\eta_k(t)$ are the amplitudes of the rigid-body and vibration modes satisfying the normal equations:

$$\ddot{\alpha}_r = \mathbf{r}_{(r)}^T \mathbf{f}(t) \quad [69]$$

$$\ddot{\eta}_k + \omega_{(k)}^2 \eta_k = \mathbf{x}_{(k)}^T \mathbf{f}(t) \quad [70]$$

The last term of eqn [68] cannot be computed as such because the modes of index higher than q are not known. Instead, we recall the spectral expansion (eqn [66]) of \mathbf{K}^\oplus so that the mode acceleration solution is computed as:

$$\begin{aligned} \mathbf{x} &= \sum_{r=1}^p \alpha_r(t) \mathbf{r}_{(r)} + \sum_{k=1}^q \eta_k(t) \mathbf{x}_{(k)} \\ &+ \left(\mathbf{K}^\oplus - \sum_{s=1}^q \frac{\mathbf{x}_{(s)} \mathbf{x}_{(s)}^T}{\omega_{(s)}^2} \right) \mathbf{f}(t) \end{aligned} \quad [71]$$

Solution by Generalized Inverses and Finding the Nullspace \mathbf{R}

Factorization of a Singular Matrix: Constructing a Generalized Inverse

If a solution exists, it can be computed using the generalized inverse $\mathbf{A}^{[11]+}$ defined in eqn [42] so that:

$$\begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{A}_{11}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \end{bmatrix} \quad [72]$$

namely by solving the system $\mathbf{Ax} = \mathbf{b}$ for a maximum set of independent variables and equations, i.e., $\mathbf{x}_1 = \mathbf{A}_{11}^{-1}\mathbf{b}_1$, and setting to zero the remaining unknowns \mathbf{x}_2 .

When a factorization technique is used, it corresponds to advancing the elimination process as long as nonzero pivots exist. When factorizing a nondefinite system, pivoting must then be used and the factorization is stopped when the remaining submatrix is zero. For semidefinite matrices, pivoting is not required since zero pivots appear only when the row of the pivot is a linear combination of all preceding rows. In that case, when a zero pivot is found at step k , the corresponding unknown x_k is flagged as being part of \mathbf{x}_2 and the factorization is continued by skipping step k .

In structural mechanics, setting to zero the degrees of freedom \mathbf{x}_2 corresponds to adding fictitious links to the system to render it statically determined. Since the forces applied must be self-equilibrated for a static solution to exist if the structure is floating, applying temporary constraints for the system to be exactly statically determined does not affect the solution as far as deformations are concerned, but simply sets the rigid-body displacement of the solution.

Computing the Nullspace

Let us recall from eqn [29] that the nullspace of \mathbf{A} can be computed as:

$$\mathbf{R} = \begin{bmatrix} -(\mathbf{A}_{11}^{-1}\mathbf{A}_{12}) \\ \mathbf{I} \end{bmatrix} \quad [73]$$

When a factorization technique is applied, only the nonsingular matrix \mathbf{A}_{11} is factored as explained above. Hence the rigid-body modes can be found by applying forward and backward substitutions to the submatrix \mathbf{A}_{12} . When \mathbf{A} is a stiffness matrix, eqn [73] indicates that the rigid-body modes are found by solving the system for \mathbf{x}_1 when setting to one a degree-of-freedom \mathbf{x}_2 , the other \mathbf{x}_2 being set to zero.

Since, in order to minimize memory usage, the matrix \mathbf{A} is overwritten by its factored form, \mathbf{A}_{12} no longer exist after the factorization. Nevertheless, from the factorization methods described earlier it is understood that when a null pivot is found at step k , column k stores a column of \mathbf{A}_{12} transformed by a forward substitution. Hence computing $\mathbf{A}_{11}^{-1}\mathbf{A}_{12}$ simply requires one to perform a backward substitution on the columns of the null pivots.

When the nullspace of a matrix is computed as a by-product of its factorization, the threshold used to detect null pivots plays an essential role in finding the null space of a matrix. Since the threshold to detect correctly the null pivots strongly depends on the conditioning of the matrix and on the machine precision, the automatic detection and computation of the nullspace as described above might yield a wrong nullspace. To circumvent this delicate problem in structural mechanics, some methods first detect rigid-body modes by geometric inspection and use that information to build the null space during the factorization in a more robust way.

Nomenclature

D	diagonal
I	identity matrix
L	lower triangular matrix
P ₁ , P ₂	permutation operators
U	upper triangular matrix

Introduction

Physical systems possessing inertia and elasticity are capable of relative motion. If the motion of such systems repeats itself after a given interval of time, the motion is known as vibration. This periodic motion can be rather complex, and it may take a long time before the motion repeats itself. In addition, there are generally forces of excitation and resistance to any vibratory motion. In simple terms, the subject of vibration is the study of oscillatory motion generated by the interplay of inertia, elasticity, and impressed forces. Yet vibration manifests itself in such a great variety of ways in engineering that an understanding of this subject is a prerequisite for successful design of systems.

There are several possible starting points in the analysis of vibrating systems. As a branch in classical dynamics, vibration is amenable to the formulations of Newton, Lagrange, or Hamilton. However, in the ultimate analysis, all approaches are equivalent and may be viewed as merely a mathematical representation of energy balance. Consider the small oscillatory motion of a natural vibrating system. If the configuration of the system can be specified by n generalized coordinates q_i ($i = 1, 2 \dots n$), the Lagrange's equations of motion can be cast in the compact form:

$$M\ddot{q} + Kq = Q \quad [1]$$

where $\mathbf{q} = [q_1, q_2 \dots q_n]^T$ is the vector of generalized coordinates and $\mathbf{Q} = [Q_1, Q_2 \dots Q_n]^T$ is the vector of impressed forces. The coefficients M and K are constant square matrices of order n . As an easy consequence of the Lagrangian formulation, M and K are symmetric and definite. The positive definite matrix M arises from system inertia and, for this reason, is called the mass matrix. The positive semidefinite matrix K arises from system elasticity and is called the stiffness matrix. Clearly, eqn [1] shows how system inertia, system elasticity, and impressed forces can together bring about oscillatory motion, described by the vector of system response \mathbf{q} .

Equivalent Viscous Damping

In engineering applications, it is customary to separate the vector of impressed forces \mathbf{Q} into forces of excitation $f(t)$ and resistance. Forces of excitation may be induced by unbalanced weights in rotating machinery, or they may result from natural events such as wind storms, ocean waves, or earthquakes. Characterization of the various sources of excitation is tackled in such diverse fields as machine design, wind, ocean, and earthquake engineering. In addition to excitation, there is usually some degree of friction or resistance to any vibratory motion. This type of resistance is called damping, and it may originate from air friction, Coulomb dry friction, or internal friction in materials. Energy of a system is always dissipated in damping. If damping is heavy, oscillatory motion will not occur and the system is said to be overdamped. The damping forces are regarded as viscous if they are proportional to the generalized velocities. For a viscously damped system, the impressed forces can be separated as:

$$\mathbf{Q} = f(t) - C\dot{\mathbf{q}} \quad [2]$$

The matrix C above contains the constants of proportionality for viscous damping and is thus called the damping matrix. It is also symmetric and positive semidefinite. Strictly speaking, the assumption of viscous damping is only valid if frictional forces are generated by the laminar flow of a viscous fluid. To get an intuitive feeling of this damping mechanism, one can imagine trying to walk through treacle. A commonly used device that actually uses this mechanism is the shock absorber on an automobile. The associated dashpot device is set up to cause a piston to displace a fluid. In most engineering systems, damping is rarely plain viscous. Even fluid damping need not be viscous. Frictional forces induced by the turbulent flow of a fluid is proportional to the velocity squared. Internal damping in materials is not viscous and changes with the frequency of the excitation. In fact, there are usually more than one damping mechanisms simultaneously in play in any vibrating system.

Viscous damping has a very simple mathematical representation and is easily amenable to analysis. It would be preferable if other damping mechanisms could somehow be approximated as viscous. Indeed,

a whole array of postulations was made in the classical literature to support the approximation of damping as viscous. For instance, Lord Rayleigh used viscous damping to approximate the combined effect of air damping and internal friction in a tuning fork. It seems reasonable enough to accept that the overall damping in a sounding fork is viscous. However, to say that damping in an actual building is viscous is quite different. There are many energy-dissipating mechanisms in a vibrating building. These include friction at steel connections, opening and closing of microcracks in concrete, and friction between the structure itself and non-structural elements such as partition walls. In fact, the various energy-dissipating mechanisms in an actual building have not been completely identified and understood.

Fortunately, extensive experimentation has been conducted in the past three decades on vibrating structures known to possess a multitude of dissipative mechanisms. Provided that the dissipative forces are small, it has been consistently observed that the system response generally looks like a viscous-type response. With this understanding, it appears reasonable to use equivalent viscous damping as an approximation of overall damping, so long as the approximation is not extended out of a suitably small range in which the various dissipative forces remain small. A common method for determining equivalent viscous damping is to equate the energy dissipated per cycle of oscillation to that due to a hypothetical viscous damper. This process generates the constants of proportionality for equivalent viscous damping. Another quantification of equivalent viscous damping is such that it will produce the same bandwidth in frequency response as obtained experimentally for an actual system. If equivalent viscous damping is indeed taken as representative, the governing equation of an n -degrees-of-freedom natural system becomes:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{f}(t) \quad [3]$$

This is a linear differential equation with real and constant coefficient matrices. As explained earlier, \mathbf{M} , \mathbf{C} , and \mathbf{K} enjoy the properties of symmetry and definiteness. A very powerful technique for evaluating the response of viscously damped systems is modal analysis.

Undamped Vibration

The equation of motion of an undamped system, in which $\mathbf{C} = 0$, reduces to:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{f}(t) \quad [4]$$

In general, the above matrix differential equation is coupled. The i th component equation involves not only q_i and \dot{q}_i , but also other generalized coordinates and their accelerations. If \mathbf{M} is diagonal, \ddot{q}_i occurs as the only acceleration in the i th component equation and the system is said to be inertially decoupled. Likewise, q_i occurs as the only displacement in the i th component equation when \mathbf{K} is diagonal. The system is then said to be elastically decoupled. Should both \mathbf{M} and \mathbf{K} become diagonal, the entire system is decoupled. Eqn [4] may then be regarded as composing of n independent scalar equations, the solution of which is immediate. Modal analysis is a method for decoupling the equation of motion by means of a coordinate transformation. The decoupling coordinate transformation can be determined through the solution of an algebraic eigenvalue problem.

Let \mathbf{u} be a column vector of order n and α be a scalar constant. If $\mathbf{q} = \mathbf{u}e^{\alpha t}$ is a homogeneous or complementary solution to eqn [4], the generalized symmetric eigenvalue problem

$$\mathbf{Ku} = \lambda\mathbf{Mu} \quad [5]$$

must be satisfied, where $\lambda = -\alpha^2$. Eigenvalue problems of this type have been studied rather extensively in the abstract theory of matrix pencils. Owing to the properties of symmetry and definiteness of \mathbf{M} and \mathbf{K} , there are n real and nonnegative eigenvalues λ_i . The corresponding eigenvectors \mathbf{u}_i are real and orthonormal. Let the eigenvectors \mathbf{u}_i be arranged as columns of a modal matrix $\mathbf{U} = [\mathbf{u}_1, \mathbf{u}_2 \dots \mathbf{u}_n]$, and the eigenvalues λ_i as diagonal elements of a spectral matrix $\Lambda = \text{diag}[\lambda_1, \lambda_2 \dots \lambda_n]$. Then the orthonormality of the eigenvectors can be expressed in a compact form:

$$\mathbf{U}^T \mathbf{M} \mathbf{U} = \mathbf{I} \quad [6]$$

$$\mathbf{U}^T \mathbf{K} \mathbf{U} = \Lambda \quad [7]$$

Utilizing the modal matrix, define a coordinate transformation $\mathbf{q} = \mathbf{Up}$. Eqn [4] may now be simplified to:

$$\ddot{\mathbf{p}} + \Lambda \mathbf{p} = \mathbf{U}^T \mathbf{f}(t) \quad [8]$$

which represents a completely decoupled system. The transformation from \mathbf{q} to \mathbf{p} is called the modal transformation and \mathbf{p} is termed the vector of modal coordinates. Thus, an undamped system can always be decoupled by modal transformation.

Modal analysis possesses tremendous physical insight. Each positive eigenvalue λ_i of eqn [5] is the square of a natural frequency of the system. Let $\lambda_i = \omega_i^2$, where ω_i is real and positive. In free vibration at the natural frequency ω_i , various parts of the system oscillate in the same phase, passing through their equilibrium positions at the same instant of time. This form of synchronous motion of a system is called modal vibration. The eigenvector \mathbf{u}_i associated with λ_i physically represents the relative amplitudes of the coordinates of a system in modal vibration. For this reason, \mathbf{u}_i is also called a mode shape, or a normal mode. General free vibration of a system is simply a proper superposition of the different forms of modal vibration. Lastly, the modal transformation itself can be given a geometric interpretation. It can be thought of as a coordinate transformation that determines the principal axes of an n -dimensional ellipsoid. No wonder that modal analysis is regarded as one of the most important and intuitively appealing methods of analysis to date.

Proportional Damping

A viscously damped system is governed by eqn [3]. Upon modal transformation, the system will be decoupled inertially and elastically, in accordance with eqns [6] and [7]. Expressed in modal coordinates, eqn [3] takes the form:

$$\ddot{\mathbf{p}} + \mathbf{D}\dot{\mathbf{p}} + \boldsymbol{\Lambda}\mathbf{p} = \mathbf{U}^T\mathbf{f}(t) \quad [9]$$

where $\mathbf{D} = \mathbf{U}^T\mathbf{C}\mathbf{U}$ is the modal damping matrix. In general, \mathbf{D} will not be diagonal, and a damped system remains coupled in modal coordinates. In other words, a damped system does not usually possess the same forms of modal vibration as the undamped system. However, if:

$$\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K} \quad [10]$$

for some scalar constants α and β , then $\mathbf{D} = \alpha\mathbf{I} + \beta\boldsymbol{\Lambda}$ becomes a diagonal matrix. Eqn [9] is completely decoupled and represents n independent scalar equations. A system whose damping matrix satisfies condition [10] is said to be proportionally damped. Proportional damping was first expounded by Lord Rayleigh. It includes mass-proportional damping and stiffness-proportional damping as particular cases.

The concept of proportional damping has subsequently been extended. Express eqn [10] in the form of a series: $\mathbf{C} = \mathbf{M}(\alpha\mathbf{I} + \beta\mathbf{M}^{-1}\mathbf{K})$. It is found that the modal damping matrix \mathbf{D} remains diagonal even when higher powers of $\mathbf{M}^{-1}\mathbf{K}$ are added to the series. As long as:

$$\mathbf{C} = \mathbf{M} \sum_{i=0}^{n-1} a_i (\mathbf{M}^{-1}\mathbf{K})^i \quad [11]$$

for some constants a_i , a damped system possesses the same mode shapes as the undamped one. Note that the above series need not contain powers higher than $n - 1$ because of the Cayley-Hamilton theorem in matrix analysis. Proportional damping and its power-series extension are perhaps the best known examples of damping for which modal transformation decouples the entire system. There are other forms of damping under which modal analysis remains operational.

Classical Damping

A vibrating system is said to be classically damped if \mathbf{C} transforms into a modal damping matrix \mathbf{D} that is diagonal. The terminology stems from the observation that a damped system is decoupled by the classical method of modal analysis only when the damping mechanism is classical. Clearly, proportional damping is a special case of classical damping. However, classical damping need not be proportional. The same can be said for the power-series extension of proportional damping. A system subjected to non-classical damping will have a modal damping matrix \mathbf{D} that is nondiagonal. Such a system is not amenable to modal analysis, and it does not possess the same normal modes as the undamped system.

A necessary and sufficient condition under which a system is classically damped is:

$$\mathbf{C}\mathbf{M}^{-1}\mathbf{K} = \mathbf{K}\mathbf{M}^{-1}\mathbf{C} \quad [12]$$

In other words, the modal damping matrix \mathbf{D} is diagonal if and only if the matrices $\mathbf{M}^{-1}\mathbf{C}$ and $\mathbf{M}^{-1}\mathbf{K}$ commute in multiplication. Condition [12] is obviously satisfied if \mathbf{C} has either the form [10] or [11]. In general, there are no particular reasons why condition [12] should hold to permit modal analysis to operate. However, owing to the great convenience furnished by decoupling, engineers routinely invoke a large array of rather bold approximations to justify the use of classical damping in their analysis. The many approximations used in the postulation of classical damping may be grouped into three categories.

The first technique involves the construction of a damping matrix \mathbf{C} that is classical at the outset. This approach is particularly useful for a complex system with similar damping mechanisms distributed throughout the system. An example is a multistory

building with a nearly identical floor plan and similar structural materials on each story. In contrast to the construction of M and K , the damping matrix C for many complex structures is neither calculated from the structural dimensions nor the damping properties of the constituent structural materials. That should not be surprising since the properties of many damping mechanisms are not known precisely. It would seem impractical to try to account theoretically for the energy dissipated in mechanisms such as friction at steel connections, opening and closing of microcracks in concrete, or the friction between the structure itself and a non-structural member such as a fireproofing partition wall. For a large and complex structure, the damping matrix C is usually estimated from the modal damping ratios, which are themselves estimated from available data based upon experimentation on the concerned or similar structures. If either equation [10] or [11] is incorporated as a constraint in the estimation, a classical damping matrix C will always be obtained. Other constraints may be used alternatively, but all such constraints must be derivable from eqn [12].

A second type of approximation that results in classical damping is simply to ignore the off-diagonal elements of the modal damping matrix. This procedure is termed the decoupling approximation in damping, and is commonly used when the off-diagonal elements of D are small. Many different arguments, some more appealing than others, have been given in support of the procedure. Intuitively, if the off-diagonal elements of D are small in magnitude, these elements would only represent second-order effect and can be ignored. Thus, the errors introduced by the decoupling approximation in damping should be small if D is diagonally dominant. Even when the off-diagonal elements of D are of the same order as the diagonal ones, the sometimes positive and sometimes negative off-diagonal elements of D would at least partially annihilate the influence of each other in coupling. This would lead to an overall system response that is practically the same as if the off-diagonal elements of D were absent.

An equally persuasive and intuitive argument may be made in the frequency domain. For many structures, the nonzero natural frequencies do not cluster around each other. Suppose the natural frequencies $\omega_i = \sqrt{\lambda_i}$ of a system are distinct and well-separated: $|\omega_i - \omega_j| \gg 1$ if $i \neq j$. Then any two normal modes of the system are relatively removed from each other in the frequency domain. For this reason, the damped system may be considered decoupled for all practical purposes. Yet another argument for decoupling approximation utilizes the response bounds of a

system. Response bounds are useful in design, and decoupling approximation may sometimes be justified if it generates response bounds that are close to the exact bounds. Over the years, large-frequency separation of the normal modes or diagonal dominance of D have been accepted as sufficient conditions for the decoupling approximation in damping. However, examples have been constructed in recent years to show, surprisingly, that enhancing the diagonal dominance of D or increasing the frequency separation of the normal modes may not reduce coupling. Contrary to widely accepted beliefs, the effect of coupling can even increase over a certain range. Practically speaking, there is no objection to using the decoupling approximation in damping. Nevertheless, rigorous analysis of errors committed by such an approximation has not been reported in the literature.

A third type of approximation involves the use of indices of coupling. There are many indices of coupling, but they all quantify the extent of coupling in a damped system in some ways. Coupling indices are sometimes referred to as coupling ratios, indices of proportionality, or commutativity factors. One of the first indices thus proposed can be brought up in an intuitive way. Recall that a classically damped system must satisfy the commutativity condition [12]. Define $E = CM^{-1}K - KM^{-1}C$. Since M , C , and K are symmetric, $E^T = -E$. Thus E is a skew-symmetric matrix and its diagonal elements must vanish. The off-diagonal elements of E are numerical indicators of coupling. They are zero only if damping is classical. Let σ be the sum of magnitudes of the off-diagonal elements of E . It is obvious that σ can be taken as an index of coupling. Many different indices of coupling have been defined, and some are defined in the frequency domain. Apparently, if appropriate coupling indices are small, a damped system may be solved by invoking the decoupling approximation in damping. If the indices are not sufficiently small, the modal damping D may be replaced by a selected diagonal matrix whose elements are determined through D and the coupling indices. In essence, a different decoupled system is substituted, and the response of the new system should resemble the original one. In practice, coupling indices that can be easily computed have rather limited applicability. Also, the errors of approximation are known to depend on the excitation, and it may be necessary to use different indices for different forms of excitation.

Further research will be needed to clarify the various issues connected with approximation by classical damping. At the present time, the tremendous conceptual and computational advantages provided by a

decoupled system often outweigh the compromises needed to impose classical damping.

Nonclassical Damping

A system is said to be nonclassically damped if it is not decoupled by classical modal analysis. A system with nonclassical damping does not possess the same normal modes of vibration as the undamped system. In general, vibrating systems are nonclassically damped. As explained in the last section, each approximation of damping as classical requires certain assumptions and has only a limited range of applicability.

The assumption of classical damping is not appropriate if a damped system is composed of two or more parts with significantly different levels of damping. Certain structure–soil systems constitute one class of examples. If a structure has very short natural periods, then the underlying soil region cannot be regarded as rigid and soil–structure interaction must be taken into account. The modal damping ratio for a soil region is typically very different from that for a structure, say 15–20% for soil as compared to 3–5% for the structure. There will be coupling between the soil and structure subsystems induced by strong soil–structure interaction. It would not be proper to assume that the structure–soil system has classical damping, even if the soil and structure subsystems can be taken as classically damped. The assumption of classical damping may also be inappropriate for structures mounted on base isolation systems, or for structures containing special energy-dissipating devices.

A variety of methods, both approximate and exact, are available for the analysis of nonclassically damped systems. For the purpose of exposition, these methods are grouped into four categories. The first technique involves the use of a truncated set of normal modes. In many systems, only the modes associated with lower frequencies contribute significantly to the response. Thus, in the solution of system [9], it would only be necessary to consider a small subset of the n coupled equations. This approximate technique can be highly efficient. However, examples have been constructed to show that such an approach can generate substantial errors in some applications.

A second type of approximate methods for treating nonclassical damping is system iteration. Express the modal damping matrix \mathbf{D} as a matrix sum of its diagonal and off-diagonal elements: $\mathbf{D} = \mathbf{F} + \mathbf{G}$, where \mathbf{F} is a diagonal matrix made up of the diagonal elements of \mathbf{D} . For a system with weakly nonclassical damping, the elements of \mathbf{G} are small. An approximate solution can then be obtained through the use

of matrix perturbation series. When the elements of \mathbf{G} are not small compared to those of \mathbf{F} , a matrix iterative scheme has been devised for approximate solution. At each iteration, it is only necessary to tackle a decoupled system. An implicit assumption with any iterative method is that only a small number of iterations are required for accurate solution. However, this is not always true.

As a third approach, the simultaneous reduction of \mathbf{M} , \mathbf{C} , and \mathbf{K} to certain patterned forms will be addressed. From a mathematical viewpoint, modal analysis is a method for reducing \mathbf{M} and \mathbf{K} to diagonal forms simultaneously. In a nonclassically damped system, modal transformation does not diagonalize the damping matrix \mathbf{C} . Nevertheless, it may still be possible to reduce \mathbf{M} , \mathbf{C} , and \mathbf{K} to upper triangular forms by a common similarity transformation. Afterwards, the system can be solved by back-substitution. A necessary and sufficient condition for the simultaneous reduction to triangular forms is that \mathbf{M} , \mathbf{C} , and \mathbf{K} generate a solvable Lie algebra. It is also possible to consider the simultaneous reduction of \mathbf{M} , \mathbf{C} , and \mathbf{K} to other patterned forms. Each such conversion requires the satisfaction of certain conditions. In general, these methods of simultaneous reduction of the coefficient matrices are only applicable to a small subclass of nonclassically damped systems.

A fourth approach to nonclassically damped systems is complex modal analysis. This is a powerful method for decoupling nonclassically damped systems in the state space. As explained in an earlier section, classical modal analysis only utilizes real modes to decouple eqn [3] when damping is classical. If damping is nonclassical, recast eqn [3] into a first-order form:

$$\mathbf{R}\dot{\mathbf{y}} + \mathbf{S}\mathbf{y} = \mathbf{g}(t) \quad [13]$$

for which:

$$\mathbf{R} = \begin{bmatrix} \mathbf{0} & \mathbf{M} \\ \mathbf{M} & \mathbf{C} \end{bmatrix} \quad [14]$$

$$\mathbf{S} = \begin{bmatrix} -\mathbf{M} & \mathbf{0} \\ \mathbf{0} & \mathbf{K} \end{bmatrix} \quad [15]$$

and $\mathbf{y}^T = [\dot{\mathbf{q}}^T, \mathbf{q}^T]^T$, $\mathbf{g}^T(t) = [\mathbf{0}^T, \mathbf{f}^T(t)]^T$. Although the coefficient matrices \mathbf{R} and \mathbf{S} are symmetric, they are no longer definite. For this reason, the associated symmetric eigenvalue problem

$$\alpha\mathbf{R}\mathbf{v} + \mathbf{S}\mathbf{v} = \mathbf{0} \quad [16]$$

will admit complex eigenvalues α and complex eigenvectors \mathbf{v} . These eigenvectors are known as complex

modes, and they can still constitute a modal transformation to decouple eqn [13]. Compared to classical modal analysis, the method of complex modes is rather computationally intensive. In addition, the physical significance of various components of this exact method is not fully understood. There are alternative formulations of complex modal analysis, but they all aim at decoupling a nonclassically damped system in the state space.

The analysis of nonclassically damped systems has received a great deal of attention in recent years, due in part to the design of base-isolated structures and the use of special energy-dissipating devices in system control. As the field of vibration continues to grow, the development of new and improved techniques for nonclassical damping can certainly be anticipated.

Nomenclature

D	modal damping matrix
q	vector of system response
u	column vector of order n
U	modal matrix
α	scalar constant
Λ	spectral matrix

LIQUID SLOSHING

R A Ibrahim, Wayne State University, Detroit, MI, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0086

Sloshing means any oscillatory motion of the liquid free surface inside its container. It is created due to any disturbance to partially filled liquid containers. Depending on the excitation and container shape, the liquid free surface can experience different types of motion ranging from simple planar, nonplanar, rotational, irregular beating, symmetric, asymmetric, quasiperiodic, to chaotic. When interacting with the elastic structure of its container or its support structure, the liquid free surface can exhibit fascinating types of motion in the form of energy exchange with interacting modes. Recent studies reported complex liquid free surface motions, which occur in the presence of nonlinear resonance conditions such as

internal resonance and parametric resonance conditions. One may classify liquid motion into the following categories:

1. Normal sloshing resulting from translational or pitching excitation of the liquid container.
2. Under vertical (parametric) excitation, and depending on the excitation amplitude and frequency, the liquid free surface may exhibit intermittent small oscillations, subharmonic, and chaotic oscillations.
3. Rotational (swirl) sloshing occurs at a frequency near the natural frequency of the first antisymmetric mode. The mechanism that creates rotary fluid motion is a nonlinear coupling of the fluid motion parallel with and perpendicular to the excitation plane in circular upright tanks.
4. Vortex formation during the draining of liquid from the tank.

5. Surface spray, spatial resonance, and cross-waves.
6. Dome impact due to a sudden acceleration or deceleration.
7. Low-gravity phenomena where surface tension is dominant. The liquid may be oriented randomly within the tank depending essentially upon the wetting characteristics on the tank wall.
8. Modulated free surface motion, which occurs when the liquid free surface motion interacts with the elastic support structural dynamics in the neighborhood of internal resonance conditions.

Liquid containers constitute major components in a number of dynamical systems such as aerospace vehicles, road tankers, liquefied natural gas carriers, and elevated water towers. The dynamic behavior of these systems is greatly affected by the dynamics of the liquid free surface. The basic problem of liquid sloshing involves the estimation of the liquid natural frequencies, hydrodynamic pressure distribution, forces, and moments. These parameters have a direct effect on the dynamic stability and performance of moving containers. However, under external excitation, it is important to determine the fluid free surface natural frequencies and mode shapes in order to avoid the occurrence of resonance and large sloshing amplitudes.

The problem is of great concern to civil engineers and seismologists in studying earthquake effects on large dams, oil tanks, water reservoirs, and elevated water towers. It is also important for aerospace engineers involved in the design and development of high-speed aircraft and large rockets. Near zero gravity, the liquid volume takes an arbitrary orientation and is difficult to handle. Liquid sloshing in a moving container creates a broad class of problems of practical safety importance, including tank trucks on highways, and liquid cargo in ocean-going vessels. In populated cities, gasoline and other flammable liquid tankers are prone to rollover accidents while entering and exiting highways. This is a difficult mathematical problem to solve analytically, because the dynamic boundary condition (Bernoulli's equation) at the free surface is nonlinear and the position of the free surface varies with time in a manner not known *a priori*.

Analytical solutions are limited to regular geometric tank shapes, such as cylindrical and rectangular. The nature of slosh loading in cylindrical tanks, and its prediction, is probably understood than for prismatic tanks. However, analytical techniques for predicting large-amplitude sloshing are still not fully developed. Such loads are extremely important in designing the support structure and internal components of vehicle tanks.

The liquid motion inside a tank has an infinite number of natural frequencies, but it is the lowest few modes that are most likely to be excited by the motion of a vehicle. Most studies have therefore concentrated on investigating forced harmonic oscillations near the lowest natural frequency that can be predicted by the linear theory of fluid field equations. Nonlinear effects result in the frequency of maximum response being slightly different from the natural frequency, and dependent on amplitude. These nonlinear effects include amplitude jump, parametric resonance, chaotic liquid surface motion, and nonlinear sloshing mode interaction (internal resonance among the liquid sloshing modes).

Sloshing phenomena in moving rectangular tanks can usually be described by considering only two-dimensional fluid flow. Sloshing in spherical or cylindrical tanks, however, must usually consider three-dimensional flow effects. Tanks with two-dimensional flow are divided into two classes: low and high liquid fill depths. The low fill depth case is represented by $h/a < 0.2$, where h is the still liquid depth and a is the tank width in the direction of motion. The low fill depth case is characterized by the formation of hydraulic jumps and traveling waves for excitation periods around resonance. At higher fill depths, large standing waves are usually formed in the resonance frequency range. When hydraulic jumps or traveling waves are present, extremely high impact pressures can occur on the tank walls. Impact pressures are only measured experimentally and cannot be estimated theoretically.

Liquid Free and Forced Sloshing

The theory of liquid sloshing dynamics in partially filled containers is based on developing the fluid field equations. The boundary value problem is usually solved for either the modal analysis or the response to external excitations. The general equations of motion of fluids in closed containers can be simplified by assuming that the container is rigid and impermeable. The fluid field equations in a container undergoing planar motion are obtained based on the assumption that the fluid is inviscid, incompressible, and initially irrotational. Capillary or surface tension effects are ignored in regular gravitational field. The tank may be displaced along some trajectory in space. It is convenient to refer the fluid motion to a moving coordinate system as the variables are measured by a measuring device that is moving relative to the inertial frame. The fluid equation of motion will be developed with reference to the stationary and moving coordinates, as shown in Figure 1. Let $O'X'Y'Z'$ be a stationary

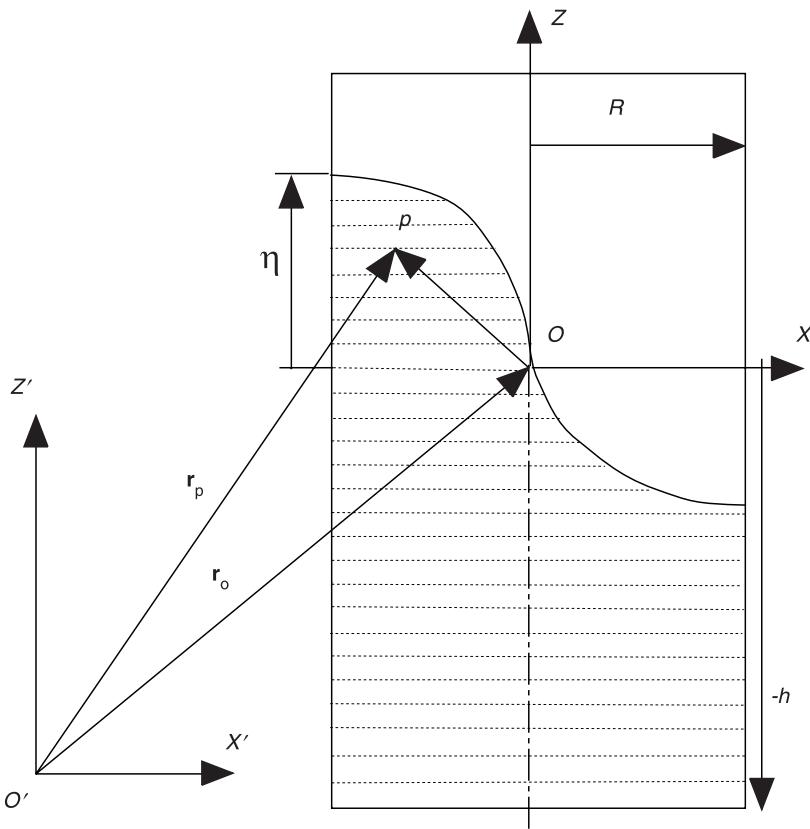

Figure 1 Fixed and moving coordinates for describing fluid particle motion.

coordinate frame in which the plane $O'X'Y'$ coincides with the undisturbed free fluid surface. For irrotational fluid motion there exists a velocity potential Φ function, whose negative gradient gives the fluid velocity, i.e.:

$$\mathbf{q} = -\nabla\Phi \quad [1]$$

where:

$$\nabla = \frac{\partial}{\partial r} \mathbf{i}_r + \frac{l}{r} \frac{\partial}{\partial \theta} \mathbf{i}_\theta + \frac{\partial}{\partial z} \mathbf{i}_z$$

for cylindrical coordinates or:

$$\nabla = \frac{\partial}{\partial x} \mathbf{i} + \frac{\partial}{\partial y} \mathbf{j} + \frac{\partial}{\partial z} \mathbf{k}$$

for rectangular coordinates, and \mathbf{q} is the fluid vector velocity.

Let $OXYZ$ be another coordinate frame fixed to the tank such that the OXY plane coincides with the undisturbed free surface. Let \mathbf{V}_0 be the velocity of the origin O relative to the fixed origin O' . The fluid

particle velocity \mathbf{q}_{rel} relative to the moving coordinates is given by:

$$\mathbf{q}_{\text{rel}} = \mathbf{q} - \mathbf{V}_0 = -\nabla\Phi - \mathbf{V}_0 \quad [2]$$

The velocity potential function Φ can now be split into two functions: a disturbance potential function $\tilde{\Phi}$, which accounts for the fluid relative to the tank, and a potential function Φ_0 , which defines the tank motion, i.e.:

$$\Phi = \tilde{\Phi} + \Phi_0 \quad [3]$$

Both $\tilde{\Phi}$ and Φ_0 should satisfy Laplace's (continuity) equation:

$$\nabla^2\Phi = 0 \quad [4]$$

The velocity of the tank:

$$\mathbf{V}_0 = \dot{X}_0 \mathbf{i} + \dot{Z}_0 \mathbf{k} \quad [5a]$$

can also be expressed in terms of cylindrical coordinates as:

$$\mathbf{V}_0 = (\dot{X}_0 \cos \theta) \mathbf{i}_r - (\dot{X}_0 \sin \theta) \mathbf{i}_\theta + \dot{Z}_0 \mathbf{i}_z \quad [5b]$$

In this case, one can obtain Kelvin's equation for an unsteady flow:

$$\frac{P}{\rho} + \frac{1}{2} \left(\vec{\nabla} \tilde{\Phi} \vec{\nabla} \tilde{\Phi} \right) + (g + \ddot{Z}_0) Z + \ddot{X}_0 r \cos \theta - \frac{\partial \tilde{\Phi}}{\partial t} = 0 \quad [6]$$

where ρ is the fluid density and g is the gravitational acceleration. Eqn [6] is the fluid field equation referred to the moving coordinate system that is moving with acceleration components \ddot{X}_0 and \ddot{Z}_0 . The complete solution of eqn [4] must satisfy the relevant boundary conditions of the problem. These conditions are:

1. At the wetted rigid wall and bottom, the velocity component normal to the boundary must vanish.
2. At the free surface, the pressure is zero, which gives the dynamic free surface condition. It is obtained from eqn [6] after setting $P = 0$.
3. The kinematic free surface condition requires that the vertical velocity of a fluid particle located on the free surface should be the same as the vertical velocity of the free surface itself.

The solution of such boundary value problem for a rectangular tank is:

$$\begin{aligned} \tilde{\Phi}(X, Y, Z, t) &= \sum_{m=0}^{\infty} \cdot \sum_{n=1}^{\infty} \alpha_{mn}(t) \cos \left(\frac{m\pi x}{a} \right) \\ &\times \cos \left(\frac{n\pi y}{b} \right) \cosh[k_{mn}(Z + h)] \end{aligned} \quad [7a]$$

where a and b are the tank width and breadth, respectively, and:

$$k_{mn} = \pi \sqrt{\frac{m^2}{a^2} + \frac{n^2}{b^2}}$$

m and n are positive integers.

For an upright circular container the velocity potential function takes the form:

$$\begin{aligned} \tilde{\Phi}(r, \theta, Z, t) &= \sum_{m=0}^{\infty} \cdot \sum_{n=1}^{\infty} \alpha_{mn}(t) J_m(\lambda_{mn}r) \\ &\times \cos m\theta \frac{\cosh[\lambda_{mn}(Z + h)]}{\cosh \lambda_{mn}h} \end{aligned} \quad [7b]$$

where $J_m(\cdot)$ is the Bessel function of the first kind of order m , $\lambda_{mn} = \xi_{mn}/R$ are the roots of $\partial J_m(\lambda_{mn}r)/\partial r|_{r=R} = 0$. An expression for the free surface elevation η can be written in the series form,

for the rectangular tank:

$$\eta(X, Y, t) = \sum_{m=0}^{\infty} \cdot \sum_{n=1}^{\infty} A_{mn}(t) \cos \left(\frac{m\pi x}{a} \right) \cos \left(\frac{n\pi y}{b} \right) \quad [8a]$$

and for the circular tank:

$$\eta(r, \theta, t) = \sum_{m=0}^{\infty} \cdot \sum_{n=1}^{\infty} A_{mn}(t) J_m(\lambda_{mn}r) \cos m\theta \quad [8b]$$

The generalized coordinates α_{mn} and A_{mn} are time-dependent and obtained through satisfying the free surface conditions. Note that the time dependence of the wave height results in variation of the position of the container center of mass. Introducing the expressions (7) and (8) in the nonlinear fluid free surface boundary condition given by eqn [6] after setting $P = 0$ and the kinematic condition produces a major difficulty because of the high degree of nonlinearity of different modes. In order to get quantitative information, it appears essential to introduce approximation in the free surface equations. Note that the analysis can be significantly simplified if the fluid field equations are linearized. In this case, one can determine all dynamical parameters such as natural frequencies, mode shapes, hydrodynamic pressure, and sloshing forces and moments. Hydrodynamic pressure can be estimated in terms of the potential function using eqn [6]. The normal mode frequencies can be determined from the linearized free surface boundary condition:

$$\frac{\partial \tilde{\Phi}}{\partial t} + g\eta = 0 \quad [9]$$

Substituting eqns [7] and [8] into [9] gives the natural frequencies, for a rectangular tank:

$$\omega_{mn}^2 = g k_{mn} \tanh(k_{mn}h) \quad [10a]$$

and for a cylindrical container:

$$\omega_{mn}^2 = \frac{g \xi_{mn}}{R} \tanh(\xi_{mn}h/R) \quad [10b]$$

Under forced sinusoidal excitation $\delta \cos \Omega t$ along $\theta = 0$, the total force exerted by the fluid on to the tank walls, for a circular cylindrical tank, is estimated by integrating the hydrodynamic pressure over the wetted area and the force along the x -axis is:

$$F_x(t) = M\delta\Omega^2 \sin\Omega t \\ \times \left\{ 1 + \sum \frac{R/h}{\xi_{mn}} \frac{\Omega^2}{(\omega_{mn}^2 - \Omega^2)} \frac{2 \tanh(\xi_{mn}h/R)}{(\xi_{mn}^2 - 1)} \right\} [11]$$

where M is the total mass of the liquid. The liquid sloshing force given by expression [11] is accurate as long as the excitation frequency is not close to the liquid natural frequency. Near resonance, one should perform nonlinear analysis.

Parametric Sloshing

In 1831, Faraday observed that the fluid inside a glass container oscillates at one-half of the external vertical excitation frequency. Generally, the liquid free surface dynamics under parametric excitation is described by the system of Mathieu equations:

$$\frac{d^2 A_{mn}}{dt^2} + 2\zeta_{mn}\omega_{mn} \frac{dA_{mn}}{dt} + \omega_{mn}^2(1 - 2Z_0 \cos \Omega t)A_{mn} = 0 [12a]$$

where A_{mn} is a nondimensional wave height parameter, ω_{mn} and ζ_{mn} are the sloshing mode natural frequency and damping ratio, respectively, Ω is the excitation frequency, and Z_0 is the excitation amplitude parameter. Depending on the excitation amplitude, frequency, and damping ratio the solutions of eqn [12a] can be stable or unstable. The regions of instability are given by the inequality:

$$1 - \sqrt{Z_0^2 - 4\zeta_{mn}^2\omega_{mn}^2} < \left(\frac{\Omega}{2\omega_{mn}}\right)^2 [12b]$$

$$< 1 + \sqrt{Z_0^2 - 4\zeta_{mn}^2\omega_{mn}^2}$$

It can be shown that if the plane free surface is unstable, the resulting motion could have frequency $k/2$ times the excitation frequency, where k is an integer. Thus, the motion might be a half-frequency subharmonic, harmonic, or superharmonic; however, experimental results usually show the half-frequency subharmonic. In most real fluids, there is sufficient damping such that the unstable regions, except the first several unstable ones, will be located completely above threshold excitation amplitude.

Eqn [12a] is adequate to predict the stability of fluid motion. However, it fails to give a unique bounded solution for the liquid response wave amplitude. In this case, it is important to include the liquid free surface nonlinearity. The modern theory of

nonlinear dynamics has attracted several investigators to revisit the problem of parametric excitation of liquid in closed containers. The most interesting phenomena, including chaotic behavior, are due to internal resonance, which occurs when the ratios of natural frequencies of two or more modes of motion are near some small positive integers. In the case of a nearly square container, all the nonsymmetric modes have nearly equal natural frequencies independent of the fluid depth. The liquid free surface may be capable of exhibiting periodic and quasiperiodic standing, as well as traveling waves.

Under parametric random excitation, one can determine the stochastic stability of the liquid free surface in terms of mean square response or sample (with probability one) stability analysis. The linear stability analysis is based on the stochastic differential equation of the sloshing mode mn , i.e.:

$$a''_{mn} + 2\zeta_{mn}a'_{mn} + [1 + \xi''(\tau)]a_{mn} = 0 [13]$$

where a_{mn} is a dimensionless liquid free surface amplitude of mode mn , a prime denotes differentiation with respect to the nondimensional time parameter $\tau = \omega_{mn}t$, ω_{mn} is the natural frequency of the sloshing mode mn , ζ_{mn} is the corresponding damping ratio, and $\xi''(\tau)$ is a dimensionless vertical random acceleration of spectral density $2D$. The mean-square stability of the response of eqn [13] is given by the condition:

$$D/2\zeta_{mn} < 1 [14a]$$

On the other hand, the sample stability condition is:

$$D/2\zeta_{mn} < 2 [14b]$$

It was observed experimentally that the liquid free surface might follow one of the following regimes:

1. Zero liquid free surface motion, characterized by a delta Dirac function of the response probability density function. The excitation spectral density of this regime is so weak that it overcomes the liquid damping force.
2. Uncertain zero-motion of the liquid free surface, characterized by occasional small surface oscillations.
3. Partially developed (or intermittent) random liquid sloshing, characterized by the occurrence of significant liquid-free surface motion for a certain period of time which then ceases for another period of time. At higher excitation spectral density, the time period of liquid motion exceeds the time of zero motion.

4. Fully developed random sloshing. This regime exhibits continuous random liquid motion for all excitation levels, exceeding the afore-mentioned ranges. When the first symmetric sloshing mode is excited, other higher sloshing modes are excited as well. This is why the bandwidth of the symmetric mode excitation is narrow.

Equivalent mechanical models are useful in solving the complete dynamic problem of a system containing liquid. They can be incorporated in the overall dynamic analysis liquid tanks. This will be discussed in the next section.

Equivalent Mechanical Models

Experimental and analytical studies of liquid sloshing in different containers revealed that approximately the lower third of the liquid behaves essentially as a rigid mass, while most of the sloshing effects occur near the surface. This is in fact the basis upon which the idea of equivalent mechanical models are developed. A realistic representation of the liquid dynamics inside closed containers may be introduced by an equivalent mechanical system. The equivalence is taken in the sense of equal resulting forces and moments acting on the tank wall. The characteristics of the models are determined only from consideration of fluid motion in a stationary tank. Dashpot elements can also be incorporated to account for energy dissipation. The principles of constructing a mechanical model are based on satisfying the following conditions:

1. The equivalent masses and moments of inertia must be preserved.
2. The center of gravity must remain the same for small oscillations.
3. The system must possess the same modes of oscillations and produce the same damping forces.
4. The force and moment components under certain excitation of the model must be completely equivalent to that produced by the actual system.

Generally, the liquid hydrodynamic pressure in moving rigid containers is comprised of two distinct components. One component is directly proportional to the acceleration of the tank. This component is caused by part of the fluid moving in unison with the tank. The second component is known as convective pressure and experiences sloshing at the free surface. This component can be modeled by a set of mass spring-dashpot systems or by a set of pendulums. For the first liquid sloshing mode, an equivalent pendulum may be used. Three dynamic regimes are possible, as demonstrated in Figure 2:

1. Small oscillations, in which the fluid free surface remains planar without rotation of its nodal diameter (Figure 2A). This regime can be described by a linear equation for the first asymmetric sloshing mode which is equivalent to a pendulum describing small oscillations such that $\sin \theta \approx \theta$.
2. Relatively large amplitude oscillations, in which the liquid free surface experiences both nonplanar and rotational motions (Figure 2B). This regime is described by a differential equation with weak nonlinearity and can be analyzed using the standard perturbation techniques. The equivalent mechanical model is a simple pendulum describing relatively large motions such that $\sin \theta \approx \theta - \theta^3/3!$.
3. Strongly nonlinear motion, where the nonlinearity is mainly due to rapid-velocity changes associated

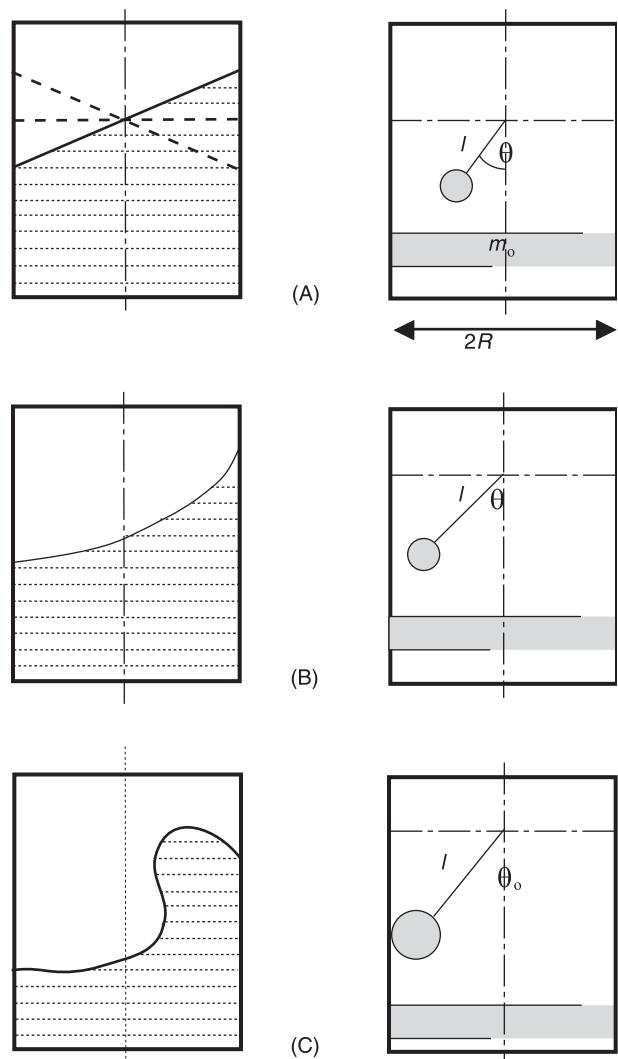

Figure 2 Regimes of liquid-free surface motion and their modeling. (A) Linear modeling; (B) weakly nonlinear modeling; (C) hydrodynamic impact modeling.

with hydrodynamic pressure impacts of the liquid motion close to the free surface (Figure 2C). The velocity changes of the liquid free surface are usually treated as being instantaneous (velocity jumps) and they lead to various strongly nonlinear features of the system behavior. The equivalent mechanical model of this regime is a pendulum describing impacts with the tank walls.

Expressions for the sloshing forces and moments are available for a number of simple tank shapes, such as rectangular, cylindrical, and ellipsoidal.

Model Parameters for Rectangular Tank

For a rectangular tank with cross-section dimension $a \times b$, and liquid depth b , the liquid free surface wave height $\eta(x, y)$ and natural frequencies ω_{mn} are given by the following expressions:

$$\eta(x, y) = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} A_{mn} \cos \left[\frac{m\pi}{a} x \right] \cos \left[\frac{n\pi}{b} y \right] \quad [15a]$$

$$\omega_{mn}^2 = g\pi \sqrt{\left(\frac{m^2}{a^2} + \frac{n^2}{b^2} \right)} \tanh \left(\pi \sqrt{\left(\frac{m^2}{a^2} + \frac{n^2}{b^2} \right)} b \right) \quad [15b]$$

where m and n are integers, and a and b are the tank width and breadth, respectively. For specific tank dimensions $a \times b$ the liquid natural frequencies increase with the liquid depth up to $b/a = 1$; then it becomes almost constant as the liquid depth increases.

The pendulum model For the pendulum model shown in Figure 3, each pendulum represents one sloshing mode. A rigidly attached mass is chosen to represent the effect of the liquid that moves in unison with the tank as a frozen mass. By comparing the expression of hydrodynamic force due to lateral excitation of the tank and the total force expression due to the system of pendulums and the rigid mass, the following model parameters are obtained:

$$\begin{aligned} m_n &= \frac{8\rho ba^2}{(2n-1)^3 \pi^3} \tanh(2n-1) \frac{\pi b}{a} \\ m_0 &= \rho abh - \sum_{n=1}^{\infty} m_n \\ \ell_n &= \frac{a}{(2n-1)\pi} \coth(2n-1) \frac{\pi b}{a} \\ H_n &= \ell_n + \frac{b}{2} - \frac{2a}{(2n-1)\pi} \tanh(2n-1) \frac{\pi b}{a} \end{aligned} \quad [16]$$

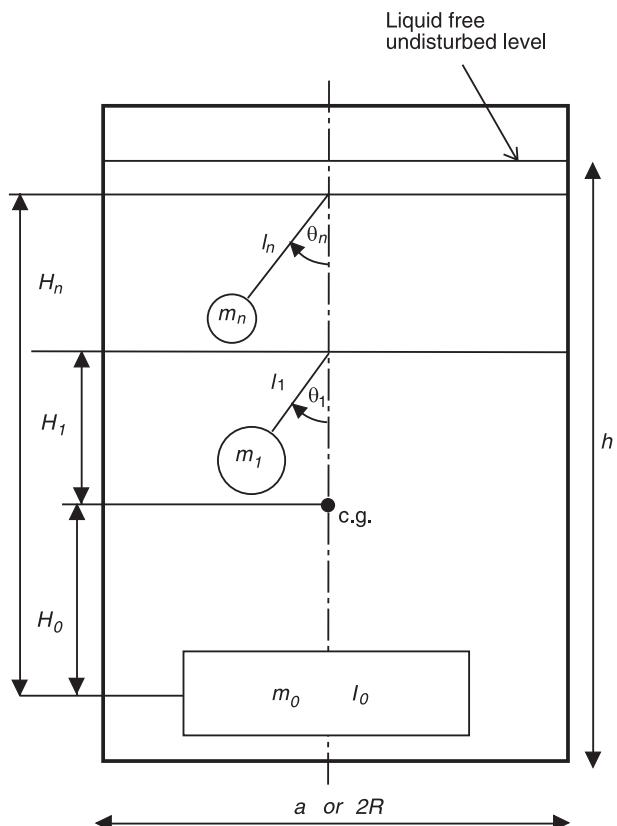

Figure 3 Pendulum equivalent modeling.

Similarly, the resulting moment about the center of mass yields the following constants. The mass moment of inertia of the frozen mass is:

$$I_0 = I_F - m_0 H_0^2 - \sum_{n=1}^{\infty} m_n (H_n - \ell_n)^2 \quad [17a]$$

I_F is the fluid mass moment of inertia given by the expression:

$$I_F = \left\{ \rho abh \frac{b^2}{12} + \frac{a^2}{16} - 2a^2 \sum_{n=1}^{\infty} \frac{16}{(2n-1)^4 \pi^4} \right. \\ \left. \times \left[1 - \frac{2a}{(2n-1)\pi b} \tanh(2n-1) \frac{\pi b}{2a} \right] \right\} \quad [17b]$$

With reference to Figure 3, m_n is the n th pendulum mass, and l_n represents the n th pendulum length. H_0 is the distance of the tank center of mass to the center of mass of the frozen fluid portion of mass m_n . H_n is the distance of the n th pendulum support point to the tank center of mass.

The mass spring model The parameters of mass spring equivalent model shown in Figure 4 are:

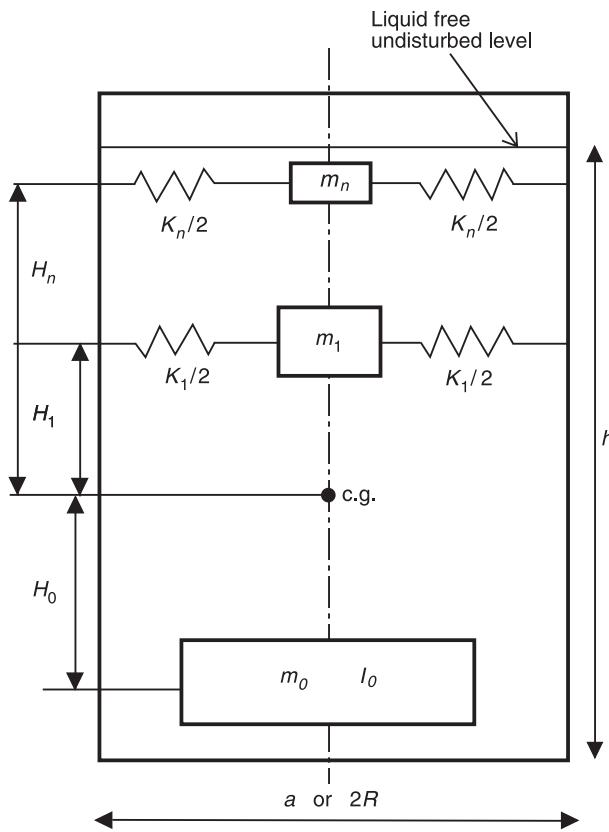

Figure 4 Mass spring equivalent modeling.

$$\begin{aligned} K_n &= \frac{8\rho gab}{\pi^2} \left(\tanh \frac{\pi(2n-1)b}{a} \right)^2 \\ m_n &= \frac{8\rho a^2 b}{\pi^2 (2n-1)} \tanh \left((2n-1) \frac{\pi b}{a} \right) \\ m_0 &= m_T - \sum_{n=1}^{\infty} m_n \end{aligned}$$

where m_T is the total mass of the liquid:

$$\begin{aligned} H_n &= \frac{b}{2} - \frac{2a}{(2n-1)\pi} \tanh \left((2n-1) \frac{\pi b}{2a} \right) \\ H_0 &= \frac{1}{m_0} \sum_{n=1}^{\infty} m_n H_n \end{aligned} \quad [18]$$

for one mass spring equivalent modeling:

$$\begin{aligned} I_0 + m_0 \left(H_0 - \frac{b}{2} \right)^2 + m_1 \left(\frac{b}{2} - H_1 \right)^2 &= \frac{m_T}{12} (b^2 + a^2) \\ \times \left[1 - \frac{4a^2}{a^2 + b^2} + \frac{2.52a^3}{ba^2 + b^3} \tanh 1.57 \frac{b}{a} \right] \end{aligned}$$

For n sloshing modes, the dependence of the mass moment of inertia I_0 on the fluid depth ratio h/a is shown in Figure 5, or given by the following discrete values:

$$I_0 + m_0 H_0^2 + \sum_{n=1}^{\infty} m_n H_0^2 = \begin{cases} 1.0 & \text{for } h/a = 0 \\ 0.45 & \text{for } h/a = 0.5 \\ 0.17 & \text{for } h/a = 1.0 \\ 0.45 & \text{for } h/a = 2.0 \end{cases} \quad [19]$$

Model Parameters for Cylindrical Tank

The liquid free surface wave height and natural frequencies of a circular upright tank are, respectively:

$$\eta(r, \theta) = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} A_{mn} \sin(m\theta) \times \cosh(\xi_{mn} b/R) J_m(\xi_{mn} r/R) \quad [20a]$$

$$\omega_{mn}^2 = \frac{g\xi_{mn}}{R} \tanh(\xi_{mn} b/R) \quad [20b]$$

where R is the tank radius.

The same mechanical models shown in Figures 3 and 4 are also applied to the cylindrical tank with radius R . With reference to Figure 3, and for both models the following parameters are common:

$$m_T = \pi \rho R^2 b \quad I_{\text{rigid}} = 4m_T R^2 \left[\frac{1}{12} \left(\frac{b}{2R} \right)^2 + \frac{1}{16} \right]$$

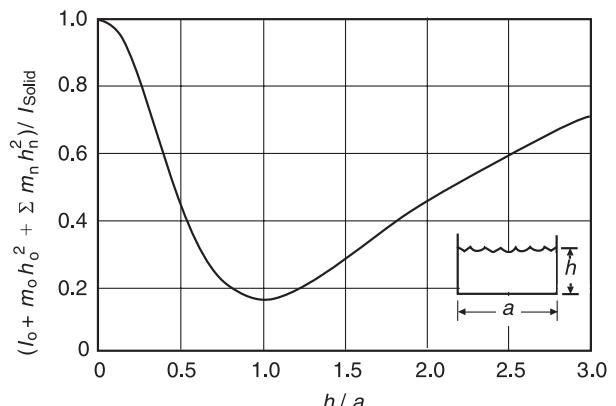

Figure 5 Ratio of effective liquid to rigid moment of inertia as function of liquid depth ratio for rectangular tanks. From Abramson HN (ed.) (1966) *The Dynamic Behavior of Liquids in Moving Containers*. SP 106. NASA.

$$\begin{aligned}
I_0 + m_0 H_0^2 + m_1 (H_1 + NL_1)^2 \\
= I_{\text{rigid}} + m_T \left(\frac{b}{2} \right) - \frac{m_T R^2}{2} \\
\times \left[1.995 - \frac{2R}{b} \left(\frac{1.07 \cosh 1.84(b/R) - 1.07}{\sinh 1.84(b/R)} \right) \right] \quad [21]
\end{aligned}$$

The pendulum model

$$\begin{aligned}
L_1 &= \frac{d}{3.68} \coth 3.68 \frac{b}{d} \\
m_1 &= m_T \left(\frac{d}{4.4b} \right) \tanh 3.68 \frac{b}{d} \\
m_0 &= m_T - m_1 \quad \ell_1 = - \frac{d}{7.36} \cosh 7.36 \frac{b}{d} \\
\ell_0 &= \frac{m_T}{m_0} \left[\frac{b}{2} - \frac{d^2}{8b} \right] - (\ell_1 + L_1) \frac{m_1}{m_0} \quad [22]
\end{aligned}$$

The mass spring model

$$\begin{aligned}
K_1 &= m_T \left(\frac{g}{1.19b} \right) \left(\tanh 3.68 \frac{b}{d} \right)^2 \\
m_1 &= m_T \left(\frac{d}{4.4b} \right) \tanh 3.68 \frac{b}{d} \\
m_0 &= m_T - m_1 \quad \ell_1 = \frac{d}{3.68} \tanh 3.68 \frac{b}{d} \\
\ell_0 &= \frac{m_T}{m_0} \left[\frac{b}{2} - \frac{d^2}{8b} \right] - \ell_1 \frac{m_1}{m_0} \\
b_0 &= b_{cg} + \frac{1}{m_0} \sum_{n=1}^{\infty} (b_n + b_{cg}) m_n \\
b_{cg} &= \frac{3L}{4} \left[\frac{(2 - b/L)^2}{3 - b/L} \right] \quad [24]
\end{aligned}$$

The mass moment of inertia of a rigid body I_{rigid} , having the same shape and mass of the liquid, is:

$$\begin{aligned}
I_{\text{rigid}} &= \pi \rho R^4 L \\
&\times \left\{ \frac{b^4}{R^2 L^2} \left[\frac{5 - b/L}{30} - \frac{(4 - b/L)^2}{48(3 - b/L)} \right] \right. \\
&\left. + \frac{b^3}{L^3} \left[\frac{1}{3} - \frac{b}{4L} + \frac{b^2}{20L^2} \right] \right\} \quad [25]
\end{aligned}$$

Since the fluid is not rigid, the above relation overestimates the mass moment of inertia of the fluid. The actual moment of inertia can be obtained by deter-

mining the ratio of the actual liquid to rigid liquid moment of inertia for a cylindrical tank having an identical fluid height and fluid mass, which is shown in Figure 6.

The previous models are very useful in studying the problem of linear sloshing dynamics. For nonlinear sloshing, the amplitude of motion of these elements can be extended to include the model inherent nonlinearities. The nonlinear rotational motion of the liquid free surface can be understood by studying the stability of the forced excitation of the spherical pendulum.

Damping of Liquid Sloshing

Liquid sloshing is usually associated with some energy dissipation due to the effect of boundary layers with the tank walls. Under free oscillations, the motion of the liquid free surface decays due to damping forces created by viscous boundary layers. It is necessary to measure the reduction of the peak of hydrodynamic forces during forced oscillations. The boundary layers approximation techniques can be applied to the case of standing waves where viscous dissipation in an assumed laminar boundary layer is taken to be the primary cause of damping. The analysis is in principle based on successive approximation of the vector potential function \mathbf{A} such that the velocity vector is given in the Helmholtz form:

$$\mathbf{V} = -\nabla\Phi + \nabla \times \mathbf{A} \quad [26]$$

where the first expression stands for the velocity component due to the irrotational flow, while the second takes into account the effect of rotational flow

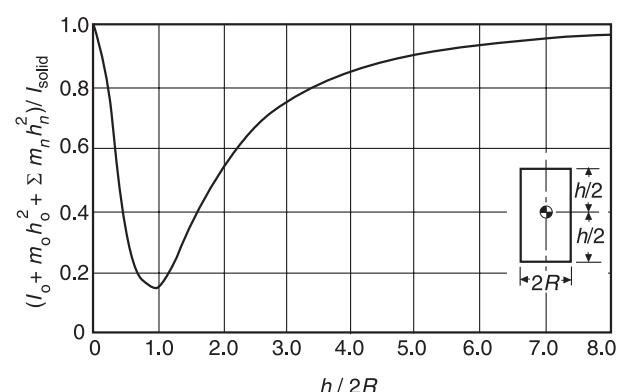

Figure 6 Ratio of effective liquid to rigid liquid moment of inertia as function of liquid depth ratio for cylindrical tanks. From Abramson HN (ed.) (1966) *The Dynamic Behavior of Liquids in Moving Containers*. SP 106. NASA.

adjacent to the walls. Note that the normal velocity at the boundaries must vanish, i.e., $-\nabla\Phi + \nabla \times \mathbf{A} = 0$. Most of the damping takes place at the rigid walls and the damping in a circular cylinder is only 18% less than that for a square tank of the same cross-sectional area. The complete analysis of liquid damping in circular cylindrical containers was developed by Case and Parkinson.

It is not difficult to measure the logarithmic decrement of the first asymmetric sloshing mode. Basically, the damping factor depends on the liquid height, liquid kinematic viscosity, and tank diameter (or tank width for rectangular cross-section). Dimensional analysis and empirical correlations showed that the damping ratio in a circular cylindrical tank is given by the empirical relationship:

$$\zeta = \frac{2.89}{\pi} \sqrt{\frac{\nu}{R^{3/2}g^{1/2}}} \times \left[1 + \frac{0.318}{\sinh(1.84h/R)} \left(\frac{1 - (b/R)}{\cosh(1.84h/R)} + 1 \right) \right] \quad [27a]$$

where ν is the kinematic viscosity, R is the tank radius, and g is the gravitational acceleration. For $h/R > 1$, relation [27a] takes the form:

$$\zeta = \frac{2.89}{\pi} \sqrt{\frac{\nu}{R^{3/2}g^{1/2}}} \quad [27b]$$

This relation can be generalized for other tank shapes:

$$\zeta = C_1 \left(\frac{\nu}{d^{3/2} \sqrt{g}} \right)^{n_1} \quad [27c]$$

where d is the characteristic dimension of the tank, it is the width of rectangular containers, radius for cylindrical or spherical containers, or the radius of the free surface of an axisymmetric tank. The constant C_1 and the exponent n_1 take the values shown in Table 1 for the corresponding tank geometry.

For other tank shapes it is recommended to use $C_1 \approx 1$ and $n_1 \approx 0.5$.

In order to minimize the sloshing hydrodynamic forces acting on the tank, it is desirable to suppress the liquid-sloshing amplitude. The inherent liquid viscosity in tanks without baffles will have a very limited effect in reducing the sloshing amplitude. Ring and cruciform baffles, floating lids and mats, and flexible baffles are very effective in liquid wave control. The effectiveness of damping devices should not be characterized by the amplitude decrement only. However, semiempirical relationships for the

damping contributed by a flat annular ring baffle have been developed in the literature. The total damping of the fundamental antisymmetric mode is due to two main sources. The first is due to the relative motion between the liquid and the tank wall, while the second is due to the relative motion between the liquid and baffles. In considering the design of baffles, the total fluid sloshing force should not exceed a certain prescribed maximum value under all possible combinations of liquid level, tank orientation, and external tank excitation. Another important requirement is to suppress the sloshing effects throughout certain designated frequency ranges in which the liquid oscillations might reinforce the fundamental vibration mode of the vehicle. The flexible baffle might be more effective than rigid baffles for damping slosh in moving containers.

Liquid Sloshing in Road Tankers

The main problems which are of concern in the design of liquid propellant rockets include the motion of the center of mass, the vehicle attitude, and lateral bending of vehicle structure. The sloshing technology developed for space applications is not applicable to road tankers, because emphasis has been placed on frequencies and total forces as they relate to control system requirements, and, therefore, the effects of local peak impact pressure on structural requirements have not been studied to any extent. Further, the excitation amplitudes considered in space applications are too small for road vehicle simulation. In road tankers, the liquid free surface may experience large excursions for even very small motions of the container. This is an undesirable feature, which may considerably endanger the stability and maneuvering quality of the vehicle. This problem is common for fuel or cargo tanks of automotive vehicles, railroad tank cars, fuel tanks of large ships and tankers. The

study of liquid sloshing dynamics within a moving vehicle involves different types of modeling and analyses.

The forces and moments from the liquid load for harmonic oscillation steering are introduced via a mechanical model approach. Each compartment includes one rigid and one moving mass. It is speculated that liquid-carrying vehicles have more accidents than other vehicles in part because of the large movement of the liquid cargo, with the attendant forces and moments. Liquid sloshing during a highway maneuver can lead to lateral and roll instabilities, decreased controllability/maneuverability, and increased stress on tank structures.

When hydraulic jumps or traveling waves are present, extremely high impact pressures can occur on the tank walls in gasoline tankers and ship cargo tanks. The liquid sloshing can be more severe longitudinally than laterally if no transverse baffles are introduced. The longitudinal acceleration peaks are larger than the lateral ones. The liquid impact is probably much more severe to the structure for longitudinal than for lateral sloshing. The peak pressure on the end of the tank is strongly affected by the fill level and the tank length-diameter ratio. For a certain value, the pressure in the tank acted like either water hammer or an accelerated fluid column, depending on the duration of the impact relative to the pressure wave transient time.

The influence of large-amplitude liquid sloshing on the overturning and skidding stability of road tankers is very serious during dynamic maneuvers. Experimental investigations have been conducted to measure liquid sloshing force in laterally oscillated model tanks, with or without baffles and cross-walls. The effects of liquid forces on overturning and skidding tendencies were evaluated from simplified vehicle models (no roll, no yaw). The poorest lateral stability mainly arises due to a combination of two factors. The first is that the value of dynamic forces from liquid sloshing can reach twice the rigid load force. The second is that the liquid center of mass can experience large displacement, which may reach about 40 cm. The ratio between the center of mass height and effective width is often higher for heavy than for light tankers. This results in poor lateral stability and less capacity to perform escape maneuvers than for automobiles. The heavy vehicle often overturns for a less severe maneuver than what is required for skidding. In fact, poor overturning stability contributes to the skidding tendency due to lateral load transfer and nonlinear tire characteristics. The liquid impact loading is much more severe to the structure for longitudinal than for lateral sloshing.

When the steering frequency is close to the natural frequency of the liquid free surface, the liquid mass will act like a pendulum swinging with the vehicle. This will result in a distinct increase in load transfer and overturning risk factor. The overturning factor \mathfrak{R} is defined by:

$$\mathfrak{R} = \left| 1 - \frac{F_l}{F_{lo}} \right| \quad [28]$$

where F_l is the instantaneous wheel load on the left side, and F_{lo} is the static wheel load on the left side.

As $\mathfrak{R} \rightarrow 1$, the vehicle is close to inner wheel lift and overturning. \mathfrak{R} depends on the lateral acceleration whose critical value, known as the overturning limit, is reached when $\mathfrak{R} = 1$.

If the steering frequency is greater than the natural frequency, the liquid pendulum motion will lag the tank motion. Close above resonance, this may be especially dangerous if the risk factor peak with sloshing load is close to its resonance level and therefore well above the corresponding peak for rigid loads. Above resonance the liquid will oscillate against the tank and stabilize the vehicle. Unfortunately, this stabilization is not effective in real practice because the actual high steering frequencies are very rare. Furthermore, the roll motions act like a low-pass filter, suppressing high-frequency motions in the chassis before they reach the tank.

Large liquid motion inside the tank will cause larger overturning moment due to pure displacement of the center of mass and larger overturning forces when the relative motion of the liquid is reversed by the tank wall. With reference to Figure 7, the side force coefficient (SC) has been defined by the expression:

$$SC = \frac{m_e a_l - F_y}{(m_e + m_l)g - F_z} \quad [29]$$

where m_e is the empty vehicle mass, m_l is the liquid mass, F_y is the resultant force to the left from the liquid load, F_z is the resultant upward force from the load after subtracting the weight, and a_l is the lateral acceleration.

The overturning limits are compared for different tank partitions in Figure 8. Figure 9 shows the side force coefficient skidding. Depending on tank cross-sectional shape, keeping the tank bottoms at the same level, the center height is more raised for the circular horizontal tank than for the elliptic tank. The overturning limit minimum value and the worst oscillation frequency are smaller for the elliptic tank than for the circular horizontal one.

Note that the liquid impact loading is not a smooth force and its treatment is not a simple task. The sloshing impact loading cannot be viewed as a single loading event since it can be repeated due to the inertia and restoring forces. Systems involving vibro impact with masses colliding with rigid or elastic barriers during their oscillations constitute a specific class of strongly nonlinear systems. The nonlinearity is mainly due to extremely rapid velocity changes during impact. These changes are usually treated as being instantaneous (velocity jumps) and they lead to various strongly nonlinear features of system behavior. If the system is linear with constant coefficients and is subjected to impact loading it will experience non-

linear behavior. Liquid pressure impacts are one of the sources of strong nonlinearity in a liquid tank system.

The liquid hydrodynamic forces can be simulated by the impact of an equivalent pendulum. The pendulum can reach the walls of the tank if its angle with the vertical axis is $\theta = \pm\theta_0$. One can phenomenologically describe the interaction between the pendulum and the tank walls with a special potential field of interaction, which is very weak in the region $|\theta| < \pm\theta_0$, but becomes fast-growing in the neighborhood of the points $|\theta| = \pm\theta_0$. For example, the desirable properties of the potential field can be provided by means of the following function of the potential energy:

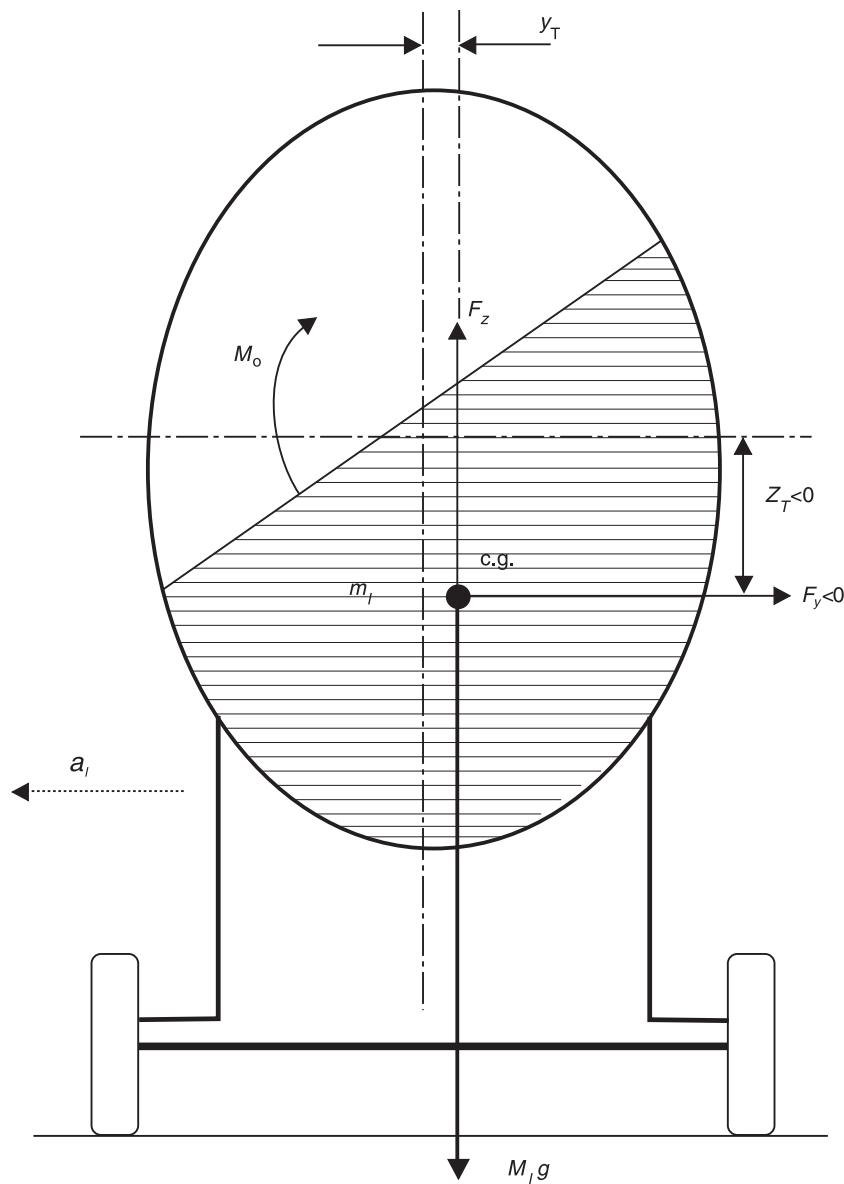

Figure 7 Schematic diagram of liquid displaced in a moving vehicle.

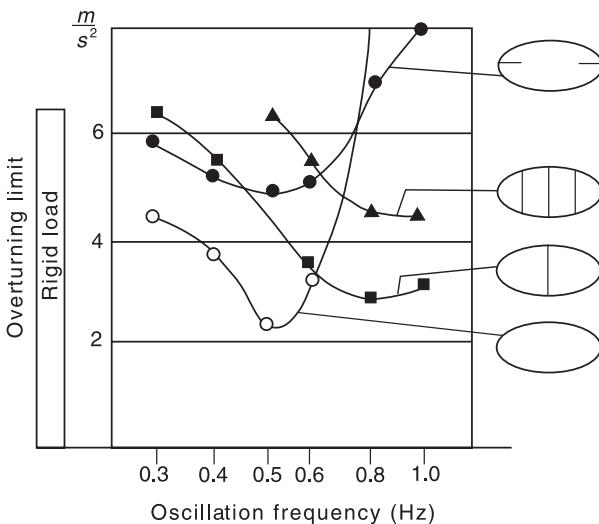

Figure 8 Dependence of overturning limits on the frequency for different tank baffles. From Strandberg (1978) *Lateral Stability of Road Tankers*, National Road and Traffic Research Institute Report 138A. Sweden, with permission.

where $n \gg 1$ is a positive integer, and b is a positive constant parameter.

The force of interaction is:

$$F_{\text{impact}} = \frac{d\Pi_{\text{impact}}(\theta)}{d\theta} = b \left(\frac{\theta}{\theta_0} \right)^{2n-1} \quad [31]$$

One has a limit of absolutely rigid bodies interaction, if $n \rightarrow \infty$. For this case, the potential energy (30) takes the square well form. If the exponent $2n - 1$ is large and finite, then the interaction field is not absolutely localized at the points $\theta = \pm\theta_0$. This means that the tank walls and the pendulum mass are not absolutely rigid, but admit a small deformation about the points of contact $\theta = \pm\theta_0$. Accordingly, a finite value of n seems more realistic than the rigid body limit; yet, the approach considered includes the rigid body limit as a particular case. **Figure 10** shows the force distribution across the tank for different values of n .

The energy dissipation of the pendulum basically results from the pendulum interaction with the container walls. This means that the dissipation is spatially localized around the points $\theta = \pm\theta_0$. The localized dissipative force will be approximated by the expression:

$$F_d = d \left(\frac{\theta}{\theta_0} \right)^{2p} \dot{\theta} \quad [32]$$

where d is a constant coefficient, $p \gg 1$ is a positive integer (generally $p \neq n$), and a dot denotes differentiation with respect to time, t . Note that the constants b and d are determined experimentally. This modeling had been introduced into the equations of motion of a nonlinear system simulating liquid sloshing impact in tanks supported by an elastic structure.

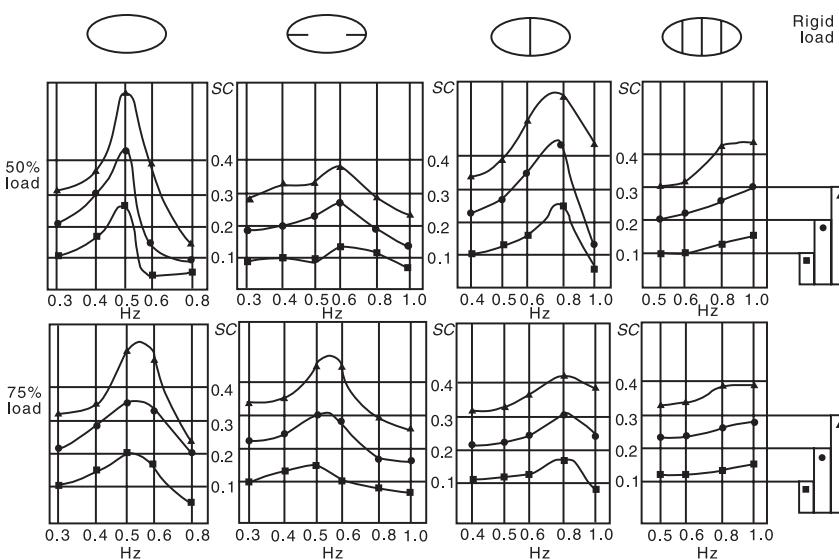

Figure 9 Side force coefficient (SC) as function of the oscillation frequency for different baffle settings. Later acceleration peaks: squares, 1 m s^{-2} ; circles, 2 m s^{-2} ; triangles, 3 m s^{-2} .

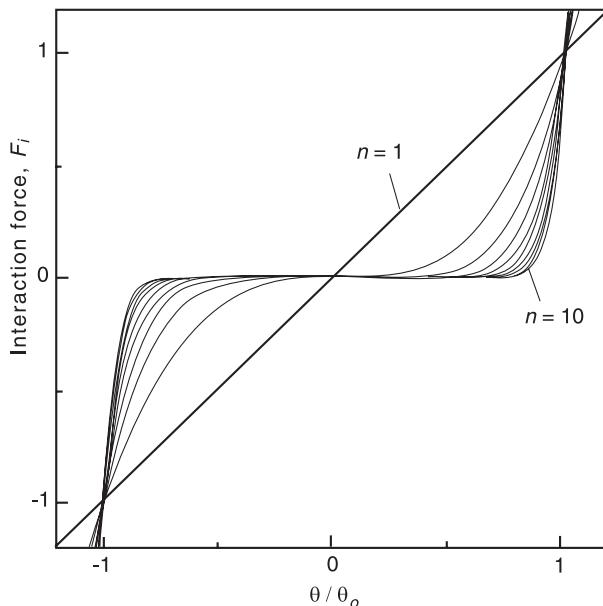

Figure 10 The force of impact between the tank walls and the pendulum for different values of the exponent n .

Sloshing under Low Gravitational Field

The liquid sloshing dynamics under microgravity involves different problems from those encountered under regular gravitational field. These problems include the reorientation of the liquid in its container and the difficulty of moving it since the body forces are almost negligible. Under microgravity, surface tension forces become predominant. The Bond number, given by the ratio of the gravitational to capillary forces, plays a major role in the liquid free surface characteristics. For very small values of the Bond number $\ll 1$, capillary forces predominate and the liquid free surface will not be any longer flat in its container, but will rise around its vertical walls. The Bond number for a cylindrical tank is defined by the expression $B_0 = \tilde{g}R^2/(\sigma/\rho)$, where \tilde{g} is the equivalent gravitational acceleration (cm s^{-2}), R is the tank radius (cm), σ is the surface tension (dyn cm^{-1} or 10^{-5}N cm^{-1}), and ρ is the liquid density (g cm^{-3}). The experimental results of Salzman *et al.*, with 5 s free-fall facility, revealed that the value of the centerline liquid depth depends on the magnitude of the Bond number and the liquid volume. The maximum Bond number during a free-fall drop was 0.002, while most of free-fall drops result in Bond numbers close to 0.001. For deep liquid depth $h/R > 2$ and zero static contact angle, the following relationship was obtained empirically for the liquid first mode natural frequency ω_1 :

$$\omega_1^2 = (2.6 + 1.84B_0) \frac{\sigma}{\rho R^3} \quad [33]$$

where the constant 2.6 represents the capillary contribution to the lateral natural frequency. Eqn [33] reveals that capillary effects begin to appear for Bond numbers below about 20. The dependence of the nondimensional natural frequency $\Omega_1^2 = \omega_1^2 R^3 / \beta$, where $\beta = \sigma/\rho$, on the Bond number parameter ($B_0 + 1.4$) is plotted on a log-log graph, as shown in Figure 11. For shallow liquid depth $h/R < 2$ and for zero Bond number, the following relation may be used:

$$\omega_1^2 = \frac{2.6\beta}{R^3} \tanh \frac{2h}{R} \quad [34]$$

The fundamental slosh-mode shape exhibited a similar dependence on Bond number. In the fundamental mode, the vertex of the liquid surface remains at the centerline of the cylinder and maximum displacement occurred at the cylinder wall.

The damping coefficient c was obtained in the form:

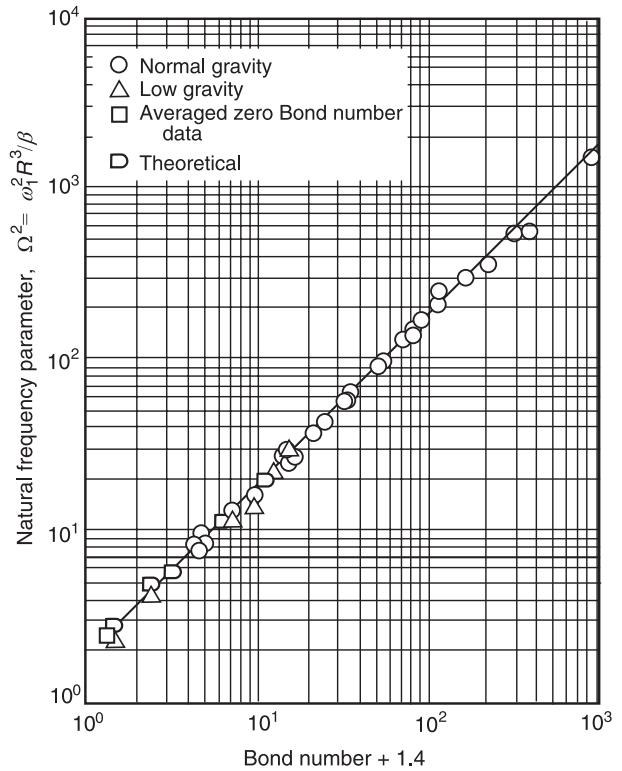

Figure 11 Dependence of liquid natural frequency of the Bond number for liquid depth ratio > 2 . From Salzman JA, Labus TL and Masica WJ (1967) *An Experimental Investigation of the Frequency and Viscous Damping of Liquids During Weightlessness*. TN D-4132. NASA.

$$\frac{c}{(c)_{B_0=0}} = \frac{1}{35.7} K_d (2.6 + 1.8 B_0)^{1/4} \quad [35]$$

where:

$$(c)_{B_0=0} = \frac{28.1}{2\pi} \sqrt{\frac{\mu}{\rho R^2}} \left(2.6 \frac{\sigma}{\rho R^3} \right)^{1/4}$$

is the damping coefficient at zero Bond number, K_d is an explicit function of Bond number, and μ is the liquid viscosity. The measured results showed that the normalized damping coefficient $c/(c)_{B_0=0}$ tends to remain constant for all Bond numbers below 100. The decrease in the natural frequency compensates for the increase in the damping coefficient. For identical radii and liquids, the damping coefficient c is relatively independent of acceleration in the Bond number region from about 0 to 100.

Remarks

Liquid containers constitute major components in a number of multibody systems such as aerospace vehicles, road tankers, and liquefied natural gas carriers. Unfortunately, the basic theory of multibody dynamics does not take into account the effect of liquid sloshing loads on the overall system dynamics. Furthermore, the available multibody dynamics codes cannot handle systems with liquid containers.

There is no doubt that the modern theory of dynamics has promoted our understanding of liquid free surface motion under different types of parametric and internal resonance conditions. Finite element and boundary element algorithms have been developed to determine the hydroelastic coupling of elastic tank with the liquid free surface dynamics. The most significant contributions have dealt with the influence of sloshing loads on the stability and behavior of moving liquid tankers, ships, liquid storage subjected to earthquakes, and near zero-gravity liquid behavior.

Few attempts have considered some random excitation of liquid tanks and predicted stochastic stability boundaries under random parametric excitation. The difficulty arises when the excitation spectral density exceeds a certain level, above which other sloshing modes exist, and the liquid may experience other different regimes such as large-amplitude motion and surface disintegration. This problem may be understood by studying the stochastic bifurcation of the liquid surface motion regimes and Monte Carlo simulation of nonlinear coupled modes. The stochastic analysis needs further studies under regular and microgravitational fields in order to establish the possibility of stabilizing the free surface through a multiplicative noise.

Nomenclature

a	tank width
b	tank breadth
F	force
g	gravitational acceleration
h	liquid depth
I	inertia
M_T	total mass
\mathbf{q}	fluid vector velocity
R	tank radius
\mathfrak{R}	overturning factor
v	kinematic velocity
Z_0	excitation amplitude parameter
ρ	fluid density
Ω	excitation frequency

Introduction

It is common practice in engineering to analyze the dynamics of periodic structures by assuming perfect regularity. A periodic system consists of an assembly of identical subsystems, or bays, repeated along one or more spatial directions, and coupled in some identical fashion. Typical examples of periodic structures are truss beams, rib antennas, and turbomachinery blade assemblies, as depicted in Figure 1. The analysis of these structures is considerably simplified by the assumption of perfect periodicity, essentially because this allows one to reduce the size of the problem to that of one substructure. For example, for a perfectly cyclic turbomachinery rotor such as that in Figure 1B, one simply needs to model a single sector of the disk, along with the corresponding attached blade, and carry out vibration analysis of this reduced model for various phase boundary conditions between adjacent sectors – a tremendous computational saving compared to a full-bladed disk analysis. In reality, however, departure from periodicity always occurs because of manufacturing and material tolerances, imperfect joints, in-service degradation, and other structural defects. These periodicity destroying irregularities, which are also referred to as disorder, or mistuning, are typically small, and one would expect their effect on dynamics of nearly periodic structures to be small as well. Nevertheless, under certain circumstances, irregularities have the potential to alter the vibrational response drastically, in a qualitative fashion, thereby resulting in a phenomenon known as normal mode localization. This is the topic of this article.

Intuitive Interpretation of Mode Localization

Consider the periodic structure shown in Figure 2. It consists of a one-dimensional chain of single-degree-of-freedom oscillators, coupled through identical linear springs. Note that this simple periodic structure can be generalized, at least conceptually, to one featuring periodicity in two or even three dimensions, with bays (or substructures) that possess many

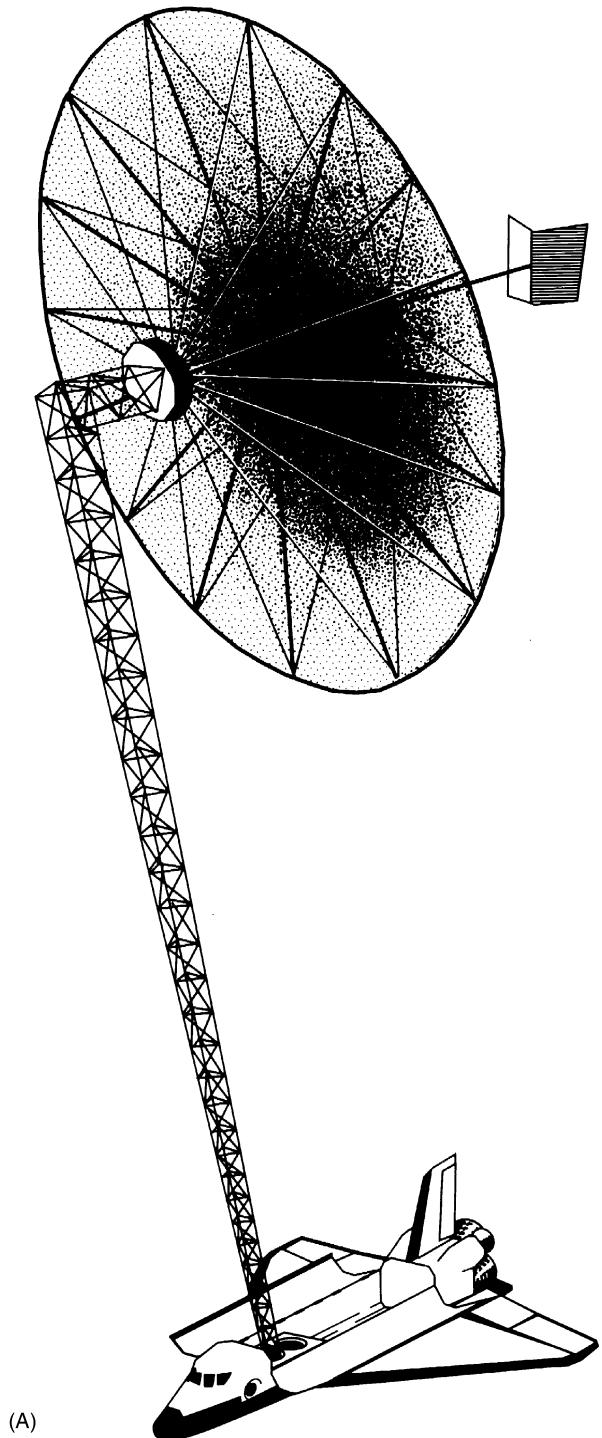

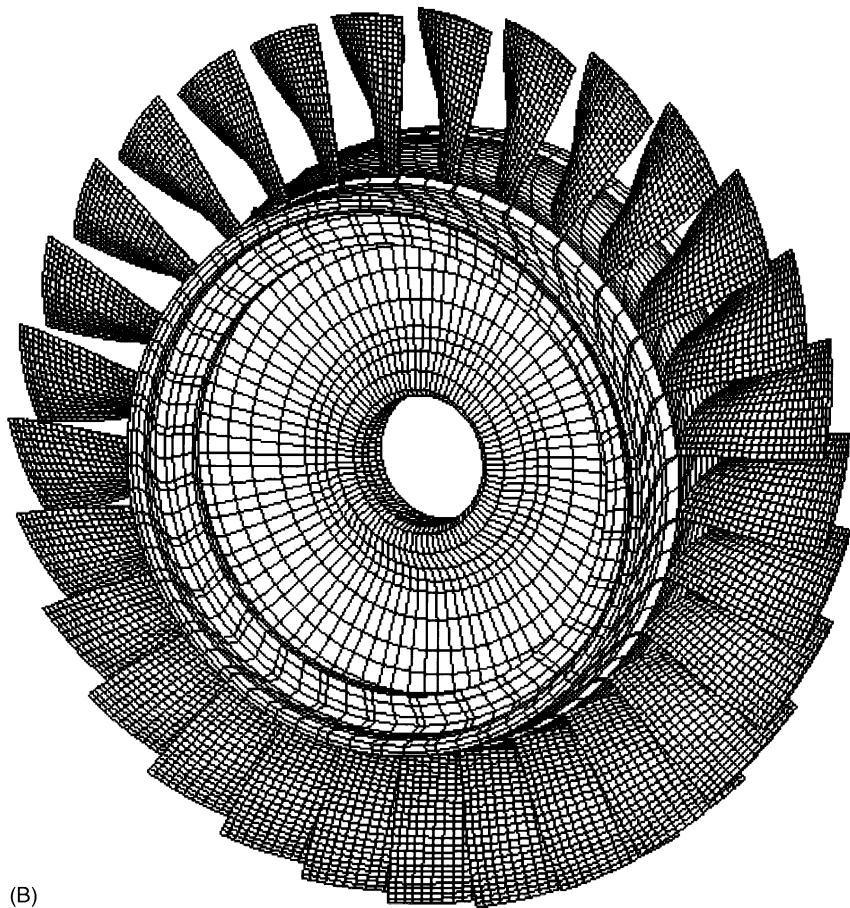

Figure 1 Examples of periodic engineering structures. (A) A periodic truss beam with a cyclic radial rib antenna.

(B)

Figure 1 contd. A cyclic turbomachinery bladed disk assembly (compressor stage).

degrees-of-freedom, and with adjacent bays that are coupled through multiple coupling coordinates, thus indicating that periodic structures can be fairly complex. The structure in **Figure 2A** is said to be ordered, or tuned, if all oscillators are identical. One can easily calculate, in closed form, the linear modes of free vibration of the perfectly periodic system. These mode shapes, three of which are shown in **Figure 2B** for a 10-oscillator system, are sinusoidal in space. They feature the participation of the entire structure in the motion, and thus are referred to as extended modes. One can show that the modes of the perfectly periodic system are always extended, even for arbitrarily small, however nonzero, coupling between the oscillators. Now consider the corresponding disordered, or mistuned, structure shown in **Figure 2C**. It features slightly dissimilar oscillators with random natural frequencies. (Note that the disorder has been exaggerated in the figure; typically, unavoidable structural irregularities of a few percent or smaller are considered in engineering localization studies.) Typical modes for the disordered system are shown in **Figure 2D**. One immediately notices that the vibration modes have completely changed char-

acter with the introduction of disorder. The modes no longer extend throughout the structure as in the ordered case, but rather each mode shape primarily features the vibration of a single oscillator and a limited participation of the neighboring ones. These mode shapes are said to be spatially localized. Note how the three modes shown are localized about three different oscillators, a feature that would also hold for the other seven modes of the system.

This simple example demonstrates that the introduction of a small disorder can alter the free dynamics of a periodic structure in a fundamental, qualitative way. Clearly, the effects of disorder are not always as dramatic, but mode shapes with an arbitrary degree of localization can be obtained in the limit of vanishingly small coupling between oscillators. An intuitive explanation of this phenomenon is given below.

To explain the occurrence of the localized mode shapes depicted in **Figure 2D**, it is first useful to note that such strong localization occurs when the coupling between oscillators is small or, more accurately, when the ratio of the internal coupling strength to the disorder strength is small. Now consider the disordered system shown in **Figure 2C** in the limit of zero

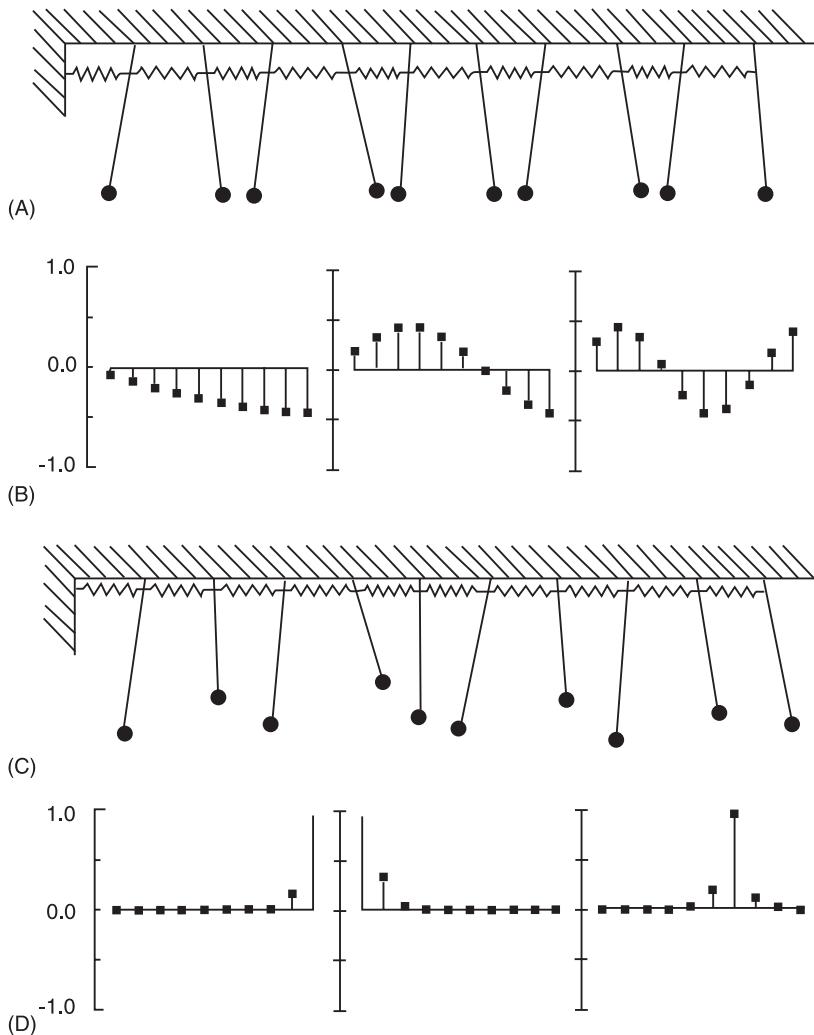

Figure 2 Mode localization for a simple chain of single-degree-of-freedom oscillators. (A) A periodic chain; (B) three extended mode shapes of the periodic chain; (C) a disordered oscillator chain; (D) three localized modes of the disordered chain.

coupling. One obtains a chain of slightly dissimilar, uncoupled oscillators (for the sake of simplicity, assume that no two oscillators have the same random natural frequency). The mode shapes of this limiting system each feature the motion of a single oscillator, with all other oscillators remaining quiescent; in mathematical terms, the associated eigenvectors are the canonical basis vectors, each with a single nonzero element and all other elements equal to zero, representing the oscillations of uncoupled oscillators. Now, if one considers a small perturbation of the uncoupled disordered system, by introducing small coupling between the oscillators, the modes of this weakly coupled system can be expected to be small perturbations of those of the uncoupled system. Thus, each mode of the weakly coupled disordered system is a perturbation of the oscillations of a single oscillator, and is precisely a localized mode such as those shown

in Figure 2D. Therefore, by viewing not the disorder, but the small coupling as a perturbation, one can provide a physically intuitive explanation of the occurrence of localized modes, namely as perturbations of uncoupled oscillations. Paradoxically, while the localized modes now appear as entirely expected, it is the extended modes of the ordered system that seem to be anomalous. Indeed, based on the above reasoning, one would expect that for weak coupling the modes of the ordered system are also localized. However, the uncoupled ordered system features an N -fold degenerate natural frequency, where N is the number of oscillators, such that any arbitrary deflection pattern is an eigenvector. The arguments developed above for the individual uncoupled modes are invalid in the ordered case, and any amount of coupling, however small, is sufficient to remove the natural frequency degeneracy and cause a resonance among

all oscillators, yielding the extended mode shapes in Figure 2B. In this light, it is the ordered system with its extended modes, rather than the disordered system with its localized modes, that appears as the anomalous case.

Brief History of Localization

The mode localization phenomenon was first discovered in 1958 by P. W. Anderson in the field of solid state physics. He showed that the electron eigenstates in disordered solids may become localized, henceforth limiting metallic conduction. Since Anderson's ground-breaking work, localization has continuously excited the interest of solid state physicists, and the resulting body of research has been the precursor to the study of localization in the field of structural dynamics. Two lines of thought in solid state physics have particularly impacted vibration localization studies. In the first approach, localization in random chains is analyzed by applying Furstenberg's theorem on the limiting behavior of products of random matrices. Modeling each bay, or subsystem, of the nearly periodic system by a transfer matrix, one can represent the assembly dynamics by a product of random transfer matrices – an approach based on the traveling of waves from bay to bay. The second approach consists of a modal formulation, in which one relies on the frequency spectrum of the entire disordered chain to characterize localization. These two perspectives form the cornerstone of the study of localization in engineering structures. They differ in that the wave formulation deals with local properties (transfer matrix for each bay), while the modal method uses global information (frequency spectrum of the entire structure).

In 1982, C. H. Hodges was first to recognize that localization can occur in engineering structures and to suggest that some of the knowledge acquired by physicists could be applied to studies of structural dynamics and acoustics. Using both wave and modal arguments, Hodges discussed localization for simple periodic structural systems, such as chains of coupled oscillators and beams on randomly spaced supports. Following Hodges' pioneering work, a large number of localization studies were carried out for a variety of structural systems. In the first stage, research was mostly limited to deterministic analyses of the free vibration modes of disordered one-dimensional structures with single-degree-of-freedom bays, such as oscillator chains. In particular, various perturbation methods were developed to elucidate the underlying physical mechanisms of mode localization. Researchers then considered more complex periodic structures with multimode bays and showed that confinement

effects generally increase rapidly with frequency. The occurrence of mode localization was also formally related to that of another phenomenon already known in the field of vibration, namely curve veering. It was shown that mode localization in disordered periodic structures can be predicted by the abrupt veering away of the loci of the natural frequencies when plotted against the disorder parameter.

Beginning in the late 1980s, stochastic investigations of localization were conducted, which recognized the probabilistic nature of the irregularities. The concept of the localization factor was introduced. This frequency dependent scalar characterizes the strength of localization, and is defined as the exponential spatial decay rate of the vibration amplitude along the disordered periodic structure, in an average or an asymptotic sense. It can be calculated either from the transmission of harmonic forced vibration from a local source of excitation, or from the limiting behavior of products of random bay transfer matrices. Localization factors can be approximated analytically, typically using perturbation ideas, but more accurate determinations require a numerical evaluation of the Monte Carlo type. In recent years localization factors have been determined for various periodic structures: chains of oscillators, chains of multimode systems, multispan beams, stretched strings with attached masses, truss beams, etc. These works exhibited the occurrence of two types of localization, weak or strong, depending on the internal coupling in the structure and on the frequency range. Stochastic perturbation methods, based upon modal or wave formulations, were developed for these two localization regimes. It was shown that strong localization effects are most relevant to the structural dynamicist, as they manifest themselves as rapid spatial attenuation over a few bays, whereas weak localization, though of concern to solid state physicists, affects engineering structures very little, because the small spatial attenuation rate due to localization is readily obscured by that caused by the small damping present in all structures.

In order to confirm the occurrence of localization and validate analytical and numerical findings, experiments were conducted on engineering structures beginning in the late 1980s. Simple structures were tested: a taut string with attached beads, a two-span beam, and a 12-span beam. This led to the quantitative confirmation of localization effects, both on free vibration mode shapes and on steady-state and transient forced responses, and also to the experimental estimation of localization factors. Experiments were also performed on realistic engineering structures, namely a full-scale, 12-rib, loosely coupled space antenna, and several industrial jet

engine bladed disks. The latter tests confirm that localization may take place in practical engineering situations.

The study of mode localization has recently generated intense research activity in the fields of structural dynamics and acoustics, and original contributions are being made in the areas of nonlinear periodic systems, bladed-disk assemblies, computer disk drives, and structures submerged in a fluid.

Key Localization Results

Periodic structures have characteristic properties that make much of their dynamics qualitatively the same. Thus useful results for engineering structures can be obtained from elementary models. Periodic structures are made of bays coupled through one or more coordinates, and are accordingly classified as monocoupled or multicoupled. For example, the pendulum assembly shown in Figure 2 is monocoupled through the springs connecting adjacent oscillators. Also, a multispan beam on rigid supports is monocoupled through the bending rotation at the supports. The same beam on elastic supports is, however, bicoupled, as energy is also transmitted through the bending displacement of the supports. Finally, the bladed disk in Figure 1B is multicoupled, through possibly many coupling coordinates at adjacent blade-disk sectors. A periodic structure carries as many pairs of (left- and right-traveling) independent free waves as there are coupling coordinates. Alternating frequency bands in which the waves either propagate freely (passbands) or are attenuated (stopbands) correspond to each pair of harmonic waves. The number of passbands equals the number of degrees of freedom of a subsystem (which can possibly be infinite), and energy is only transmitted along the structure through the passbands. A typical passband–stopband pattern is shown in Figure 3 for a monocoupled periodic system.

A pair of waves is characterized by a propagation constant, $\mu = \gamma + jk$, such that waves propagate according to $\exp(\pm\mu)$. The propagation constant thus accounts for the change in wave amplitude (γ) and phase (k) at the bay interfaces. In particular, the spatial decay of the wave amplitude is governed by the real part of the propagation constant, γ , a quantity of special interest in localization. The nature of the propagation constant (real or complex) at a given frequency determines the propagation and attenuation characteristics of the corresponding wave pair at that frequency, as follows (Figure 3). In the frequency passbands of periodic (undamped) structures, μ is purely imaginary, thus $\gamma = 0$ and a characteristic wave propagates freely without attenuation but

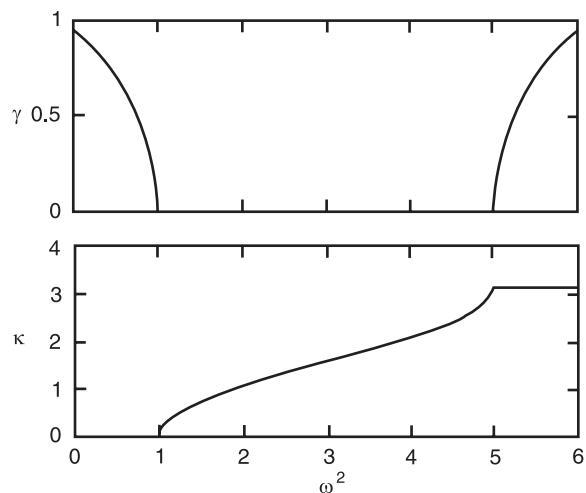

Figure 3 An illustration of stopband and passband patterns versus harmonic frequency in a periodic structure. When $\gamma = 0$, a wave propagates without amplitude attenuation, and the corresponding frequency range [1, 5] defines a passband. Frequency ranges [0, 1] and [5, 6] define two stopbands representing waves that are attenuated with a phase change of 0 or π at each bay.

with a phase change at each bay. In the frequency stopbands, attenuation occurs and $\gamma = 0$, with a phase change of 0 or π radians per bay. In complex-bands, waves propagate with attenuation and with a phase change per bay different from 0 or π . Complex-bands require two wave pairs to exist, hence they are not present in monocoupled periodic systems. If the periodic system is damped, then the wave amplitudes decay exponentially along the system, even for frequencies in the passbands ($\gamma = 0$).

Disruption in periodicity also leads to wave attenuation at all frequencies (regardless of dissipation), because traveling waves are partly reflected by the randomized bays. In monocoupled, disordered periodic structures, when one wave impinges at the interface of two disordered, hence slightly different, bays, part of the wave amplitude is reflected and part of it is transmitted. It is this multiple scattering effect over many bays that causes the localization of waves to the region of incidence. While the spatial decay of the wave amplitude can vary greatly from bay to bay due to their random properties, the rate of spatial decay per bay is exponential asymptotically, as the number of bays tends to infinity. (Assuming spatial self-averaging, the expected value of the decay rate for a finite system is also exponential, and equivalent to the asymptotic rate for an infinite system.) For a monocoupled system, there is a single wave type, hence its spatial decay rate corresponds exactly to the spatial decay rate of the vibration amplitude. The associated exponential decay constant is known as

the localization factor. Intuitively, the localization factor can be viewed as the generalization to disordered systems of the real part of the propagation constant for ordered systems. In the disordered case, γ becomes greater than zero for all frequencies, even in the passbands of the corresponding periodic structure. As an illustration, **Figure 4** depicts one free vibration mode of a disordered 100-oscillator system, along with the corresponding decay predicted by the localization factor calculated at the mode's fre-

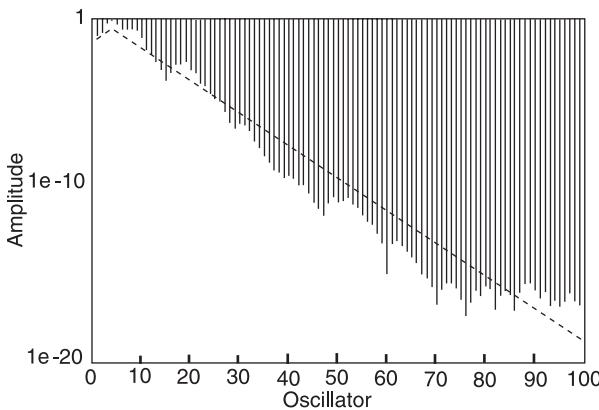

Figure 4 A localized vibration mode shape of a disordered 100-oscillator system, shown on a natural log scale to illustrate the rate of exponential decay. The decay rate predicted by the localization factor at the mode's frequency is portrayed by the slope of the line (—) superimposed on the plot.

quency. Note that even though the spatial amplitude decay featured by the mode is not purely exponential, it is well captured by the localization factor.

Localization factors can be calculated by various methods: perturbation techniques, with either coupling or disorder as the perturbation parameter in strong and weak localization regimes, respectively; Monte Carlo simulations of the forced response of a finite structure to a local excitation or of the wave response of an infinite structure to an incident wave; as the largest Lyapunov exponent of the stochastic global wave transfer matrix for the disordered periodic structure. The Lyapunov exponent method combines accuracy and efficiency, and is generally the method of choice to calculate localization factors. **Figure 5** depicts the typical variation of the localization factor throughout the passband of the corresponding periodic system, obtained by various methods. Observe that γ is largest near the passband edges ($\omega^2 = 1$ and 1.4) and minimum at midpassband ($\omega^2 = 1.2$).

Similarly to damping, localization manifests itself by a spatial decay of the vibration amplitude along the structure. However, the mechanisms for localization and damping differ fundamentally. The localization phenomenon is one of energy redistribution, whereby the energy is confined, trapped by the wave-scattering disorder near the excitation source. The damping mechanism, on the other hand, dissipates energy as the vibration is transmitted through the bays without reflections.

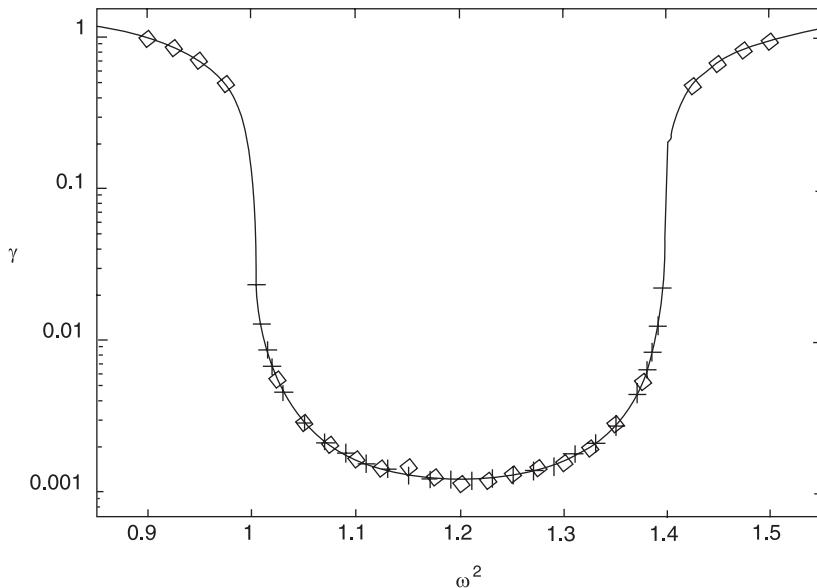

Figure 5 Localization factor for a chain of coupled oscillators, for a disorder of standard deviation $\sigma = 1\%$ and weak coupling. Results are shown for perturbation approximation (—), Lyapunov exponent using the Wolf algorithm (◊), and Monte Carlo method (+).

Localization in multicoupled systems is much more difficult to analyze, because the decay rates of the multiple wave pairs present in the structure must be considered. At any given bay, a wave type may not only be partially reflected and transmitted into waves of the same type, but into other wave types as well. The partial reflection and/or transmission of one wave type into another is referred to as wave conversion or wave interaction, because energy ‘leaks’ from one wave type to another, indicating that the waves are coupled. Typically, waves that are most subject to localization leak their energy to waves that are less prone to it, in an effort to sustain propagation. Multiwave localization thus exhibits a rich wave conversion mechanism caused by multiple scatterings. One way to characterize localization in multicoupled systems is to find the Lyapunov exponents of the matrix that relates the wave amplitudes at one end of the structure to the wave amplitudes at the other end – the stochastic global wave transfer matrix. The Lyapunov exponents provide a measure of the rates of amplitude decay for the various wave types. For an ordered system, the positive Lyapunov exponents simply equal the propagation constants. For a monocoupled system, the largest Lyapunov exponent is equivalent to the localization factor.

Dual to the wave properties of periodic structures are the modal properties. The natural frequencies of a finite periodic system are (almost always) found inside the frequency passbands, with N natural frequencies in each passband for an N -bay monocoupled system. The mode shapes of finite periodic structures are periodic, or extended, and feature a nonattenuated shape (Figure 2B). Mode shapes can be obtained from the free traveling waves of the same frequency by the phase closure principle. The localized mode shapes of disordered structures are governed, on the average, by the same exponential envelope as the free waves of same frequency, $\exp(-\gamma N)$. Obviously, this holds for a periodic structure, as $\gamma = 0$ and the mode shapes are extended.

Finite periodic structures feature closely spaced modes when the number of bays becomes large and/or the frequency passbands are narrow. This high modal density occurs because the number of natural frequencies in each passband equals the number of bays in the periodic system, and also because the passband edges characterize an infinite periodic structure and henceforth are independent of the number of bays. This property leads to another interpretation of localization, one that is based upon sensitivity arguments, as follows. Recall, from the perturbation theory for the eigenvalue problem, that the sensitivity of the mode shapes to small parameter perturbations is inversely proportional to the distance between the

eigenvalues of the unperturbed structure. Considering the periodic structure to be the unperturbed system and the perturbation to be the disorder, it follows that the mode shapes of a finite periodic structure are sensitive to disorder when the number of bays is large and/or the passbands are narrow. Since narrow passbands occur when the internal coupling among the bays is small (to understand this, consider the limiting case of vanishing coupling and hence vanishing passband width for uncoupled, identical bays), it means that the mode shapes are highly sensitive to disorder for small interbay coupling. This high sensitivity of the modes is indicative of the occurrence of localization. It also follows that mode shape sensitivity increases with the number of bays and that, for a given coupling (even large), arbitrarily large sensitivity can be obtained provided the number of bays is sufficiently large. This is in agreement with the finding that localization is characterized by an exponential decay of the amplitude: for a given localization factor γ , localization becomes stronger as the number of bays in the structure increases, and even an arbitrarily small localization factor (such as one obtained for strong coupling and large passband width) can yield severe localization if the structure comprises a sufficiently large number of bays. From a sensitivity viewpoint, as the number of bays increases, the modal density – and hence the mode shape sensitivity to disorder – increases as the number of eigenvalues contained in the constant-width passband increases.

Engineering Significance of Localization

The degree of localization in a structure depends on the ratio of disorder strength to internal coupling strength and increases with this ratio. Under conditions of weak coupling between bays or, equivalently, high modal density, the effects of small disorder can be drastic. To illustrate such strong localization, consider the monocoupled assembly of component beams in Figure 6. Figure 7 displays typical free

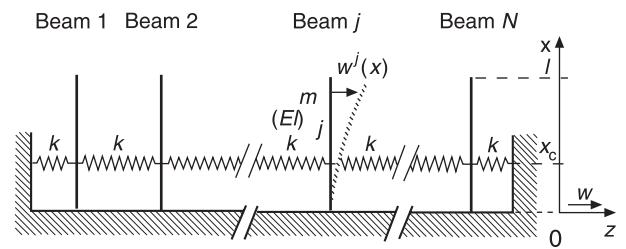

Figure 6 A monocoupled assembly of multimode component systems (cantilevered Euler-Bernoulli beams).

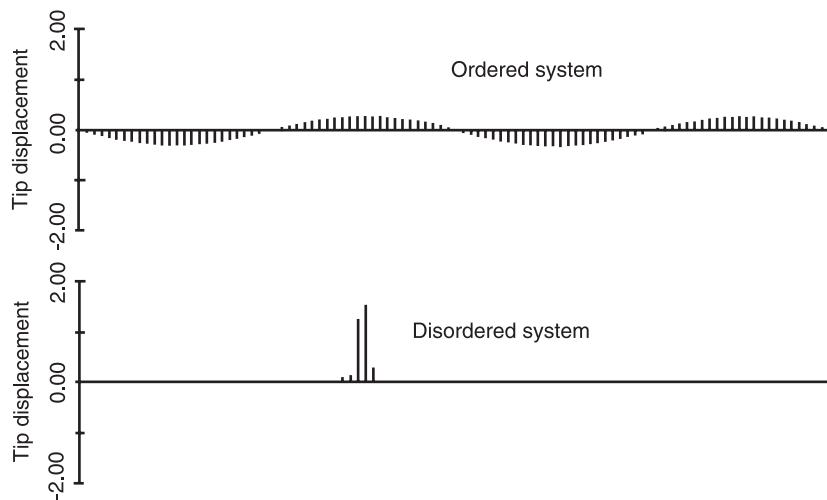

Figure 7 Fourth mode in the third passband (204th mode) for ordered and disordered assemblies of 100 cantilevered Bernoulli–Euler beams. The beams are coupled at the tip, and the coupling stiffness equals the beams' static stiffness. Tip displacements are shown. For the disordered system, the standard deviation of beam stiffness mistuning is 1%. Note the severe change from extended to localized modes.

vibration modes for an ordered assembly of 100 identical beams and a slightly disordered system. The standard deviation of disorder is on the order of typical manufacturing tolerances and the inter-beam coupling stiffness is significant. While the mode of the ordered assembly extends through the

structure, the corresponding mode for the disordered assembly is localized about a few beams. Note that energy confinement also results in larger amplitudes (both modes were normalized by the same energy). Other illustrations of mode localization are shown in Figures 8 and 9, for a multispan beam on randomly

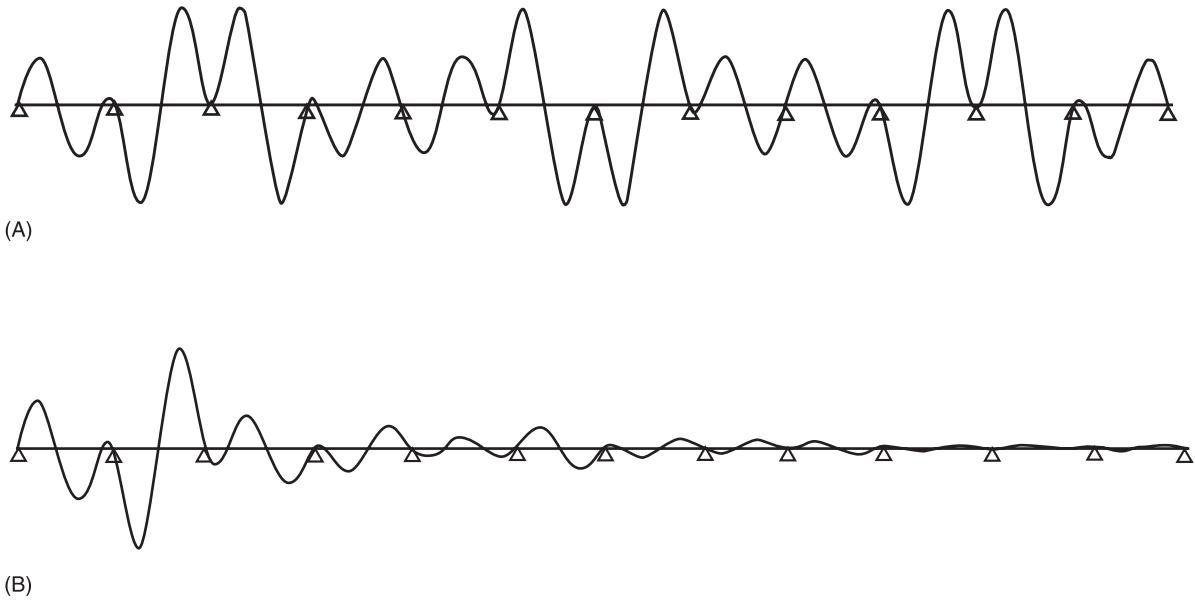

Figure 8 Modes of a multispan beam on rigid supports. (A) One extended mode of a periodic beam on equally spaced supports; (B) Mode localization in a disordered beam with slight random support spacing.

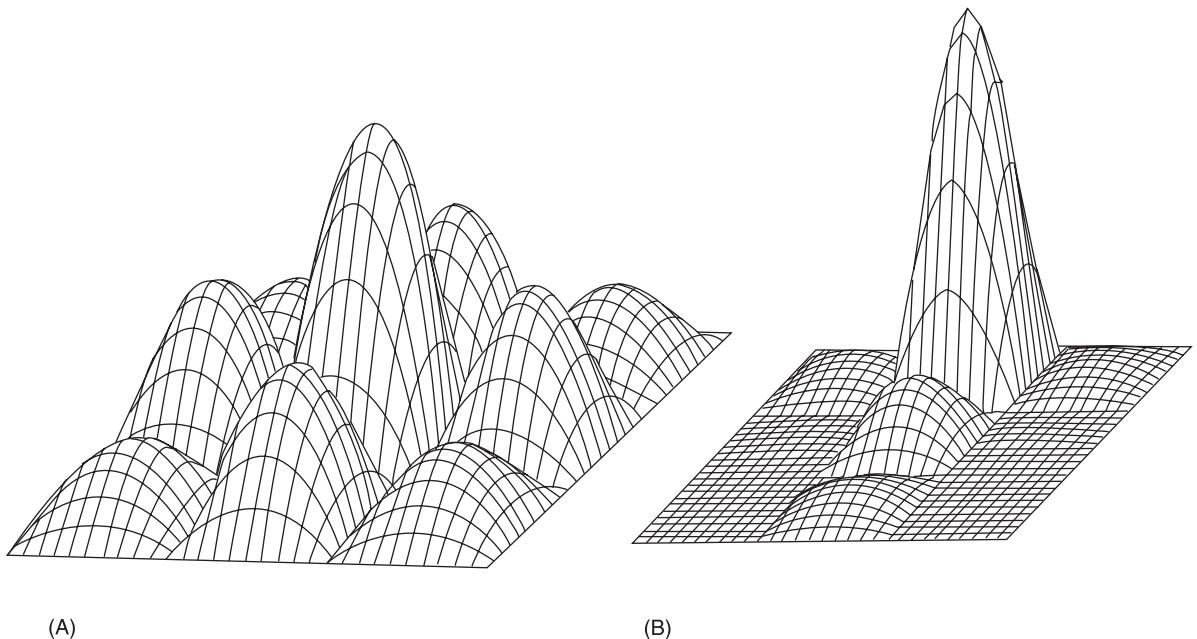

Figure 9 Mode localization in a nine-bay membrane resting on continuous lines of linear springs. (A) Ordered system; (B) disordered system. For the disordered membrane the areas of the individual bays are randomized, such that the standard deviation of support spacing is approximately 0.5%. Observe the severe localization in a single bay in (B).

spaced supports and a two-dimensional multipanel membrane resting on randomly spaced elastic line supports, respectively.

Localization can occur in a plethora of engineering structures, essentially all structures that feature spatial periodicity. An especially important class are bladed-disk assemblies such as those found in jet engines. There, the localization is induced by small blade mistuning and it can cause large increases in response amplitudes and stresses (increases of 300% are not uncommon), resulting in serious high-cycle fatigue problems. Figures 10 and 11 illustrate forced and free response localization for bladed disks, respectively. Other structures susceptible to localization are space antennas with cyclic symmetry, truss beams in space, airframes (skin-stringer panels), laminated composites, overhead power lines, offshore jack-up structures, submarine hulls, towed-array sonars, rail road tracks, computer drives with stacked disks, etc. Thus, localization may impact virtually every engineering application in structural dynamics.

The underlying motivation for studying localization is threefold. First, through the occurrence of localization, parameter uncertainties have the potential to invalidate the predictions of commonly used

deterministic modeling and analysis techniques, which reduces the effectiveness of structural models, associated control schemes, and identification techniques. For example, a control strategy based upon the erroneous extended modes of a perfectly periodic structure would be unpredictable. Also, to an experimentalist unaware of disorder effects, the spatial amplitude decay caused by localization could be easily mistaken for, and result in, an over-determination of damping. Second, localized vibrations increase amplitudes and stresses locally and may result in severe damage. For instance, single-blade failure in turbomachinery rotors is a plausible result of blade mistuning. Third, when localization occurs, irregularities exhibit a damping-like effect that could be used as a passive control of vibration transmission. This has applications in flexible and lightly damped structures such as truss beams in space.

The bidirectional coupling between the magnetic and mechanical states of a magnetostrictive material provides a transduction mechanism that is used in both sensing and actuation. The current interest in the design of adaptive smart structures, coupled with the advent of materials which exhibit high sensor figures of merit such as Metglas and the so-called giant magnetostrictive materials such as Terfenol-D has led to a renewed interest in the engineering of optimized magnetostrictive transducer designs. An overview of magnetostriction and of recent sensing and vibration control applications for magnetostrictive materials is presented along with a brief discussion of some pertinent magnetostrictive device design issues. Schematics of several actuator and sensor configurations are included, as are typical experimental results.

Magnetostriction and Magnetism

Magnetostrictive materials convert magnetic energy to mechanical energy and vice versa. As a magnetostrictive material is magnetized, it strains. Conver-

sely, as either a force or torque produces a strain in a magnetostrictive material, the material's magnetic state changes. The application of either an external magnetic field or an external stress breaks the material's internal energy balance and leads to both magnetic responses (domain wall motion, magnetization rotation, and a change in permeability) and elastic responses (strain of the material and a change in stiffness).

Magnetostriction is an inherent material property associated with electron spin and orbit orientations and molecular lattice geometries and will not degrade with time or with use. The effect is not present when a magnetostrictive material is heated above its Curie temperature; however, the effect returns fully as the material is cooled to below the Curie temperature. All ferromagnetic materials exhibit magnetostriction; however, in many materials the magnitude of the strain or shape change is too small to be of consequence. Nominal longitudinal saturation strains for various materials at room temperature are shown in Table 1.

Sensors are commonly based on the reciprocal magnetostrictive effects, the change in magnetization and permeability of a sample that accompanies a change in an external stress or torque. The magnetization change produced due to the application of a stress is known as either the Villari effect or the magnetomechanical effect. The magnetization

change produced due to application of a torque is known as either the inverse Wiedemann effect or the Matteuci effect.

Actuators are commonly based on the shape change that accompanies magnetization of a magnetostrictive material. The most common shape change is a change in sample length, accompanied by a change in transverse dimensions. This is known as the Joule effect (after James Prescott Joule (1818–89) for positive identification of the change in length of an iron sample) or the magnetostrictive effect. Magnetostriction can also occur as a twisting which results from a helical magnetic field, often generated by passing a current through the magnetostrictive sample. This is known as the Wiedemann effect.

At low applied magnetic field strengths, domain wall motion occurs as a consequence of the growth of domains whose magnetization is aligned favorably with respect to the applied field, at the expense of domains with magnetization opposing the field. At moderate field strengths, the magnetic moments within unfavorably oriented domains overcome the anisotropy energy and suddenly rotate (jump) into one of the crystallographic easy axes closer to the external field direction. This jump coincides with a relatively large change in strain for a small change in applied field. At moderate to high field strengths, the magnetic moments align along crystallographically easy axes lying closest to the field direction. As the field is increased further, the magnetic moments undergo coherent rotation until they reach alignment with the applied field resulting in a single-domain material and technical saturation.

Crystalline growth can be tailored or optimized so as to enhance the magnetostrictive effect in a material of a given stoichiometry. For example, in the highly magnetostrictive alloy Terfenol-D ($Tb_xDy_{1-x}Fe_y$, where $x = 0.27\text{--}0.3$ and $y = 1.92\text{--}2.0$) energy

minimization is satisfied with random alignment of the magnetic domain orientations along the eight outward diagonals from the center of the molecular cubic lattice such that the bulk sample has zero (or almost zero) net magnetization. Commercially available material is grown using directional solidification techniques and patented crystallographic growth methods that lead to crystal growth and magnetic moment orientations such that jumping of magnetization between easy axes perpendicular and parallel to the sample growth direction is facilitated.

Exchanges between magnetic and mechanical energy are the primary transduction effects employed in magnetostrictive sensing and actuation applications. The two coupled linear equations given in eqns [1] and [2] model these relationships. These equations neglect temperature effects and hysteresis, and have been reduced from a three-dimensional vector form to reflect only axial behavior. These magnetostrictive equations of state are expressed in terms of mechanical parameters (strain ε , stress σ , Young's modulus at constant applied magnetic field E^H), magnetic parameters (applied magnetic field H , magnetic induction B , permeability at constant stress μ^σ), and two piezomagnetic coefficients (these are also known as magnetomechanical coefficients and as axial strain coefficients: $d_{33} = d\varepsilon/dH|_\sigma$, and $d_{33}^* = dB/d\sigma|_H$, where for small strains, these two coefficients can be shown to be equal):

$$\varepsilon = \sigma/E_y^H + dH \quad [1]$$

$$B = d^* \sigma + \mu^\sigma H \quad [2]$$

where ε and B are dependent on the externally applied quantities σ and H . The elastic modulus, permeability, and piezomagnetic coefficients can vary significantly with operating conditions. They need to be experimentally determined and are usually provided by the material manufacturer. At present, most modeling codes rely on look-up tables to capture the time-varying and load-dependent nature of these coefficients.

These equations capture the low signal, linear, coupled mechanical, and magnetic nature of magnetostriction. Eqn [1] indicates that the net strain of a magnetostrictive element is the combined response to changes in stress (Hooke's law behavior, $\varepsilon = \sigma/E$) and applied magnetic field (Joule effect magnetostriction, λ). Eqn [2] indicates the simultaneous change in the magnetic induction of the element due to change in stress (reciprocal Joule or Villari effect magnetization) and applied field. This later effect can also be

expressed as a change in permeability by writing eqn [2] in a more general form:

$$B = \mu H \quad [3]$$

In eqn [3] the effects of stress are included in the permeability, μ . Permeability can be monitored since both B and H can be related to measurable electrical quantities as described in eqns [4] and [5].

In the early nineteenth century, Oersted discovered that a moving charge generated a magnetic field in a plane perpendicular to the direction of charge motion. Thus, a current in a conductor could be used to produce a magnetic field around the conductor. Ampere's law describes this electromagnetic relationship. For a long, thin solenoid having a number of turns N_c and a length L_c a simple expression is derived;

$$H = (N_c I) / L_c \quad [4]$$

Placing a magnetostrictive element inside such an excitation coil (solenoid) with an impressed current I provides an efficient means of magnetizing the element and producing controlled strain and force output.

The law of electromagnetic induction (Faraday-Lenz law) describes how a magnetic flux, $\varphi = BA_c$ in area A_c , induces a potential in an electrical conductor to which it is flux-linked. In its simplest differential form, the Faraday-Lenz law is given by:

$$V = -N_c \frac{d\varphi}{dt} = -N_c A_c \frac{dB}{dt} \quad [5]$$

where V is the induced voltage in the solenoid of constant area A_c . According to this law, a potential will be induced in any electrically conducting material that makes up the magnetic circuit.

The excitation coil described by eqn [4] can be used to generate a magnetic field in a sample spatially separated from the coil. According to Gauss's law of magnetism:

$$\nabla \cdot B = 0 \quad [6]$$

the divergence of B is zero. This means that the magnetic flux is always conserved. Thus magnetic flux lines close, defining a magnetic circuit, and elements of the magnetic circuit through which magnetic flux flows are said to be flux-linked. This makes it possible to magnetize one component of the magnetic circuit by generating a magnetic field in another component. Based on the principle expressed by eqns

[5] and [6], it is possible to measure the magnetic flux density in a magnetic circuit by the voltage induced in a flux-linked detection coil.

Transduction

Magnetostrictive materials are magnetoelastic in the sense that they do work in the process of converting between magnetic and elastic (or mechanical) energy states. However, magnetostrictive transducers are generally classified as electromechanical devices or electromagnetomechanical because their input and output are generally electrical and mechanical in nature. The conversion of magnetic energy to and from electrical and/or mechanical is transparent to the device user. A common two-port schematic appropriate for both magnetostrictive sensing and actuation devices is given in Figure 1. The magnetostrictive driver is represented by the center block, with the transduction coefficients T_{me} (mechanical due to electrical) and T_{em} (electrical due to mechanical), indicative of both the magnetoelastic attributes characterized by eqns [1] and [2] and the electromagnetic attributes associated with conversion between electrical and magnetic fields characterized by eqns [4] and [5].

The transduction process relating the electrical and mechanical states can be described with two coupled linear equations. These canonical equations are expressed in terms of mechanical parameters (force F , velocity v , mechanical impedance Z_m), electrical parameters (applied voltage V , current I , electrical impedance Z_e), and the two transduction coefficients:

$$V = Z_e I + T_{em} v \quad [7]$$

$$F = T_{me} I + z_m v \quad [8]$$

Common magnetostrictive transducer components include a magnetic circuit, a solenoid for transduction of magnetic-to-electrical energy and vice versa, mechanisms for DC magnetic and mechanical (prestress) biasing. A generic magnetostrictive device con-

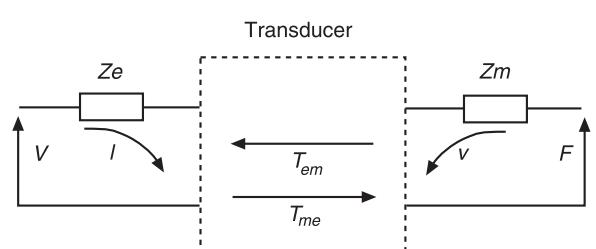

Figure 1 Two-port transducer schematic.

figuration is shown in **Figure 2**. The permanent magnet provides a DC magnetic field. The magnetic circuit passes through the magnetostrictive driver, end caps made of magnetic materials, and the permanent magnet. Belleville spring washers are used to provide

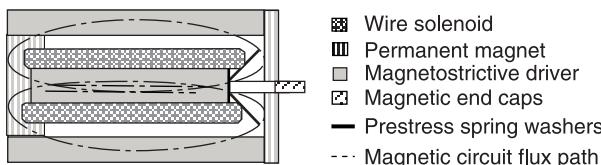

Figure 2 Components typical of a simple magnetostrictive transducer.

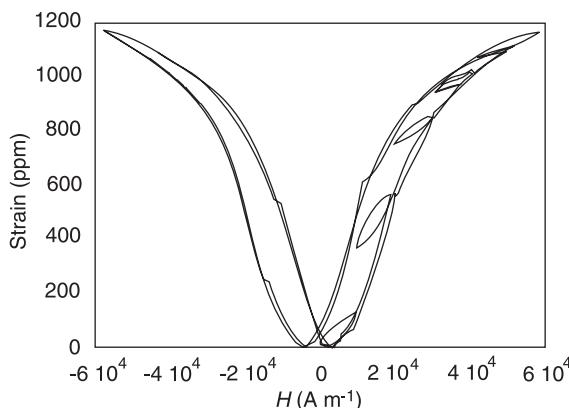

Figure 3 Strain vs applied-field major hysteresis loop and minor loops for AC fields of $\pm 5 \text{ kA m}^{-1}$ at 0.7 Hz at DC bias levels of 5, 15, 25, 35, and 45 kA m^{-1} . Device mechanical load is a prestress of 6.9 MPa .

an initial mechanical prestress. The solenoid can be used to provide both AC and DC magnetic fields for actuation purposes. Alternatively, for sensing applications, the change in voltage induced in the solenoid is to detect a change in strain and/or in the force applied to the device.

Figure 3 depicts a major hysteresis loop from an actuator similar in design to that shown in **Figure 2**. Superimposed on the major hysteresis loop are five minor hysteresis loops collected by driving at 0.7 Hz with an applied of $\pm 5 \text{ kA m}^{-1}$ as the DC magnetic bias was increased from 5 to 45 kA m^{-1} in increments of 10 kA m^{-1} . AC operation of magnetostrictive actuators is typically achieved through the use of a DC magnetic field to provide bias operation so that it is centered about the steepest portion of the major hysteresis loop. This region is called the burst region, and the DC magnetic field amplitude required for operation about the middle of the burst region is called the critical field. All subsequent data are from magnetically biased transducers.

Figure 4 shows frequency response functions of acceleration per input current, where the change in the transducer's axial resonant frequency varies from 1350 Hz to over 2000 Hz, reflecting the effect of DC bias on the elastic modulus. The reduction in elastic modulus below that at magnetic saturation is known as the delta E effect. Note that in **Figure 4** only the axial resonant frequency of the magnetostrictive driver shifts and that the structural resonance of the device housing at 3300 Hz is not affected by the changing DC field.

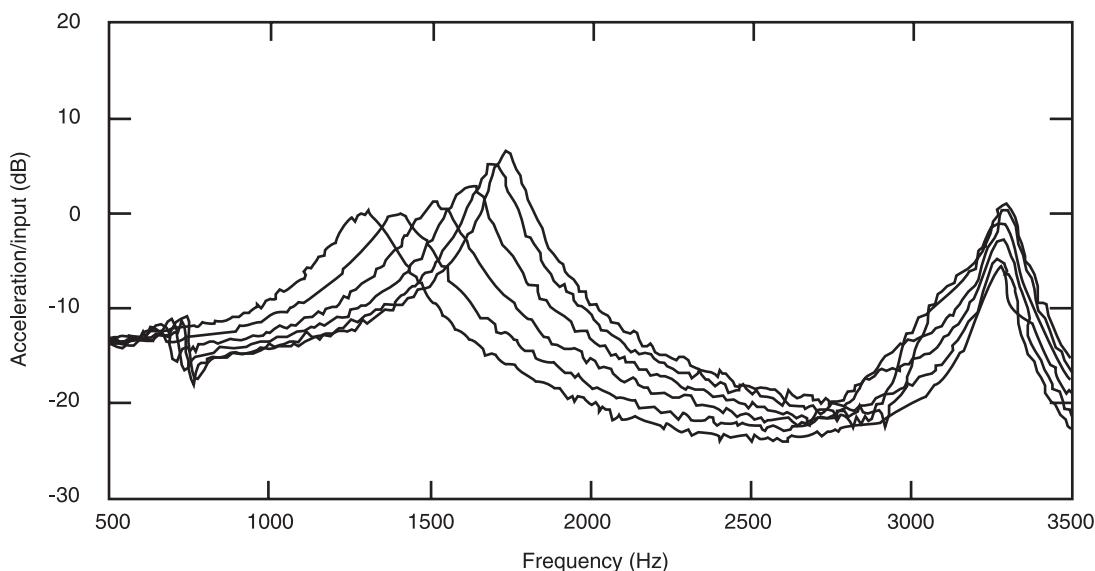

Figure 4 Acceleration per input current frequency response functions at DC bias levels of (from left to right): 20, 30, 36, 42, 50, and 60 kA m^{-1} .

Figure 5 illustrates the sensitivity of major strain-applied field hysteresis loops to variations in mechanical load or prestress. While this attribute allows tailoring of devices preloaded for optimized performance under a constant load (such as acoustic source applications), this introduces a parameter that must be optimized for operation under variable load conditions which are typical of vibration control applications. Actuators using tailored magnetostrictive composite drivers can minimize device sensitivity to variations in the external load.

The upper traces in Figures 6–8 are Bode plots of strain per applied field, strain per magnetization and magnetization per applied field, respectively. The Bode plots were obtained using a swept sinusoidal signal at a relatively low signal excitation of the device (e.g., driving the device to produce maximum strains at resonance that are less than one-third of the device full strain potential, thereby minimizing the presence of undesired harmonics). The lower traces are minor hysteresis loops of these quantities recorded at (from left to right)

frequencies of 10, 100, 500, 800, 1000, 1250, 1500, and 2000 Hz.

Information on performance is used to implement calibration, input and/or output linearization, and control schemes to facilitate the optimized use of magnetostrictive devices. For example, information from Figures 3 and 5 might be coupled to optimize the DC magnetic bias in real time to produce specified strains under varying mechanical loads. Figure 4 demonstrates the ability to tune a system's resonant frequency in real time, which is the basis for a patent pending, tunable magnetostrictive vibration absorber design. This can be coupled with information on frequencies that minimize losses by using hysteresis loop data from Figures 6–8 to tailor the frequency operation for the most efficient electromechanical performance. Additionally, this suggests the ability to target operating conditions for minimization of internal heating under continuous operation, which is of particular concern for ultrasonic operation.

Another significant loss factor that is associated with the transduction of electric to magnetic energy under dynamic operation is eddy currents. Eddy current power losses increase with approximately the square of frequency and thus have a significant impact on the operational bandwidth of devices. Laminations in the magnetostrictive core help to mitigate the effects of eddy currents, however, materials such as Terfenol-D are brittle and costly to laminate. Materials such as insulated magnetic particles or the silicon steels in common use in motors and power systems are suitable for the magnetic circuit components that make up the transducer housing, as they simultaneously support flux conduction and offer high resistivities. Magnetostrictive composites that use nonelectrically conducting matrix material yield reductions in eddy current losses. They have been proposed for extending device output bandwidth by an order of magnitude, from roughly 10 kHz to close to 100 kHz. Such composites offer great promise as high-frequency magnetostrictive drivers.

Actuation Configurations

Nickel was used in many of the early magnetostrictive sonar devices and is still being used in commercially available ultrasonic cleaners available from, for example, Blue Wave Ultrasonics. Other examples of magnetostrictive material use in commercial applications include Terfenol-D-based devices such as the underwater communication systems produced by Trigger Scuba, Inc., the acoustic pressure wave source (P-wave) produced by ETREMA Products, Inc. for enhancing oil well production rates, and precision micropositioners produced by Energenic, Inc.

Dynamic strains are of primary importance in low-frequency high-power transducers, namely those for sonar and underwater communications. At and near mechanical resonance, strains greater than the static saturation strain can be obtained. Three of the more common devices for sonar applications are the flex-tensional, the piston, and the 'ring' types of actuators. Flex-tensional transducers radiate acoustic energy through flexing of a shell, usually oval-shaped, caused by the longitudinal extension and contraction of a cylindrical drive motor mounted in compression inside the shell. The Tonpilz (Tonpilz is German for 'sound mushroom') transducer is a common piston-type design. The transducer has a magnetostrictive rod surrounded by a drive coil that provides AC and DC magnetic field excitation, a mechanism for pre-stressing the rod, a front radiating surface (piston), and a counter-mass. An advantage of piston-type designs over conventional flex-tensional transducers is that they lack parts likely to suffer fatigue-induced failure due to bending. A typical ring transducer might consist of four magnetostrictive rods that are arranged to form a square with four curved pistons that are the radiating surfaces enclosing the square and attached to the corners of the square. Monopole operation is achieved with the rods acting in unison. Dipole operation is accomplished by switching the magnetic bias on two of the rods and maintaining a constant direction on the AC magnetic field on all four rods. The interest in ring transducers during those early days was based on their ruggedness and lower cost compared to other available transducer technologies.

There is a growing interest in use of magnetostrictive devices as a source for motion and/or force, and in particular for use in conjunction with smart structures for active vibration control. These linear motor systems fall into the two general categories of piston devices and inchworm devices. An example of the performance that can be realized using magnetostrictive actuators for active vibration control is presented in Figure 9 in which a simple analog proportion control scheme was applied to achieve significant vibration control (>33 dB at both mode 1 and 2). There are several variations on the inchworm motor concepts that move a shaft relative to the motor housing, and they all generally rely on two separate capabilities, a clamping force and a pushing force. Motors with linear shaft output rates of 20 mm s^{-1} have been designed that can develop 1000 N of force with a 200 mm stroke.

Although generic ultrasonic devices are similar to their low-frequency counterparts, e.g., they require the same components described in Figure 2, there are several problems associated with operation at

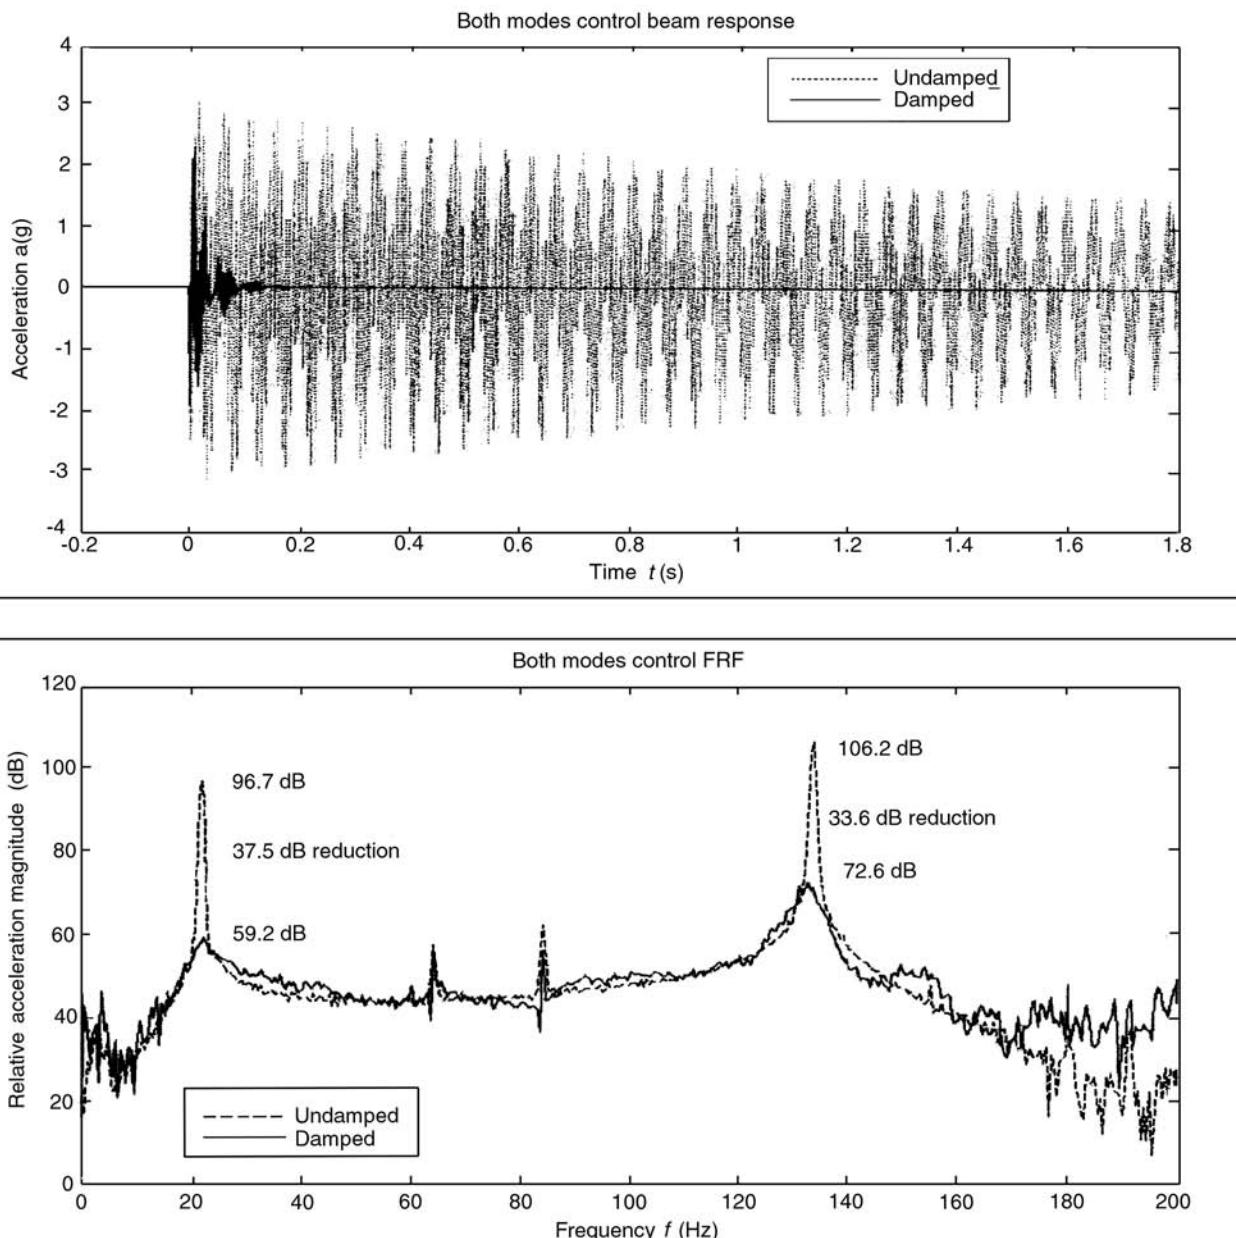

Figure 9 Magnetostrictive actuator performance for active vibration control of the transient responses of a $40 \times 2 \times 1$ 0.125-thick aluminum 'C' channel beam to impact excitation.

frequencies above 20 kHz. Hysteresis losses within a magnetostrictive driver will introduce high internal heat dissipation. Eddy currents will introduce both heat and a skin effect that effectively shields the core of the driver from an applied magnetic field. Impedance mismatches at ultrasonic frequencies make transfer of energy from the driver to the surrounding medium difficult. The use of laminated and/or composite magnetostrictive materials reduces losses associated with eddy currents. Device operation at resonance for enhanced energy output is often

obtained through the use of quarter-wavelength-long drivers in conjunction with half-wavelength amplifying horns having application specific profiles.

Sensing Configurations

Magnetostrictive sensors can be classified as passive sensors, active sensors, and combined or hybrid sensors, based on how the magnetomechanical properties of the system components are used to measure the parameters of interest.

Passive sensors rely on magnetomechanical coupling to link a measurable change in the magnetostrictive material to the external property or condition of interest. For example, according to the Villari effect, the change in the magnetization of the magnetostrictive sample is correlated to an externally imposed change in stress. A coil flux-linked to the magnetostrictive sample can be used to measure changes in magnetic flux as per eqn [5]. Quantities such as external load, force, pressure, vibration, and flow rates can then be measured.

Active sensors use an internal excitation of the magnetostrictive element to facilitate some measurement of the magnetostrictive element that changes with the external property of interest. For example, an excitation coil could be used to excite the magnetostrictive sample with a known H as per eqn [4] and the detection coil used to measure B as per eqn [5]. The permeability from eqn [3] can then be monitored for changes due to an external condition. Designs that employ two coils, one to excite the magnetostrictive element and one for measurement, are known as transformer-type sensors. The most common active sensor design mentioned in the literature is the non-contact torque sensor. Many configurations employ variations on a general theme of a magnetostrictive wire, thin film, or ribbon flux-linked to a target shaft subject to a torque. The change in the magnetic induction or permeability can then be related to the torque on the specimen.

Finally, combined or hybrid sensors use a magnetostrictive element actively to excite or change another material to allow measurement of the property of interest. For example, a fiberoptic magnetic field sensor uses the change in length of a magnetostrictive element in the presence of a magnetic field (Joule effect) to change the optical path length of a fiberoptic sensor. Stress can be measured using photoelastic material, and highly accurate displacement measurements can be made with the help of a magnetostrictive guide.

Magnetostrictive transducers are particularly attractive for noncontact torque and position sensor applications. As a magnetostrictive shaft is torqued, stress develops at $\pm 45^\circ$ from the shaft axis, and the Villari effect produces changes in the shaft magnetization and permeability. The change in magnetization can be measured directly with a Hall probe. Alternatively, the change in permeability can be measured using a two-solenoid active technique in which an excitation solenoid is used to apply a constant magnetic field to a magnetic circuit flux-linked to the shaft and a detection solenoid monitors the torque-induced changes in the magnetic circuit permeability. These torque-induced changes can also be monitored

by tracking electrical impedance function changes in flux-linked excitation and/or detection solenoids, as suggested by the data in Figure 10.

Several approaches exist for extending this technology to nonferromagnetic materials, by applying magnetostrictive materials directly to the surface of the rotating shafts. One technique relies on using amorphous magnetostrictive wire or ribbons that are helically wrapped around and bonded to a shaft. In another, at a high temperature the wire is exploded into fine particles which adhere strongly to the shaft.

Similarly, noncontact position sensors and force distribution sensors are available that respond to the influence of reflected signals and gaps on magnetostrictive components of a magnetic circuit (magnetostrictive waveguides and magnetostrictive delay lines, respectively). Metglas amorphous ribbons are an attractive strain sensor material because they exhibit large permeability changes in response to strain.

Velocity and force can be directly measured in a magnetostrictive transducer, as depicted in Figure 2, where the voltage induced in the solenoid is proportional to the velocity of the force applied to the free end of the magnetostrictive element. Similar transducers have been used as colocated sensor–actuator devices; e.g., devices that simultaneously actuate and sense. The telephone, scanning sonar, and active vibration control applications have made use of this dual operation mode. Although this can be accomplished by separating the voltage induced in the excitation solenoid via the Faraday–Lenz law from the applied (excitation) voltage, the sensed voltages is generally much smaller than that needed for actuation. Hence, it is common for a dual-mode transducer to use separate excitation and detection solenoids.

MEMBRANES

A W Leissa, Ohio State University, Columbus, OH, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0132

A membrane is a structural element which is very thin in one direction compared with the other two, and is flat. In contrast with a plate, it has no bending

or twisting stiffness. If a membrane is not flat, it is called a ‘membrane shell’ (see **Shells**). The membrane is stretched in its plane by tensile and (perhaps) shear stresses. It is these stresses which provide the restoring forces during transverse free vibrations. It is also assumed that these stresses are sufficiently large so that, if the transverse vibrational displacement (*w*) is kept small, the stresses will remain constant during

vibration. **Figure 1** depicts a membrane in its static equilibrium position, stretched over a boundary of arbitrary curvilinear shape. The stress (force/area) applied externally is shown as a normal stress σ_n which may vary along the boundary. In addition, a variable shear stress, which is not shown, may also act in the plane (xy) of the membrane, and tangent to its boundary. These boundary stresses cause internal normal stresses (σ_x and σ_y) and shear stress (τ_{xy}), as shown on an internal element of the membrane in **Figure 1**, which may vary with the coordinates (x and y), but not with time (t).

The equation of transverse motion of the membrane is:

$$T_x \frac{\partial^2 w}{\partial x^2} + 2T_{xy} \frac{\partial^2 w}{\partial x \partial y} + T_y \frac{\partial^2 w}{\partial y^2} + q = \rho b \frac{\partial^2 w}{\partial t^2} \quad [1]$$

where T_x , T_{xy} , T_y are the stress resultants (force/length) obtained by multiplying σ_x , τ_{xy} and σ_y , respectively, by the thickness (b). Transverse forcing pressure (force/area) is indicated by q , which could be present in a forced vibration situation, and ρ is the mass density/volume. In eqn [1], T_x , T_{xy} , T_y , ρ and b may each be functions of x and y , but not t .

Considering free, undamped vibrations ($q = 0$), the most widely used form of eqn [1] is the special case wherein the in-plane shear stress is zero, and the remaining tensile stress is constant and the same in all directions ($T_x = T_y = T$). In this case eqn [1] becomes:

$$T \nabla^2 w = \rho b \frac{\partial^2 w}{\partial t^2} \quad [2]$$

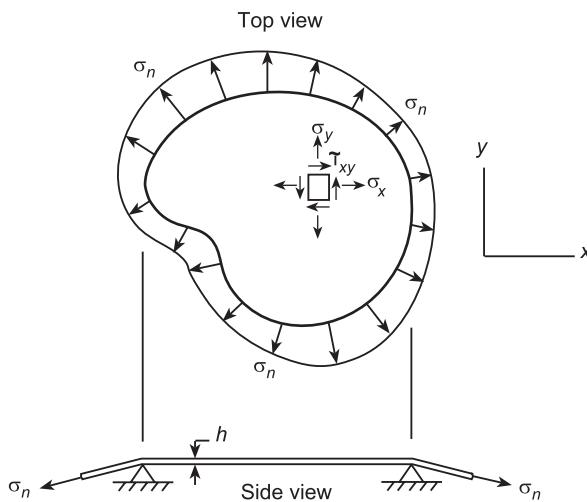

Figure 1 Membrane of arbitrary shape subjected to nonuniform tensile stress.

where $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the Laplacian differential operator.

Rectangular Membranes

Consider first a rectangular membrane with dimensions $a \times b$, stretched by uniform tension (T). Let the origin of the xy coordinate system be in one corner, so that the four edges ($x = 0, a$; $y = 0, b$) are fixed ($w = 0$). An exact solution for the transverse, free vibration displacement is:

$$w(x, y, t) = \sin(m\pi x/a) \sin(n\pi y/b) \sin(\omega t + \phi) \quad [3]$$

where m and n are integers, ranging from one to infinity ($m, n = 1, 2, \dots, \infty$), and ϕ is an arbitrary phase angle. It is seen that eqn [3] satisfies the boundary condition ($w = 0$) along all four edges. Substituting it into eqn [2] yields the natural frequencies (ω), which are conveniently expressed in terms of the nondimensional parameter:

$$\omega a \sqrt{\rho b/T} = \pi \left[m^2 + (a/b)^2 n^2 \right]^{1/2} \quad [4]$$

Looking at eqn [4] it is clear that the fundamental (i.e., lowest) frequency of a rectangular membrane, regardless of the aspect ratio (a/b) will be for a mode shape having one half-sine wave in each direction ($m = n = 1$). **Figure 2** shows the first nine nodal patterns of free vibration for a rectangular membrane having $a/b = 1.5$. The dashed lines are node lines ($w = 0$). The corresponding nondimensional frequencies $\omega a \sqrt{\rho b/T}$ are 5.664, 7.854, 9.935, 10.538, 11.327, 13.329, 13.421, 14.482, and 15.471, according to eqn [4]. It is seen that some frequencies may be quite close together.

One may also have two mode shapes having the same frequency. These are called ‘degenerate modes’. For example, consider the square membrane ($a = b$) and its degenerate frequencies $\omega_{12} = \omega_{21}$. Because they both vibrate with the same frequency, superposition of the two mode shapes may be taken as:

$$W(x, y) = C_{12} \sin(\pi x/a) \sin(2\pi y/a) + C_{21} \sin(2\pi x/a) \sin(\pi y/a) \quad [5]$$

where C_{12} and C_{21} are arbitrary constants, determined by how the membrane is set into motion (the initial conditions). **Figure 3** shows how the node line varies with the relative magnitude (C_2/C_1) of the superimposed modes. **Figure 3** also shows some

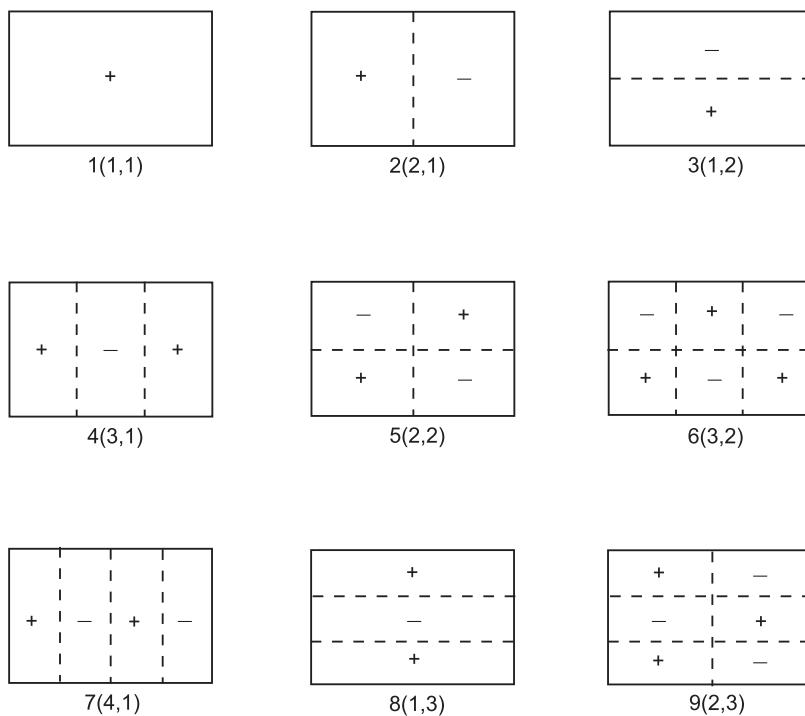

Figure 2 First nine nodal patterns of a rectangular membrane with $a/b = 1.5$.

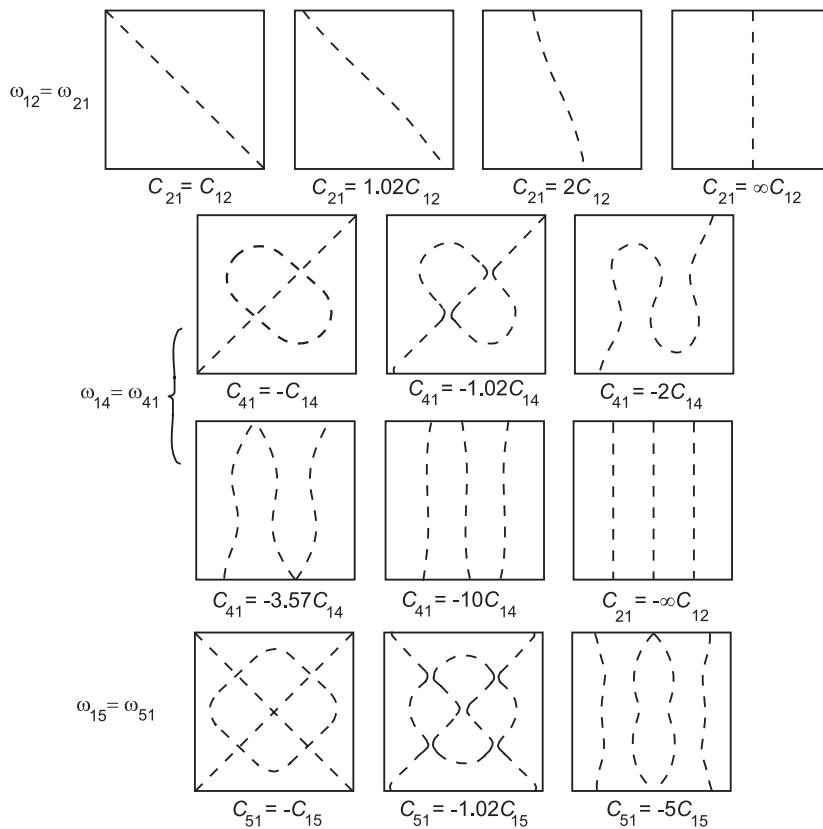

Figure 3 Some superimposed degenerate nodal patterns for square membranes.

superimposed degenerate modes for $\omega_{14} = \omega_{41}$, and for $\omega_{15} = \omega_{51}$.

Circular Membranes

For a circular membrane it is convenient to use polar coordinates, as shown in Figure 4. Then $\nabla^2 = \partial^2/\partial r^2 + (1/r)\partial/\partial r + (1/r^2)\partial^2/\partial\theta^2$. By separation of variables one finds the transverse displacement:

$$w(r, \theta, t) = [A_n J_n(kr) + B_n Y_n(kr)] \cos n\theta \sin(\omega t + \phi) \quad [6]$$

which satisfies eqn [2] exactly, where J_n and Y_n are Bessel functions of the first and second kinds, respectively, $k^2 = \omega^2 \rho b/T$, A_n and B_n are arbitrary constants, and n is an integer, beginning with zero. Because $Y_n(0) = -\infty$, it is necessary to set $B_n = 0$ to have finite displacement at the center ($r = 0$). Setting $w = 0$ along the boundary ($r = a$) results in the frequency equation:

$$J_n(ka) = 0 \quad [7]$$

The first five roots $ka = \omega a \sqrt{\rho b/T}$ of eqn [7] are given in Table 1 for each n . Nodal patterns for the first nine frequencies of a circular membrane are shown in Figure 5, along with the corresponding $\omega a \sqrt{(\rho b/T)}$. It is seen that modes 1, 4, and 9 are axisymmetric ($n = 0$), having 0, 1, and 2 interior nodal circles, respectively, whereas modes 2, 3, 5, and 7 have 1, 2, 3, and 4 nodal diameters, respectively, with no interior nodal circles. Exact shapes of the vibration modes along diameters may be seen from plots of the Bessel functions $J_n(kr)$.

An annular membrane is bounded by two concentric circles, an inner one at $r = b$, and an outer one at $r = a$, with both circular boundaries being fixed and exerting uniform radial tension T (force/length). The solution (eqn [6]) of eqn [3] is again

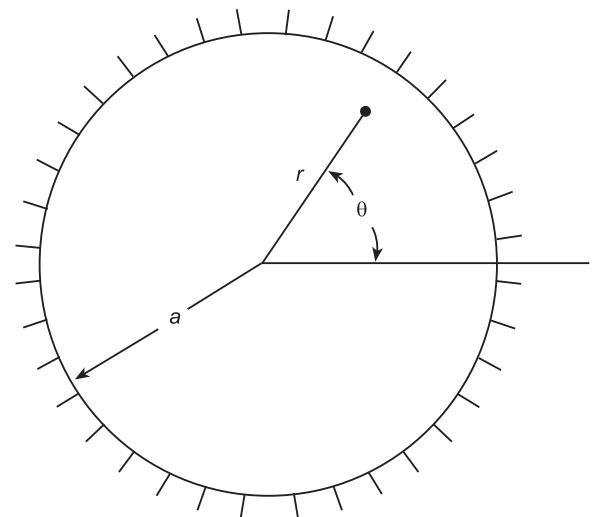

Figure 4 Circular membrane and polar coordinates.

appropriate. But both A_n and B_n are now retained, because $r = 0$ does not apply to the membrane. Setting $w = 0$ at $r = a$ and $r = b$ gives, for a nontrivial solution, the following frequency equation:

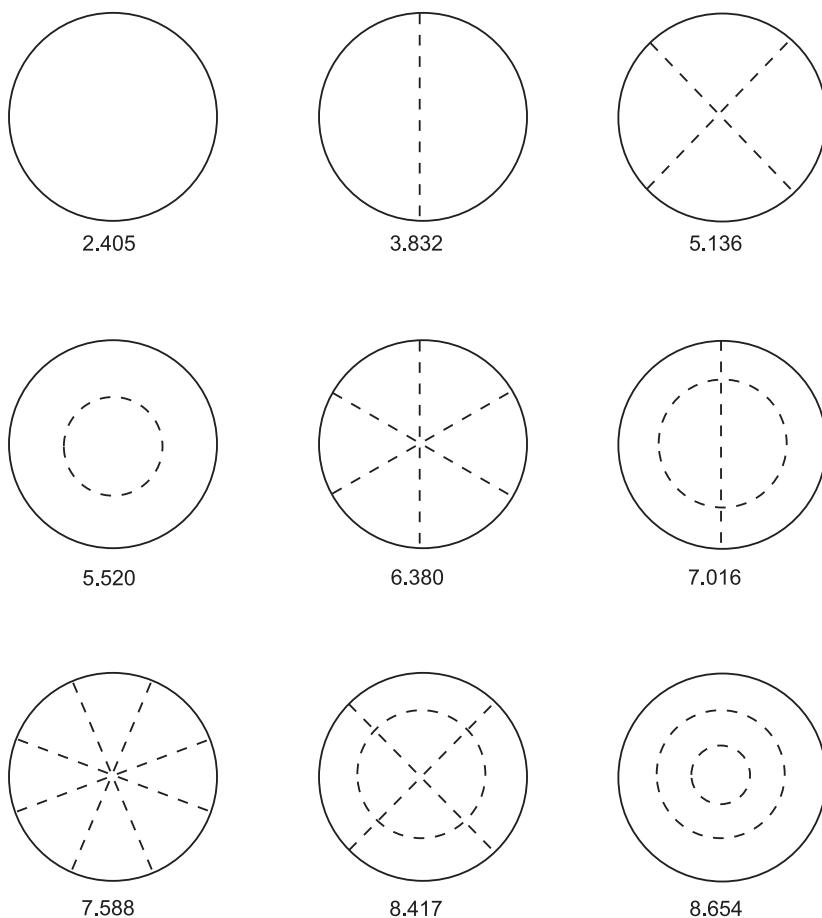

$$J_n(\lambda) Y_n\left(\frac{b}{a}\lambda\right) - J_n\left(\frac{b}{a}\lambda\right) Y_n(\lambda) = 0 \quad [8]$$

where $\lambda = ka = \omega a \sqrt{\rho b/T}$. For any desired value of b/a , all frequencies of the annular membrane are obtainable from eqn [8]. The first three frequencies (corresponding to 0, 1, and 2 interior nodal circles) are listed in Table 2 for the $n = 0$ (axisymmetric) and $n = 1$ (one nodal diameter) modes of annular membranes having various b/a ratios, especially for $b/a < 0.5$. It is interesting to note that, as b/a approaches zero, which corresponds to a central point support, the frequency for $n = 0$ becomes the same as for the unsupported membrane (Table 1). This is because membranes are incapable of transmitting transversely applied concentrated forces (reactive in this situation)

Other Shapes

A sectorial membrane has the shape of a sector of a circle (Figure 6), with a sector angle, α . The transverse displacement:

$$w(r, \theta, t) = [A_v J_v(kr) + B_v Y_v(kr)] \sin v\theta \sin(\omega t + \phi) \quad [9]$$

satisfies eqn [2]. Moreover, if noninteger values of v are chosen such that $v = n\pi/\alpha$ ($n = 1, 2, \dots, \infty$), then $w = 0$ along the radial edges $\theta = 0$ and α , as desired. Setting $B_v = 0$ to avoid infinite displacement at $r = 0$, and $w = 0$ at $r = a$ yields:

$$J_v(ka) = 0 \quad [10]$$

Symmetric modes result from $n = 1, 3, \dots$; antisymmetric modes from $n = 2, 4, \dots$. For every v there is an infinite number of nondimensional frequencies $ka = \omega a \sqrt{\rho h/T}$. Frequencies arising from half-integer orders of v are given in Table 3. Results for intermediate values of $\alpha = 180^\circ, 90^\circ, 60^\circ, 45^\circ$, and 36° , corresponding to integer v , may be taken from Table 1. The case of $v = 1/2$, corresponding to $\alpha = 360^\circ$ in Table 3, yields boundaries at $\theta = 0^\circ$ and $\theta = 360^\circ$, which are the same radial line, and the case of the complete circular membrane supported along an additional single radial line is thereby represented.

Annular sectorial membranes are bounded by the circle arcs ($r = b, r = a$) and the two radial lines ($\theta = 0, \theta = \alpha$). Frequencies for arbitrary α and b/a may be found from eqn [8], replacing n by v , where $v = n\pi/\alpha$ ($n = 1, 2, \dots, \infty$).

Because node lines have the same zero transverse displacement as a constrained boundary, considerable miscellaneous results for other membrane shapes

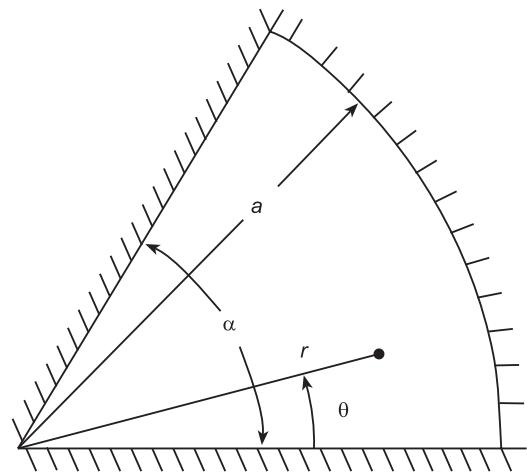

Figure 6 Sectorial membrane.

can be found by studying nodal patterns. For example Figure 3 shows that the exact frequency for an isosceles right triangle with sides $a \times a$ is that of the (1, 2) and (2, 1) modes of a square $-\omega a \sqrt{\rho h/T} = \sqrt{5}\pi$. Considering the node lines as boundaries, Figure 3 also shows a variety of shapes, each having straight and curvilinear lines as boundaries.

Additional information for straight-sided membranes may be obtained from published results for plates having the same configurations and all edges simply supported, using the correspondence:

$$\left(\frac{\omega_m^2 \rho h}{T}\right)^2 \sim \frac{\omega_p^2 \rho h}{D} \quad [11]$$

where the subscripts m and p correspond to membrane and plate natural frequencies, respectively (see Plates). Using this one can, for example, obtain the accurate frequencies for right triangular membranes of various aspect ratios (b/a) presented in Table 4. Corresponding nodal patterns for the second, third,

and fourth modes are exhibited in Figure 7. (The first modes have no interior node lines.)

Some Complicating Effects

Results for frequencies and mode shapes of free vibrations given above have all been for membranes which are initially stretched by a uniform tensile stress resultant (T) in all directions. If a rectangular membrane is subjected to different, but uniform, tensile stresses in its lengthwise and breadthwise direction ($T_x = \sigma_x h = \text{constant}$, $T_y = \sigma_y h = \text{constant}$), the sine wave mode shapes of eqn [3] remain valid. Substituting eqn [3] into eqn [1], with $q = 0$ and $T_{xy} = 0$, yields the exact frequencies:

$$\omega a \sqrt{\rho h / T_x} = \pi \left[m^2 + (T_y / T_x) (a/b)^2 n^2 \right]^{1/2} \quad [12]$$

If shear stress is also present then no exact solution is possible. Let σ_x , σ_y , and τ_{xy} all be constants. Reasonably accurate frequencies for a square membrane ($a/b = 1$), with $\sigma_y = \sigma_x$ and varying amounts of additional shear stress (τ_{xy}/σ_x), were obtained by the Ritz method, and are presented in Table 5. For this combination of stresses, the stresses along 45° diagonal planes are principal stresses:

$$\sigma_1 = \sigma_x + \tau_{xy}, \quad \sigma_2 = \sigma_x - \tau_{xy}, \quad \tau_{12} = 0 \quad [13]$$

as shown in Figure 8. As τ_{xy}/σ_x approaches unity, σ_2 becomes zero, and σ_1 becomes $2\sigma_x$. This is a special case of diagonal tension where the membrane is stretched in the direction of one of its diagonals, but is slack in the other diagonal direction. This is a limiting case, for if $\tau_{xy}/\sigma_x > 1$, σ_2 is compressive, and

the membrane will buckle (wrinkle) in its initial state. Contour plots of mode shapes corresponding to some of the frequencies are shown in Figure 9. For $\tau_{xy}/\sigma_x = 1$, the node lines are all straight, and parallel to the direction of the applied principal stress (σ_1).

doi:10.1006/rwvb.2001.0075

Introduction

Microelectromechanical systems (MEMS) applications have been conceived for both substitution and for new products. The decreased cost associated with very large production is directing the utilization of the microsystems into applications that require mass production. Pressure, temperature, proximity, acceleration or chemical integrated microsensors for automotive application represent a large family of substitution MEMS. Intelligent transportation systems (ITS) technology is another motor of development for new microsystems. The health care devices are also regarded as great potential applications for either substitution or new products.

The primary feature of MEMS applications is that they adequately detect and influence phenomena where microscale interactions are adjoining to macro-scale effects. The small-size, low-energy consumption endorsed by high reliability, low cost, and capability to process and deliver undistorted measurement signals in a form that the user can easily exploit constitute the major strengths of MEMS. Microsensors usually do not interfere with macrophenomena, while they could track microscale events accurately. MEMS are thus capable of perceiving the nature to a much lower scale size than the normal-sized sensors do. They can be implemented in time-varying spatial microscale configurations to survey the borderline transition from micro to macro phenomena. Thus, applications of MEMS sensors in resonant structures, buckling, turbulent flow, acoustics, thermo-stress phenomena, and phase change, are befitting. The low cost of the microsensors permits allocations of much larger numbers of measurement points in systems that require synchronization of distributed response, in dynamic allocation of scarce resources systems, or in redundant control and decision management systems.

Although the great majority of the present commercially available devices are based on bulk micromachining, surface micromachined microsystems represent the desired turnout for future MEMS. The

capability to integrate on the same chip when produced during the same process, the integrated circuit (IC) circuitry, and the sensing/actuating device enable applications that up to now have been unimaginable. The large number of present MEMS-based systems represent just a small fraction of the possible conceivable and unique applications that will be available in the very near future. A number of available applications involving MEMS are shown in Table 1. The applications listed are at various levels of development, ranging from laboratory testing to the market. Most microsystems are still related to the macroscopic perception of the world, whereas those conceived to handle the matter at miniature scale have been implemented more recently. DNA-mapping kits and bioanalysis systems on a single chip are an application that will probably soon be commercially available. However, the endowment of MEMS has become quite common, such that the acknowledgment of the microtechnology in newly developed systems is no longer publicized by the manufacturer.

The related applications of MEMS to the dynamics of mechanical systems are mostly limited at this time to those accomplished by the normal-sized sensors. Accelerometers, angular rate sensors, vibrometers, microphones, and pressure sensors, are the most common applications available at this time. There are very few MEMS devices in large-scale commercial use, other than microsensors and microvalves. However, sustained research is being carried out to accomplish fully integrated systems in one single chip. Thus, single-chip autonomous microrobot or computer hard-drive units on a single chip, implantable drug delivery systems equipped with sensors, valve, reservoir, and controller, or ion propulsion miniature systems for space application are only a few of the microsystems which have been thoroughly investigated. If the progress in accomplishing fully integrated microsystems is considered to be moderate, microelements such as new microsensors and microactuator concepts and prototypes are constantly being reported.

Mechanical Microsensors

Most MEMS mechanical sensors are alternatives for existing normal-sized sensors. Regardless of the physical quantity detected, MEMS mechanical sensors

Table 1 Potential applications of MEMS

exhibit a larger measurement range, higher sensitivity, better linearity, and lower hysteresis. Besides, all commercially available MEMS mechanical sensors easily comply with the rule of 20% for a new product: newly developed MEMS-based products are at least 20% less expensive to build and/or perform 20% better. Many MEMS devices are developed at a cost which is 10 times less expensive and perform 10 times

better than normal-sized sensors. The most significant impact of MEMS, however, arises from their applications, which in most cases cannot be realized with normal-sized systems. A multiactive linking catheter, arrayed mirror high-resolution display, or a swimming microrobot represent only a few of the research topics which are most likely to grow into commercial products which will have a large impact on our life.

The automotive industry has had most benefit from MEMS so far. The mass production of cars requires mass production of sensors, which can be made more economical and rugged through micromachining. Research reports predict a growth of the MEMS device industry to about \$35 billion annually by the year 2002: more than half of this is attributed to the automotive industry. Figure 1 illustrates the distribution of MEMS applications on the end-user industry.

Pressure and acceleration sensors have already been successfully implemented as typical MEMS commercial products. The excellent features of micromachined accelerometers enabled a tremendous impact in the improvement of car dynamics. The low mass and reduced power consumption associated with a reduced cost in microaccelerometer have facilitated the implementation of the MEMS structure in various vehicle applications, ranging from air bag deployment system to the active suspension.

Microaccelerometers

Microaccelerometers are miniature inertial masses elastically suspended on inertial frames that are rigidly connected to the body on which the acceleration should be measured. The inertial mass moves in proportion to the acceleration amplitude of the moving body. The amplitude of motion is detected and converted into an electric signal. The lower the mass of the accelerometer, the higher the natural frequency of the microaccelerometer is. Thus, the main requirement for an accelerometer could be accomplished through miniaturization. The natural frequency of microaccelerometers is often beyond 10 kHz, while their mass can be as low as 50 µg.

Such a microsystem is illustrated in Figure 2, as an ADXL50 micromachined accelerometer. This is a complete one-axis acceleration measurement system on a single monolithic IC. Detection of acceleration is based on inertial displacement under external acceleration of an elastically suspended mass. The fixed armatures detect both amplitude and direction of the displacement through capacitive measurement with respect to the fixed electrodes. Along with the sensing structure, the chip comprises an oscillator, reference signal circuit, preamplifier, demodulator,

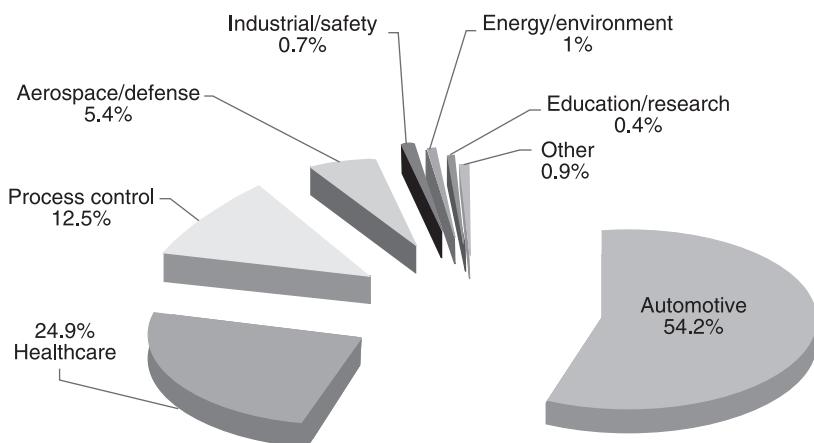

Figure 1 Applications of MEMS and end-user industries.

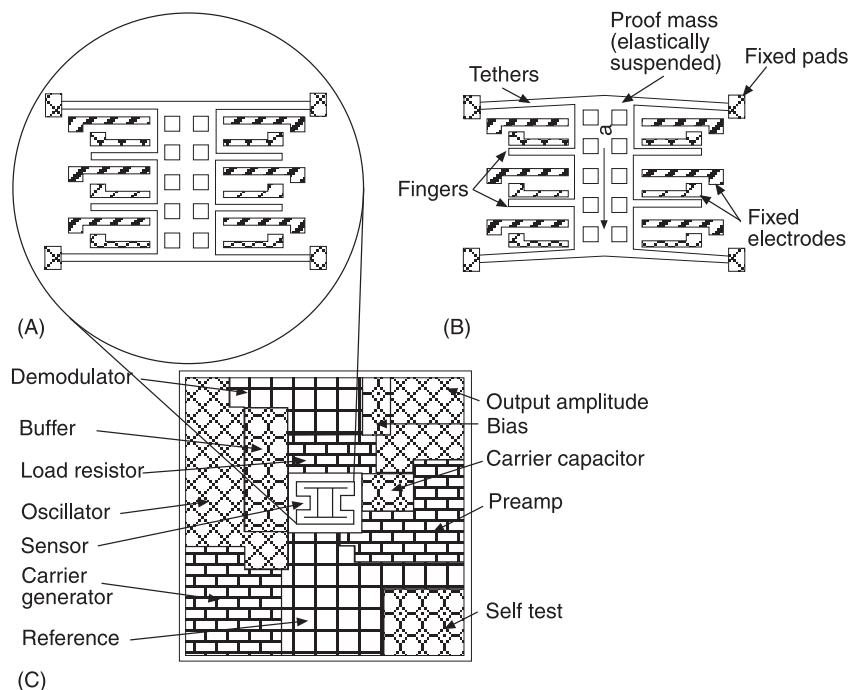

Figure 2 Schematics of the microaccelerometer ADXL50. (A) With no excitation, the proof mass rests in a balanced position. (B) Under the acceleration, the proof mass moves along with the fingers. bias compensation circuit, and self-test circuit. Traditionally, such microaccelerometers have been used in air bag deployment systems. However, other applications in vehicle and seat active suspensions make use of such microaccelerometers. The low cost and high reliability of MEMS represent an important driving factor in the progress of implementation of the intelligent vehicle system (IVS). This concept comprises implementation of sensors and marks, such that roads and vehicles would be able to interact

and improving the traffic on congested roads. Proximity sensors, impact avoidance sensors, position and guidance sensors, and remote communication devices are essential elements in the implementation of efficient adaptive traffic schemes on highways. In the vehicle industry, many other solid-state microsystems, such as thermal, optical, magnetic, or chemical sensors, have been implemented and are intensively used. Engine management, wipers, mirrors and lights and air quality control in the car are among the best

known applications of optical and chemical sensors in vehicles. However, such sensors are semiconductor-based devices and do not exhibit any detectable mechanical dynamic outcome. The distinction between solid-state sensors and MEMS is less perceivable from the point of view of function, since most MEMS utilize one or more measurement principles used by solid-state microsensors, such as piezoresistive, magnetoresistive, piezoelectric, capacitive, and ion-sensitive field effect.

One of the most critical problems faced by MEMS is packaging. The diversity of measurands makes package standardization unfeasible for all possible types of microsensors and microsystems. Figure 3 illustrates a standard packaging configuration that is presently used in IC. Some microsystems require sealed chips, whereas others call for access of the surrounding environment to the sensing area. In certain cases, simple sealed or perforated lids may accomplish specific requirements for specific sensors. In more complex situations, packaging issues are dealt with individually, from case to case. Thus, microactuators may require access to the plant and direct physical contact with the environment. Moreover, rotating parts need protection and lubrication. MEMS devices must also meet the milieu conditions of the application. To illustrate, Table 2 presents the environmental conditions that a sensor used in the automotive industry must face, as prescribed by SAE J1221 and SAE J5756.

A larger potential of MEMS applications with mechanical microsensors resides in new integrated systems for innovative and emerging applications. As an example, MEMS employed in global positioning systems (GPS) create navigation systems that can provide accurate positioning on a geographic area which are sufficiently accurate to make them appropriate for the ground vehicle traffic management applications. The low cost of MEMS sensors and

Table 2 Basic requirements for automotive sensors (SAE J1221 and SAE J5756)

Exposure to:	Range
Temperature	–40°C to 85°C inside the vehicle –40°C to 125°C under the hood –40°C to 150°C on the engine –40°C to 200–600°C in the exhaust and combustion areas

Mechanical vibration	15 g, 100 Hz to 2 kHz
Chemical exposure to:	Fuel Oil Freon Humidity Salted water Exhaust gases Ethylene glycol

GPS enables the current implementation of such devices on standard consumer vehicles.

Since the 1980s the research on MEMS has matured tremendously. The microsystems are permanently heading towards smaller features and integration of mechanical, electrical, and control subsystems on a single chip.

Acoustic Microsensors

The acoustic sensor class exhibits considerable potential for mechanical and chemical sensing. The planar geometry configuration enables compliant fabrication of sensors using standard IC technology. The principle of detection is based on the high sensitivity of the elastic wave velocity, traveling through a resonant media while crossing an active material, which is subjected to excitation from the physical

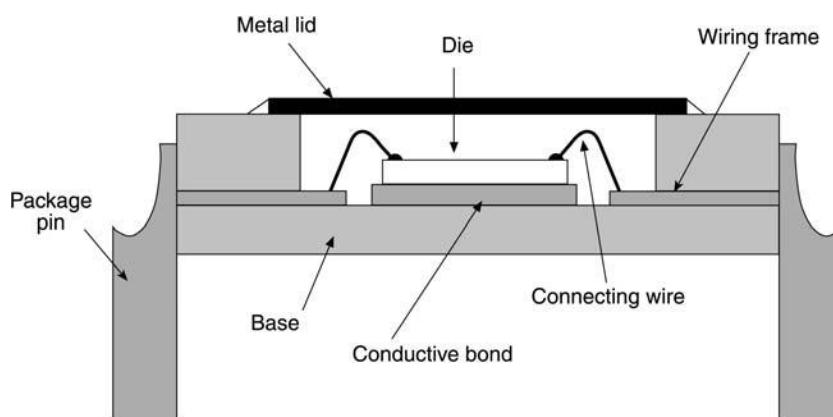

Figure 3 Standard packaging of an integrated circuit.

quantity to be measured. The acoustic wave-based sensors, such as the surface acoustic waves (SAW) and the flexural plate waves (FPW), are based on the piezoelectric properties of classes of monocrystals and ceramics. **Figure 4** illustrates the schematic configuration and functioning of an SAW sensor. One of the SAW interdigital transducers is used to excite the piezoelectric substrate of the sensor. When an electrical charge is applied to a piezoelectric structure, the structure tends to vibrate near its natural frequency or one of its harmonics. The vibration wave propagates through the substrate and travels throughout the coating, which is the active material sensitive to the quantity to be measured. The change in the active material will modify the speed of the crossing wave. The second SAW transducer detects the phase shift or amplitude modification due to the structural changes in the bulk of the sensing material. The acoustic sensors have been known since the early 1960s from their applications with large monocrystalline quartz. The piezoelectric effect can be successfully used in the miniature devices, microsensors, and microactuators. If the structure is a thin plate of mass m and thickness t , the resonance shear-mode wavelength λ (thickness is chosen such that $\lambda = t$) will be modified due to the mass change of the plate by the linear relationship:

$$\frac{\Delta m}{m} = \frac{\Delta \lambda}{\lambda}$$

Modifications to the structure of the delay line will be reflected in the signal perceived at the receiver. This information can always be related to the input exci-

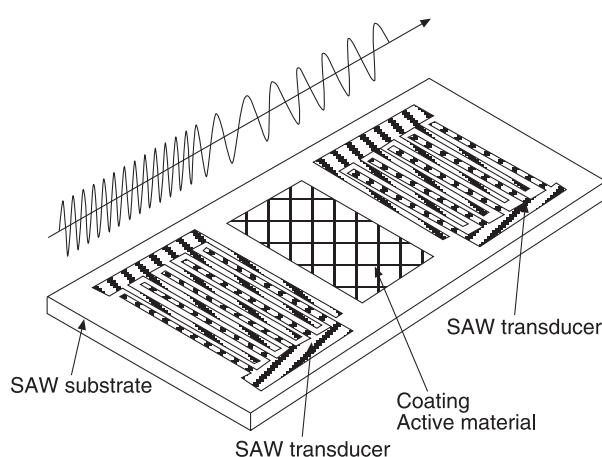

Figure 4 Schematic of a surface acoustic sensor concept. The oscillation generated by the source is changed when passing through the coating which represent the active material. The change is perceived by the surface acoustic wave (SAW) transducer, which detects the change due to the modification in the state of the active (sensing) materials.

tation, which is directly related to the physical quantity to be measured. The interdigital transducer configuration is very appropriate for MEMS implementation. IC-like technologies have been used to complete monolithic piezoelectric accelerometers along the full scale ranging from 1 to 100 g. The piezoelectric substrate deposition requires some special processing which is not specific to IC processes. Among the thin film piezoelectric materials that can be implemented with IC technology are ZnO, AlN, Pb(Zr,Ti)O₃ (PZT), and polyvinylidene fluoride (PVDF).

Microactuators

Microactuators are conceived to transform various forms of energy, mostly electrical, into mechanical rotation or translation on a miniature scale.

The first electrostatic microactuators were created making use of modified surface micromachining technology in which thick polysilicon rotors actuated by side-driver electrodes were held at the center by a hollow hub. Early designs of micromotors were conceived as small replicas of normal-sized electric motors. At 500 rpm, the life of the motor would not exceed 1 h due to the substantial friction and wear on the sliding surface. Eccentrically rotating motors (wobble motors) were then created to overcome the sliding friction which would be reduced to a roll friction. Moreover, elastically suspended moving elements driven by electrostatic or magnetic fields or actuated by fluid or thermal power have been proposed. Such designs fully eliminate the contact friction.

Some other designs use the friction force between the moving and fixed parts as driving force. Such an example is represented by ciliary motion systems. Miniature actuators making use of piezoelectric, magnetostrictive, or photostrictive or phase transformation effects or thermal effects could generate larger power per mass unit efficiency factors. More creative concepts have been proposed and tremendous progress was achieved in increasing the life of the micromotor and in improving the force/torque. Interdigitated comb-like resonant structures, linear thermal actuators, shape-memory elements, or capillary force-actuated elements are among the many proposed solutions to raise the actuation force of the micromotors. In addition to modified surface machining, high-aspect ratio machining (lithografie galvanik abeforming or LIGA, and deep X-ray lithography) was used to create microactuators. **Figure 5** illustrates the concepts of micromachined actuators. Forces in the range of μ N can be accomplished by single microactuators. Optical applications are most

suitable with the force range generated by single unit micromotors. Table 3 illustrates the work per unit of volume and the frequency range of various classes of microactuators.

Certain macroscopic tasks can be performed by arrays of microactuators. Larger displacements could be achieved by multiple microactuators with synchronized motion, as illustrated in Figure 5F, in the case of a ciliary motion conveyer where the

actuators are connected in series. Larger loads could also be supported by distributed synchronized microactuators connected in parallel. Arrays of microsensors and microactuators connected conveniently in series and parallel can produce higher forces and larger displacements and perform more complex functions than the unit microactuator. Although the energy loss in direct-driven microactuators is minimal, the undesired friction limits the type of

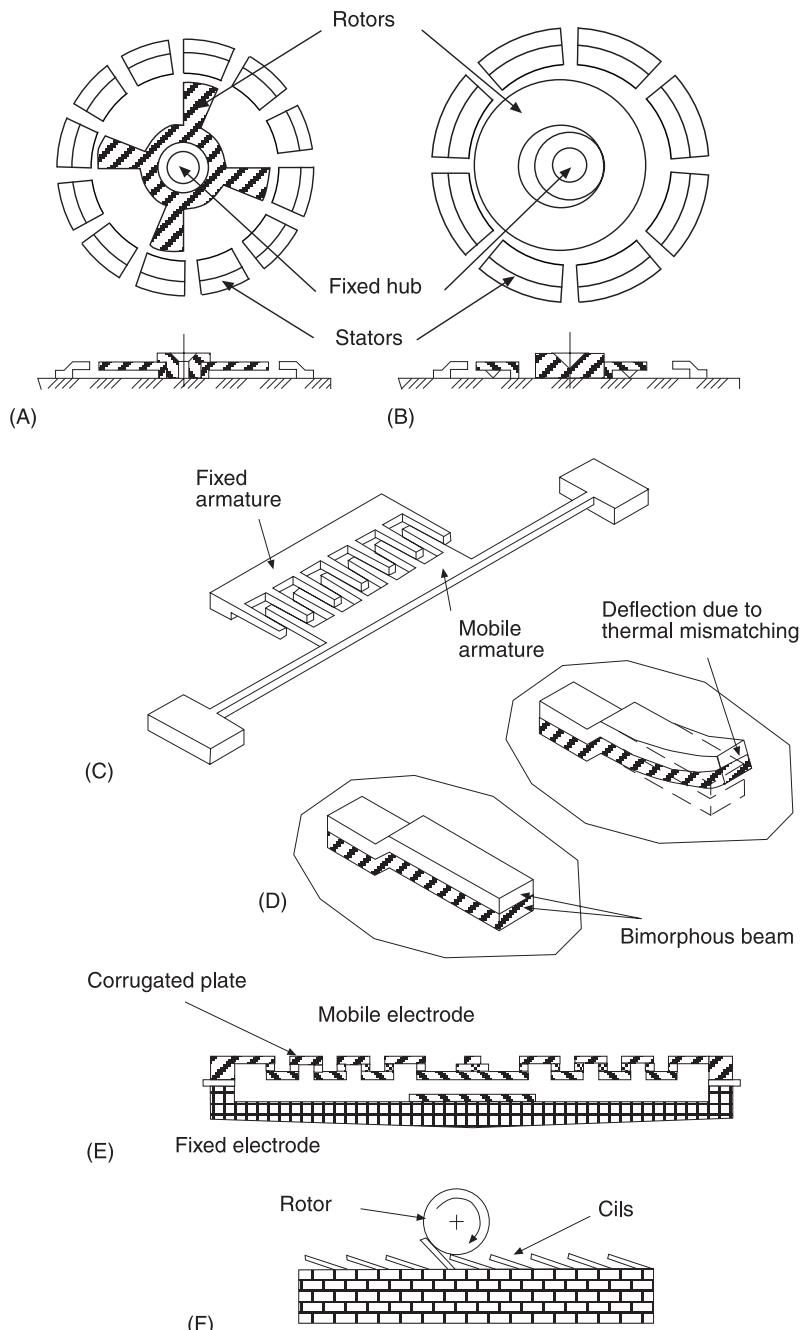

Figure 5 Microactuators. (A) Side-drive electrostatic micromotor. (B) Wobble electrostatic micromotor. (C) Comb-drive microactuator. (D) Thermal actuator (bimorphous cantilever beam). (E) Electrostatic linear microactuator. (F) Ciliary motion conveyer.

Table 3 Work per unit of volume and frequency range for selected types of microactuators

No.	Microactuator type	Work/volume ($J m^{-3}$)	Frequency (Hz)
1	Shape memory alloy (Ni-Ti)	$6 \times 10^6 - 25 \times 10^7$	10^2
2	Solid-liquid phase change	4.7×10^6	1
3	Thermal expansion	4.6×10^5	10^2
4	Electromagnetic	$1.6 \times 10^3 - 4 \times 10^5$	10^2
5	Electrostatic	$7 \times 10^2 - 1.8 \times 10^5$	10^4
6	Piezoelectric	$1.8 \times 10^2 - 1.2 \times 10^5$	10^7

transmission elements to the supported beams as linkages. Joints and gears cannot be used in microsystems due to the microscale high friction level that reduces the efficiency of the transmission to values close to zero.

Remarkable applications of microactuators to macroscopic systems have been demonstrated in the control of turbulent flow on surfaces. Augmentation of a disturbance created by a small motion of a microactuator on the surface enable formation of a vortex, which upholds the capability to control the aerodynamic macrophenomena.

Microvalves and Micropumps

MEMS applications in this group are related to fluid handling, chemical analysis, microbiology, aerodynamics, and controls. Early investigations on fluidic microdevices were directed towards the accomplishment of micropumps, microvalves, and shaped flow channels. Most devices have been accomplished through hybrid bulk and special micromachining procedures. Silicon membranes actuated by electromagnetic, electrostatic, or thermal expansion forces have been used as valves, as shown in Figure 6. The metallic conductor deposited on the thin membrane

will move the flexing element when a current is passed through the coil. The motion can be conveniently used to obstruct one of the valve orifices. Similar structures can be used as a pump if the openings of the two orifices are synchronized. The variation of volume inside the cavity due to the motion of the membrane will induce flow from the input to the output orifices.

Fluidic elements require special packaging such that the moving element is enclosed within a specific structure. Wafer-to-wafer or glass on silicon anodic bonding is usually used to seal the fluidic elements.

Fluidic logic elements have been developed as an alternate solution to the electronic logic circuits. MEMS enable downsizing of these circuits such that full logic controllers can be built on a few square millimeters of wafer. Figure 7 illustrates such a circuit. The flow stream switches the flow channel if the corresponding control signal is applied through the appropriate control channel.

Chemical analysis integrated systems comprising pumps, valves, sensors, and controllers are under intensive investigation.

Other Applications

Optical microsystems are among the most common applications of MEMS. Here, the mechanical load carried by the actuator is reduced to the intrinsic mass of the moving part. Besides, very performant optical cells can be built in IC technology. Micromachined high-resolution displays comprising arrays of micromirrors, each of $16 \mu m$ size, which can be tilted such that the reflected beam creating the pixel image becomes visible or invisible, integrated on metal oxide complementary circuits have been accomplished. Micromechanical optical switches and resonators, optical modulators, tunable filters, or deformable optical wave guides are also available. Applications

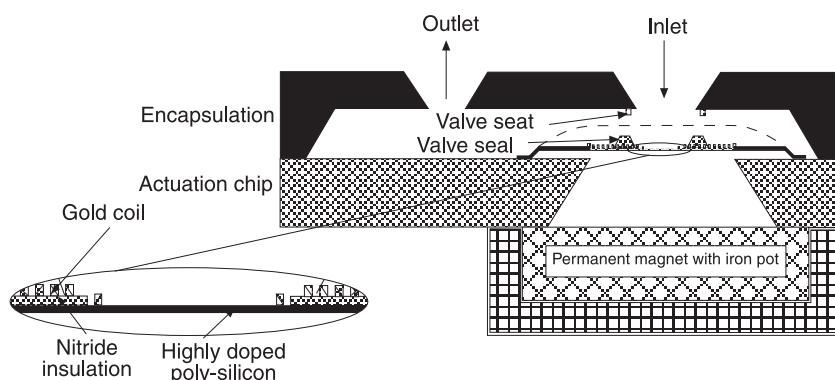

Figure 6 Scheme of a cross-section of the microvalve (actuation chip plus encapsulation and permanent magnet with iron pot).

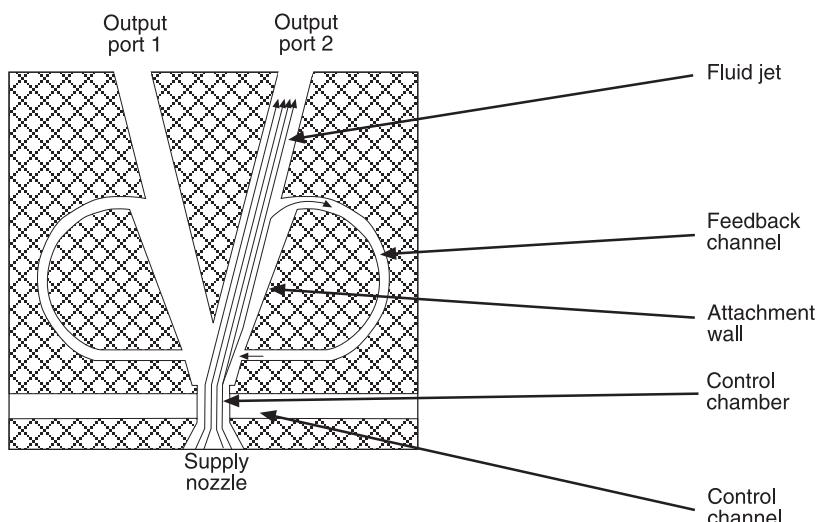

Figure 7 Schematics of a fluidic logic element.

to communications and data storage systems as well as in very high-accuracy measurement devices of the optical MEMS are quite common.

Another type of MEMS application features the investigative systems to nanoscale level of the matter. Thus, scanning tunneling or lateral force microscopy probes and arrays of probes accomplished in silicon dramatically improved the performances of the microscopes, at the same time reducing their cost. The mass of microobjects can be accurately measured, making use of simple principles such as the bending of the free end of a cantilever beam under a gravity force. Figure 8 illustrates such a measurement system made of an array of beams conceived to measure a larger range of masses.

Biotechnology and medicine also benefit from MEMS. Catheters equipped with micropressure sensors can detect the pressure variation on a portion of an artery, which indicates the existence of clots. Research on similar catheters bearing together with pressure sensors and biochemical sensors that detect enzymes composition and concentration has been carried out. Less invasive probes for tests have been manufactured in MEMS technology and the results obtained claim more effort in developing such systems. Neural probes used to detect the electric potential generated by nerve activity have been built using a hybrid surface and bulk postprocessing of silicon. Such a microelectrode is shown in Figure 9. Implantable artificial organs, a microautonomous tool for minimally invasive surgery or drug delivery systems, are among the most desired MEMS due to the enormous positive impact they will have on humans' life.

The ultimate goal of the research effort in MEMS is to create useful micromachines as full systems. Successful applications make use of standard IC

processes such that the microsystems could benefit from the coupling of the micromechanical components with the conditioning circuitry and controller on the same miniature unit. Besides, many original systems have been accomplished through bulk micromachining comprising anisotropic Si etching, wafer bonding, and advanced packaging. Since bulk

Figure 8 Microcantilever beam used to scale a small mass. The intrinsic interlayer stress will bend the beam. A micromass is used to bend back the beam. The new value of the deflection is directly related to the mass of the microparticle.

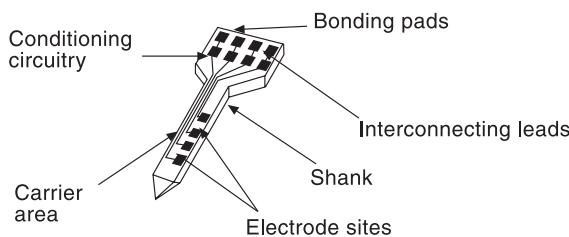

Figure 9 Neural probe.

micromachining could not enable the fabrication of the electronics on the same chip with the microstructure, the circuit is built separately and packaged on the same unit. The variance in sensitivity of the mechanical structure may range within $\pm 20\%$. Compensation is achieved through tuning of the electronic circuitry. Laser trimming as well as look-up compensation tables inscribed in EEPROM circuits are compensation methods which are currently used. The low cost and high reliability of microsystems make them serious competitors to the present sensors and controllers. The capability of MEMS to investigate further into the matter of phenomena means that microtechnology has a strong future. Breakthroughs in the following five general areas are predicted to be accomplished by MEMS and MEMS technology:

1. implementation of hierarchic intelligent systems in machines which can analyze, and conclude what the decision is to be taken
2. downsizing and redundancy of systems and deeper investigation of the matter
3. biomimetics: the development of flexible, intelligent, and sensitive autonomous micromachines
4. informatics: the acquisition of information on the state of systems equipped with sensors; exchange of real-time data among interacting systems, decision taking towards the optimization of multiple system functioning

5. environment preservation: measurement, detection, cleaning

MEMS have had, and will have, a profound impact on future technology and society.

MEMS, DYNAMIC RESPONSE

I Stiharu, Concordia University, Montreal, Quebec, Canada

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0074

Introduction

A microstructure subjected to an input signal would respond with the same oscillation pattern of ampli-

tude that correlates with the characteristics of the structure. Microstructures are particularly associated with high resonant frequencies. This phenomenon is mainly due to the extremely small oscillating masses of the microstructures, but it is also due to the notable influence of the electrostatic and electromagnetic fields, and the built-in interlaminar stress in the structural layers. Detecting the natural resonance frequency of a microstructure in conjunction with the appropriate operating frequency should be considered during the design process.

The dynamic response of microelectromechanical systems (MEMS) involves multiphysics interactions. The association between various physical quantities must be accurately established to evaluate the performance of a microsystem. Geometric downscaling by a factor does not necessarily mean downscaling within the same range for various physical quantities interacting at the microstructure level. For a given one-dimension downscaling factor, the mass and the moment of inertia decrease by the power of 3, the force decreases by the power of 2 and the acceleration grows by the power of 1, while the speed remains unchanged. Such dependence will definitely influence the dynamic response of a miniature structure.

From a dynamic point of view, most existing microsensors (optical, chemical, electromagnetic, temperature, and radiation) are static devices. They usually comprise both the transducer and the circuitry, which are built on the chip or packaged on the same circuit board. Under vibrations, the mechanical structure moves together with the circuitry and the chip. The stiffness of the connections is very high while the free pendent mass of the sensor is very small. Such devices can thus be considered as simple masses. Thus, for most microsystems mechanical vibration has no detectable influence on their functioning. However, the mechanical vibrations could induce quite destructive effects to the package and wire connections on the chip.

The influence of MEMS on the dynamics of the parts supporting the microsystem, on the other hand, is quite negligible. The mass of a standard 3×3 mm silicon chip does not exceed 10 mg, while the mass of a fully packaged chip does not exceed a few grams. Thus, rigid mounting of MEMS to normal-size mechanical systems would not interfere or yield a detectable influence on the overall dynamic response of the mechanical structure under most circumstances.

MEMS comprising flexing or free elements, which are free-standing structures released from the silicon chip by postprocessing, are clamped, supported, or free but constrained in their motion. Such structures are strongly affected by the oscillatory motion induced to their support or foundation. The dynamic response can be roughly modeled as a lump mass-spring-damper system fixed on a vibrating foundation, as shown in Figure 1. The motion along the free direction x of the swing mass of the microsystem is described by the force equilibrium equation:

$$m\ddot{x} + c(\dot{x} - \dot{x}_0) + k(x - x_0) = X_0 \sin(\omega t) \quad [1]$$

The deflection x of the free-standing microstructure follows, after a lag, the pulse of the excitation:

$$x = A \sin(\omega t - \phi)$$

where the amplitude A and phase shift ϕ are given by:

$$A = X_0 \sqrt{\frac{k^2 + (c\omega)^2}{(k - m\omega^2)^2 + (c\omega)^2}} \quad [2]$$

and:

$$\phi = \tan^{-1} \left(\frac{mc\omega^3}{k(k - m\omega^2) + (c\omega)^2} \right) \quad [3]$$

The main feature related to the dynamics of MEMS is the high value of the resonant frequency, which is mainly due to the extremely low mass of the microstructure. This attribute makes them valuable measurement tools for high-frequency bandwidth vibrations in mechanical systems.

In the case of microaccelerometers, microvibrometers, atomic force probes, and microphones, the motion of the free-standing element is beneficial and regarded as the measurable input signal, so the structure must always behave in the predicted way. The motion of the free-standing element is further transformed into electric effectual signal. The dynamic behavior of the microstructure must be predicted through modeling, before such a microsystem can be accomplished. The modeling of the mechanical structure often involves fluid, thermal, and electromagnetic interactions. The electrical circuitry requires further attention, since the resonant frequency of the mechanical microstructures is in general very high. The shift in critical natural frequency makes the microsystem exhibit stronger coupling with the electronic circuitry than the

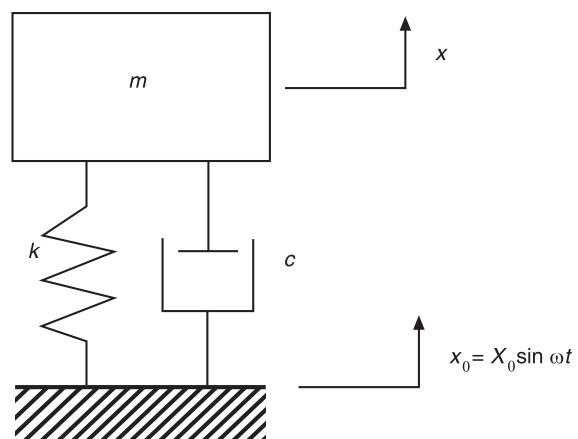

Figure 1 Lump model of damped mass elastically supported on a harmonic vibratory base.

normal-size electromechanical systems. Although MEMS are subjected to multiple physical interactions with very nonlinear effects, the lump mass model is always conceived to estimate the range of the dynamic linear response of the system.

When modeling multiple interactions among the linear physical system, it is perhaps more convenient to convert all the components to one common type of analogous system. Traditionally, all the mechanical, fluid, or thermal elements are converted to standard electrical components. The network models and the analysis methods for the electrical circuits are very popular and intuitive, such that the analysis of the analog systems is notably simplified. Furthermore, software packages can be conveniently used for the equivalent electrical network analysis.

For the normal-size world, **Table 1** gives the equivalent circuit components and signal variables among electrical, mechanical, fluid, and thermal physical quantities. The same analogy can be extended to the microworld, with some reservations due to the major influence of certain phenomena that are significant at a microscale level. However, attention is required when the figure number for the damping or stiffness or even mass is fed into the equation of the model. Moreover, it should be emphasized that microminiature systems usually exhibit noticeable nonlinearities, which should be taken into account when more accurate modeling is carried out.

Dynamic Response of MEMS

MEMS which are structured in micromechanical configurations comprising masses elastically suspended exhibit specific dynamic behavioral patterns

similar to those of the normal-sized mechanical systems. The small masses associated with relatively large stiffness bring the resonant frequency of the structure in the range of kHz. However, other forces, which are associated with the processes or with the functioning principles of MEMS, may considerably influence their dynamic behavior. Two of the most significant influences, the electrostatic field and inter-laminar stress, will be further discussed. A brief summary that helps to resolve the figure number of mass, stiffness, and damping for the lump model of simple MEMS structures is also given below.

Mass

Mass (the equivalent capacitance in electrical circuitry) can be evaluated assuming the geometry of the feature. However, due to the selectivity of the etchant, the initial shape of the feature may be distorted, as shown in **Figure 2**. The etchant removes the sacrificial film at a high rate but it will also etch from the structural layer to a lower extent. The inner walls of the structural film are sloped after the etching is carried out because the inner walls are gradually exposed to the etchant, whereas the external surfaces are permanently in contact with the etchant and thus uniformly etched. In certain conditions, the density of matter of the thin films is slightly smaller than that of the bulk, so the density figure number should be regarded with some caution. The equivalent mass method stands, when concentrated masses are considered along with the distributed masses.

Table 2 shows the standard formulation for the equivalent mass of cantilever and double-supported beams loaded with concentrated weight. The formulation presented in **Table 2** covers in the first iteration

Table 1 Analogous elements and variables

Electrical	Mechanical	Fluid	Thermal
Current (j)	Force (F)	Volume flow (q)	Heat flow (H)
Potential (V)	Speed (v)	Pressure (p)	Temperature (θ)
Resistance	Mechanical resistance (damping)	Fluid resistance	Thermal resistance
$R = \frac{\Delta V}{i}$	$\frac{1}{b} = \frac{\Delta v}{f}$	$r = \frac{\Delta p}{q}$	$R_\theta = \frac{\Delta \theta}{H}$
Inductance	Mechanical resistance (spring)	Fluid inertance (inertia)	Thermal inertance – (no significance)
$L = \frac{\Delta V}{di/dt}$	$\frac{1}{k} = \frac{\Delta v}{df/dt}$	$L = \frac{\Delta p}{dq/dt}$	
Capacitance	Mechanical capacitance (mass)	Fluid capacitance	Thermal capacitance (thermal mass)
$\frac{1}{C} = \frac{\Delta V}{\int i dt}$	$\frac{1}{m} = \frac{\Delta v}{\int f dt}$	$\frac{1}{C} = \frac{\Delta p}{\int q dt}$	$\frac{1}{C} = \frac{\Delta \theta}{\int H dt}$

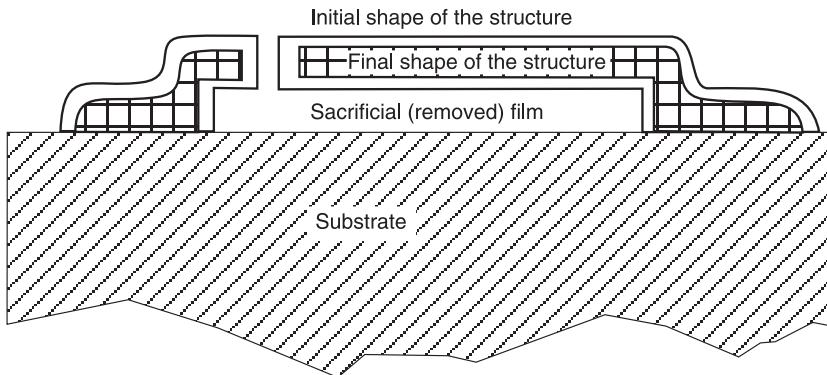

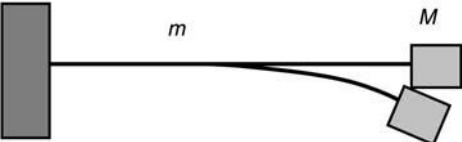

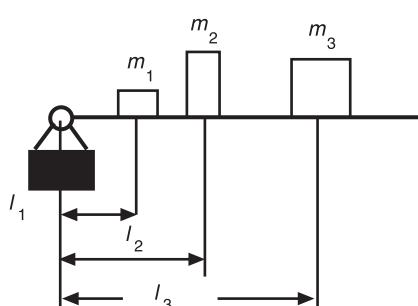

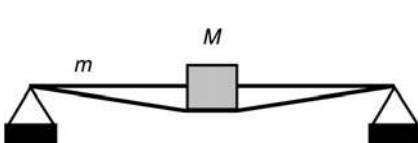

Figure 2 Cross-section through the geometry of a surface micromachined structure transformed due to the limited selectivity of the etchant.

Table 2 The equivalent mass of beams loaded with concentrated mass

	Cantilever beam of mass m carrying an end mass M	$m_{eq} = M + 0.23m$
	Cantilever beam of mass m carrying an end mass M	$m_{eq} = m_1 + \left(\frac{l_2}{l_1}\right)^2 m_2 + \left(\frac{l_3}{l_1}\right)^2 m_3$
	Simply supported beam of mass m carrying a mass M at the middle	$m_{eq} = M + 0.5m$

most of the MEMS structures, which are conceived as beams simple or double supported.

Stiffness

Stiffness (the equivalent inductance in the electrical circuit) is an essential parameter in the evaluation of the dynamic properties of microstructures. Assuming that the structures have uniform geometric features, the analogy with the helical spring can only be applied for concentrated loading. The stiffness can

thus be expressed as the ratio between load and deflection:

$$k = \frac{dF}{d\delta} \text{ or, for single concentrated torque, } [4]$$

$$k_\theta = \frac{dM}{d\theta}$$

When the loading is uniformly distributed on a section of the structure, the equivalent loading method

may be employed to determine the equivalent stiffness. **Table 3** shows the equivalent stiffness for selected types of beams loaded with concentrated and distributed loads.

When the structure is subjected to multiple concentrated loads, the energy method is instrumental in evaluating the equivalent stiffness of the system. The strain energy in the structure is equal to the equivalent energy of a theoretical spring:

$$\sum \left[\int \frac{M_b^2 dx}{2EI} \right] = \frac{k_{eq} \delta^2}{2} \quad [5]$$

for bending and:

$$\sum \left[\int \frac{M_t^2 dx}{2GI_p} \right] = \frac{k_{\theta eq} \theta^2}{2} \quad [6]$$

for torsion where M_b is the equivalent bending moment in each element of structure, M_t is the equivalent torsion moment in each element of structure, E is the Young's modulus of elasticity, G is the shear modulus of elasticity, I is the moment of inertia of the section of the structure, I_p is the polar moment of inertia of the section of the structure, K_{eq} is the equivalent bending stiffness of the structure, $K_{\theta eq}$ is the equivalent torsion stiffness of the structure, δ is equivalent deflection of the structure, and θ is the equivalent torsion angle of the structure.

Damping

Damping evaluation requires the most laborious analytical effort. The small geometric size of the flexural elements and the reduced gap between the mobile and fixed part of the structure promote squeeze damping, which can reach remarkably large values of damping coefficients. Damping is critical to the performance of the microsystem throughout the frequency bandwidth of the system. Large values of squeeze film damping, which are likely to occur in MEMS, can reduce the dynamic bandwidth of the system to an unacceptable level. Damping is determined by the geometry of the gap and of the elements, as well as by the viscosity or the pressure of the surrounding fluid. Damping is of great concern for microaccelerometers and miniature microphones. The frequency response of such systems can be improved by reducing damping by configuring flow channels through the flexing or fixed elements or through low-pressure encapsulation. For laterally oscillating microstructures, like comb-like resonant structures, the dominant nature of the damping is due to Couette-type

Table 3 The equivalent stiffness of beams loaded with concentrated and distributed load

	$k = \frac{6EI}{2l^3 - 3l^2a - a^3}$
	$k = \frac{3EI(l+2a)^2}{2(l-a)^2a^3}$
	$k = \frac{48EI}{a} \cdot \left(\frac{1}{3l^2 - 4a^2} \right)$
	$k = \frac{384EI}{5l^3}$
	$k = \frac{8EI}{l^3}$

flow. **Table 4** gives the equivalent damping values for some energy dissipation arrangements. Reduced damping requires reduced pressure of the immersing fluid/gas.

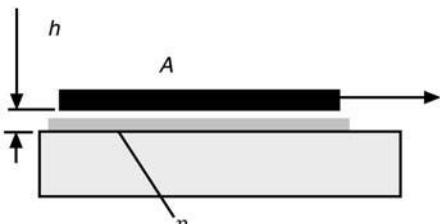

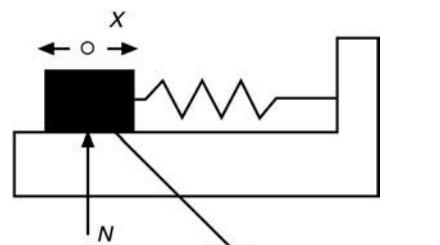

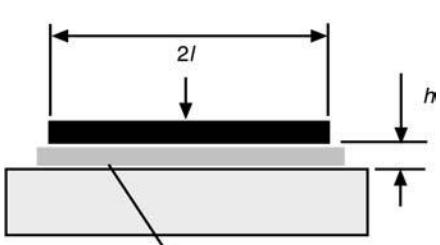

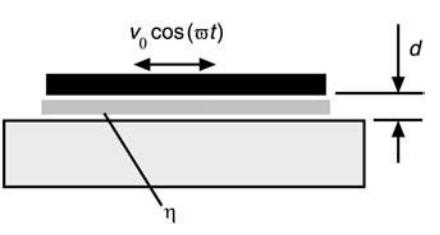

Certain classes of application require very low damping. The resonant structures (piezoelectric actuators and acoustic sensors) function based on the oscillatory properties of specific active materials (quartz, LiNbO₃, ZnO, AlN, PZT, etc.). Low intrinsic damping properties of the material ensure that the system is more efficient through reduced energy dissipation/loss.

When damping is low, the dynamic over the static amplitude ratio at resonance, the quality factor Q ,

yields considerable information about the dynamic response of the system. The bandwidth of the system represents the range of frequencies for which the amplitude ratio falls beyond $Q/2$. The Q factor of a structure is associated with the ratio of the strain energy stored in the system to the energy dissipated through damping.

When the natural frequency of a more complex system is evaluated, it is more appropriate to use one of the energy methods. One of the remarkable advantages of such a method is that one can incorporate various effects of the electric and magnetic field, and capillary forces, which would otherwise be excessively difficult to incorporate in the model. Equating

Table 4 The equivalent damping for various mechanical structures

	Relative motion between parallel surfaces	$c_{eq} = \frac{\eta A}{h}$
	Vibrating mass in rigid contact with a fixed surface (Coulomb friction)	$c_{eq} = \frac{4\mu N}{\pi\omega X}$
	Squeeze film damping	$c_{eq}^* = \frac{4\eta l^3}{h^3}$ *per unit of length
	Couette-type damping	$c_{eq}^* = \frac{\pi U_0 \eta}{\omega d}$

the maximum potential energy and the kinetic energy, one can assess the influence of the external forces and fields to the natural frequency of the structure.

The Influence of the Electrostatic Field

Assume two parallel plates separated by a small gap. One plate is fixed while the other moves along the direction z normal to the two plates. The mobile plate is subjected to elastic restoring forces. The motion of the plate in the fluid filling the gap between the two plates yields a dissipative force which is proportional to the speed of the plate. The distance between the two plates is usually measured through the value of the impedance of the variable capacitor formed by the two plates. The small size of the micromechanical structures of MEMS enables the electric field which is always present to strongly influence the dynamic response of a microstructure. The energy due to the electrostatic field can be expressed by:

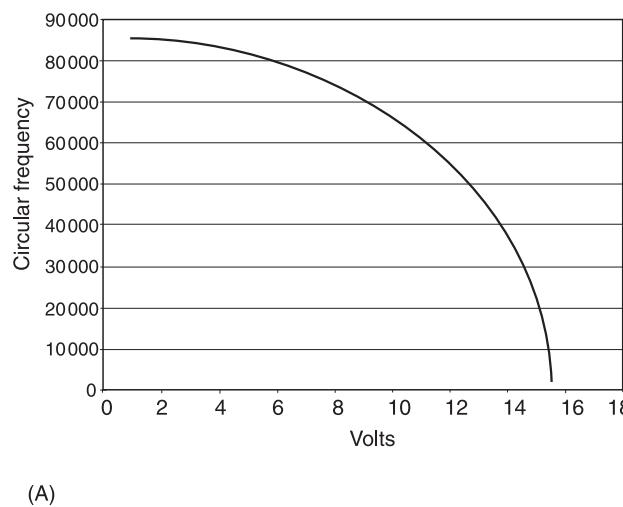

$$-\frac{\partial U}{\partial z} = \frac{V^2}{2} \frac{\partial C}{\partial z} \quad [7]$$

where U represents the stored electrostatic energy, V is the voltage differential across the capacitor plates, C is the capacitance of the capacitor, and z represents the deflection of the flexible elastic armature of the capacitor.

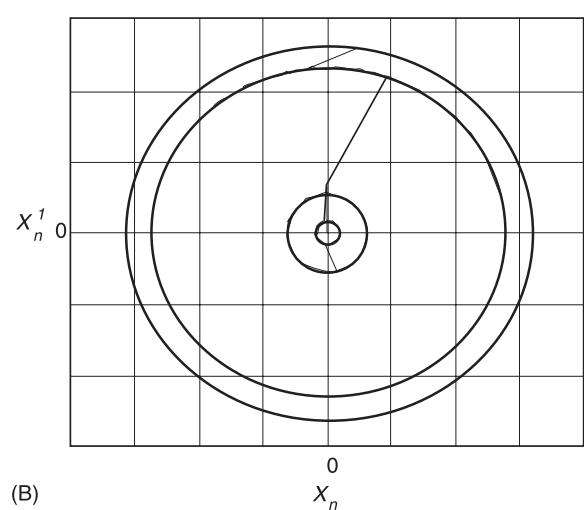

Eqn [7] shows that enhanced displacement of the mobile armature tends to augment the intensity of the electrostatic field, reducing the gap and increasing capacitance, and this field will incline to pull the

flexing element even more. The armature under the electrostatic field thus renders a larger displacement than that experienced in the absence of the electrostatic field, which could be comprehended as negative stiffening of the structure due to the existence of the electrostatic field. It must be noted that the electrostatic field, regardless the potential of the armatures, produces a weakening effect on the stiffness of the mobile plate. However, the detectable phenomenon is the attraction between the two armatures.

It has also been found that each structure exhibits a specific threshold value of static deflection due to the electrostatic force, and, if this is exceeded, the flexible armature becomes dynamical unstable. The mobile armature is perceived to be collapsing on the fixed back-plate. From the point of view of the electrical field, a threshold voltage is associated with each structure, at which pull-in and ultimately snapping occur. Usually, this condition is associated with mechanical failure of the structure, so it must be carefully avoided. The natural frequency of a plate subjected to electrostatic field will drop due to the negative stiffness effect induced by the electrostatic field. When threshold displacement is reached, the natural frequency approaches zero; this is when the balance between positive and negative stiffness is reached. The trend of the natural frequency of a double-supported plate, which is subjected to a potential difference with respect to the fixed armature, is illustrated in Figure 3. The natural frequency and the first few resonance frequency and mode shapes for simple stuctures are given in Table 5.

(A)

(B)

Figure 3 (A) Natural frequency of a microbeam $1000 \times 1000 \times 2 \mu\text{m}$ which is double-supported and subject to a variable difference of potential with respect to the fixed armature, parallel and spaced at $2 \mu\text{m}$ about the beam. The natural frequency decays such that, for voltage beyond 15 V the natural frequency of the plate is close to zero. The plate exhibit dynamic instability at even lower difference of potential, as shown in (B). (B) Phase state plot of the microbeam described in (A), subject to sinusoidal excitation and under an electric field created by 12 V potential difference between the microbeam and the fixed armature.

j, concentrated end-mass moment of inertia; *j_s*, distributed mass moment of inertia; *G*, shear modulus of elasticity; *T*, tension in string; *i*, the rank of the frequency; *f_i*, natural frequencies (Hz); *k_i*, constant; *r*, radius of the circular path; *t*, thickness of the plate; *l*, length of the beam; *w*, load per unit length (including beam weight); *I*, area moment of inertia; *g*, gravitational acceleration; *E*, Young's modulus of elasticity.

In carrying out the design of capacitive, piezoresistive, or acoustic sensors and actuators, the influence of the electrostatic field on the natural frequency decay of the structure must be carefully considered. Such analysis can be carried out using one of the energy methods (Rayleigh for natural frequency or Rayleigh-Ritz for the first few resonant frequencies). By equating the strain energy with the kinetic energy plus the electrostatic energy, the natural frequency or first few resonant frequencies can be calculated. Finite element analysis (FEA) represents another option in identifying the first few natural frequencies of a complex-shaped structure. Finite element modeling permits complex analysis of multilayered complex shape structures, including stress-strain, dynamic,

thermal, or electro-magnetic loading, and even combinations of the above.

The Influence of the Interlaminar Stress

Besides the influence of the potential fields, fabrication of thin films may be responsible for the peculiar dynamic behavior of the microstructures. Thin deposited films induce either compressive or tensile stress, which is mainly due to the thermal mismatching between the substrate and the coating encountered at the low ambient temperatures after high-temperature deposition process. The residual stress may produce unwanted bending, warping, and fracture of the structures. However, the existence of the stress in

structure produces changes in the dynamic behavior of the structure. The amount of change in the dynamic properties depends mostly on the quantity of stress built into the structure. The amount of stress is strongly dependent on the parameters of the deposition process, and the values of such stress can range from a few MPa to a few GPa. The low-stressed films are almost always present when accomplishing surface micromachined structures. Certain sequences of processes and thermal treatments could lower the amount of residual stress to close to zero. The measurement of the residual stress can be carried out using experimental techniques that have been created for various stress ranges and specimen size. For full wafer measurement and stress exceeding 10 MPa, the variation of curvature yields the value of the built-in stress, as given by the relationship (Stoney):

$$\sigma_r = \frac{Et_s^2}{6(1-\nu)t} \left(\frac{1}{R_i} - \frac{1}{R_f} \right) \quad [8]$$

where t_s is the thickness of the substrate, t is the thickness of the thin film, R_i is the curvature of the wafer before deposition (expected $R_i = \infty$), and R_f is the curvature of the wafer after deposition. The measurement of the large curvatures is performed with optical stress gauge machines, which can detect large radii of curvature of the substrate before and after thin film deposition.

For stress lower than 1 MPa, buckling of a subset of double-supported witness beams is used to range the

compressive stress value in a narrow bandwidth. For the tensile stress, special sets of structures consisting of a ring (Guckel rings) supported by a diameter beam are used to evaluate the built-in stress between the substrate and the film. The witness test structures are made from the thin film deposited on the substrate. The two structures described above are shown in Figure 4. The array of structures can be contained within a certain design and the measurement consists of confronting the observation through a microscope with a table illustrating the critical stress in buckling versus the geometric dimensions of the beams. The residual stress can be evaluated out of the critical stress at buckling:

$$\sigma_r = -\frac{\pi^2 b^2 E}{3L^2} \text{ for double-supported beams} \quad [9]$$

$$\sigma_r = -\frac{\pi^2 b^2 E}{12\xi(R)R^2} \text{ for Guckel rings} \quad [10]$$

where b is thickness, L is length, R is radius of the Guckel ring, and $\xi(R)$ is the function of the inner and outer diameters.

The residual stress strongly influences the vibration characteristics of the free-standing structures, which are part of MEMS. Flexing multilayered structures such as microbeams and microplates, as shown in Figure 5, tune their dynamic response according to the built-in residual stress. The general equation (Lagrange) describing the plate motion is:

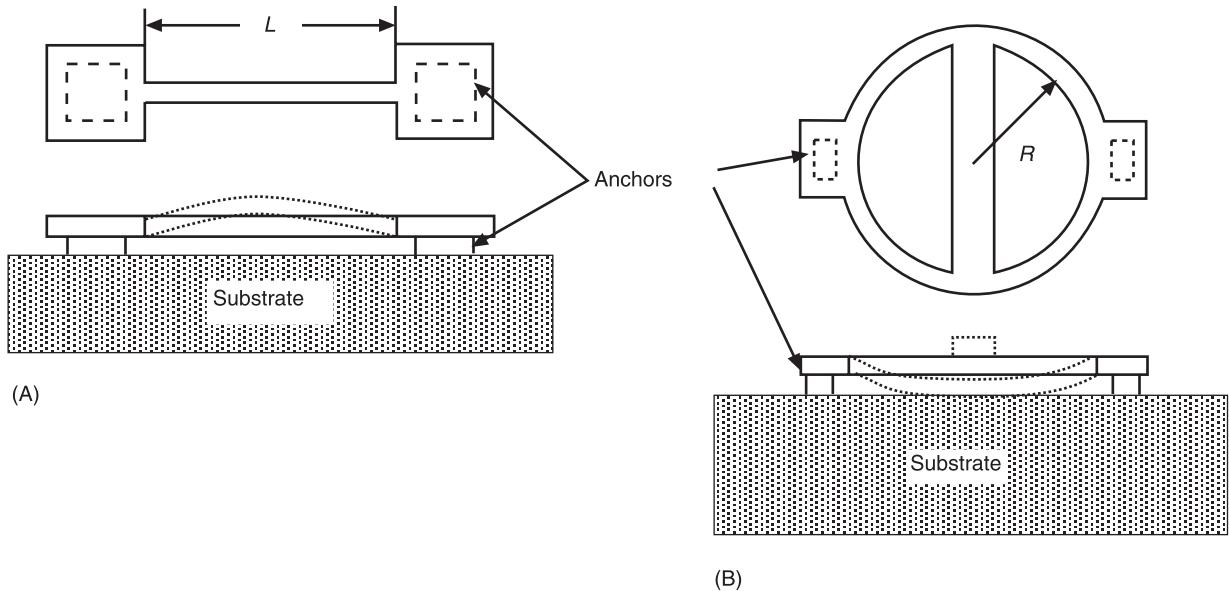

Figure 4 *In situ* structure for low residual stress measurement in thin films. (A) Double-supported beam buckles under compressive stress. (B) Gluckel ring configuration; the diameter beam buckles under the tensile stress in the ring.

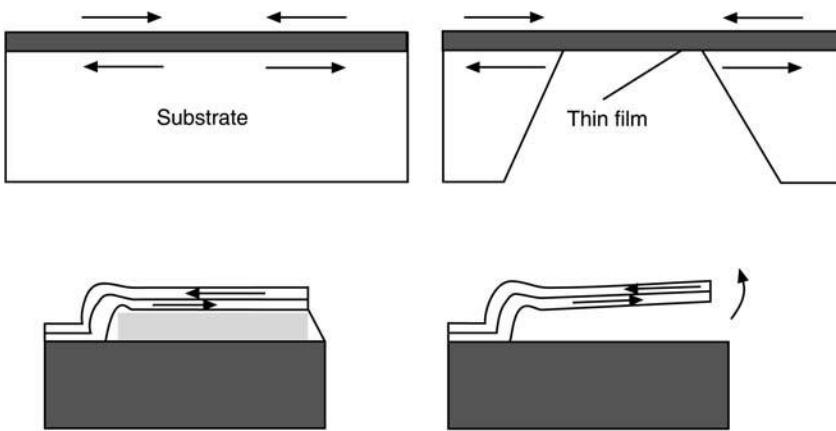

Figure 5 Mismatching stress at the thin film interface. When the substrate or the sacrificial film is etched out to reveal the microstructure, the contour stress or the built-in stress at the interface of the bimorph film will modify the static and dynamic response of the structure.

$$D\nabla^4 z + \rho \frac{\partial^2 z}{\partial t^2} = 0 \quad [11]$$

$$4\rho a^2 (f_i^2 - f_{si}^2) = N_y m^2 + N_x n^2 \left(\frac{a}{b}\right)^2 \quad [15]$$

with:

$$D = \frac{Eh^3}{12(1-\nu^2)} \quad \text{flexural rigidity of the plate}$$

$$\nabla^4 = \frac{\partial^4}{\partial x^4} + 2 \frac{\partial^4}{\partial^2 x \partial^2 y} + \frac{\partial^4}{\partial y^4}$$

$$\rho \quad \text{mass by surface unit}$$

If the plate is subjected to stress, which is equivalent to the stress yielded by the contour lineal forces N_x , N_y , and N_{xy} the previous equation changes to:

$$D\nabla^4 z + \rho \frac{\partial^2 z}{\partial t^2} = N_x \frac{\partial^2 z}{\partial x^2} + 2N_{xy} \frac{\partial z}{\partial x \partial y} + N_y \frac{\partial^2 z}{\partial y^2} \quad [12]$$

The eigenfrequencies f_i of the plate not subjected to any stress are given by:

$$f_i = \frac{1}{2\pi a^2} \sqrt{\frac{D}{\rho}} \quad [13]$$

The eigenvalues of the plate subjected to decoupled lineal forces N_x and N_y ($N_{xy} = 0$) are given in the form:

$$\lambda_{si}^2 = \lambda_i^2 + \frac{a^2 \pi^2}{D} \left[N_y m^2 + N_x n^2 \left(\frac{a}{b}\right)^2 \right] \quad [14]$$

From the above last two equations, one can identify the set of lineal forces N_x and N_y which satisfy the relationships:

where f_i is eigenfrequency of the unstressed plate, f_{si} is eigenfrequency of the stressed plate, a, b is dimensions of the sides of the plate, h is thickness of the plate, and m, n are mode numbers.

The last relationship can serve to solve the inverse problems, which are of practical interest. When the stress at the interface of the substrate with the thin layer is known, the shift in the vibration frequencies of a given structure can easily be predicted.

Microplates subjected to forced vibration will thus behave similarly, with the exception that their natural frequency is much higher than that of the normalized plates.

Annealing performed on the structures at 800–1000°C in inert gases for 2–4 h can substantially reduce residual stress. However, such treatment is too severe for the electronic circuit components and it can only be applied in the very early stages of a standard integrated circuit process, before the definition of the semiconductor junctions.

Signal Conditioning

Microsensors like any other sensors, must convert the measured physical quantity into meaningful signals. The function of the signal conditioning circuitry consists of converting the sensor output into convenient electrical signals that can be further streamed to the controller or to the data acquisition system. The output signal of the sensor should be a voltage waveform, which can be easily processed by the data acquisition circuit. The process of converting the output signal from the sensor to a voltage can be used to reduce the noise or partially to compensate

for the objective errors collected by the signal from the transducer to the conditioning circuitry.

The new generation of sensors is conceived to comprise on the same chip the signal-processing circuit, the analog to digital converter (A/D), and dedicated controllers. The resolution of the A/D can be maximized by matching the dynamic range of the input signal to the dynamic range of the data acquisition system. The source impedance of the input signal must be low, such that changes in the impedance of the data acquisition system or controller do not affect the signal. The sampling rate of the A/D must be at least twice as fast as the bandwidth of the output signal of the sensor (practically, one order of magnitude higher yields a reasonably accurate conversion).

The output signal of the sensor may include noise that must be removed before it is fed to the A/D. The noise is often associated with stray capacitance of the connection line of the circuit. The high level of integration in MEMS presents the advantage of low-level noise in the signal. However, the electrostatic of the electromagnetic fields may negatively influence the performance of the conditioning circuitry. This problem can be addressed through appropriate packaging of the integrated microsensor.

The output signal of the microsensor may not always match the required input signal of the conditioning circuitry. Thus, appropriate conversion of the signal may be required before being fed to the A/D. The conversion is carried out from voltage, current, resistance, and capacitance, to voltage. Most common conversion schemes are briefly presented below.

Voltage-to-voltage Conversion

Voltage-to-voltage conversion is required when dynamic range modifications (bandwidth reduction or impedance alteration) are necessary, when the output signal from the sensor is a voltage. The above-mentioned conversions are carried out by standard circuits. The amplifiers are used to match the output level of the sensor to the input of the data acquisition system. Some of the standard circuits, their scheme, the function carried out and their main properties are shown in **Table 6**. The output signals from the sensor can collect noise. If the frequency of the noise is off the frequency of the significant signal, the unwanted signal can be filtered out using low/high-pass filters. The filtering is usually applied before the signal is amplified. The DC component of the signal, if any, can be removed with an offset circuit.

Current-to-voltage Conversion

Current-to-voltage conversion is usually performed with an operating amplifier in an inverting config-

uration, since noninverting amplifiers draw very low current. This configuration scheme is most suitable with current-generating sensors. When the current output increases, the output potential increases proportionally.

Resistance-to-voltage Conversion

Resistance-to-voltage conversion is used when the sensor detects the electric resistance variation due to the input signal. Piezoresistive accelerometers, pressure sensors, or microphones are examples of such types of sensors. The resistance variation needs to be translated into standard voltage output to feed the A/D, the data acquisition circuit, or the controller. The two basic methods to convert resistance variation to voltage output are presented below. The simplest way consists of applying a voltage to a resistor divider network made of the variable resistor R_S (the transducer) and a reference fixed resistor R_R , as shown in **Figure 6**. The voltage detected across the sensor is amplified before being converted to digital signal. The drawback of this method is that the amplifier boosts the entire voltage across the sensor, which translates through a high DC offset. Thus, the second method of converting the resistance to voltage addresses this disadvantage. The resistance bridge configuration, as shown in **Figure 7**, only amplifies the change in voltage due to the shift in the resistance of the sensor. The resistance bridge presents the advantage of zero offset, high sensitivity, and thermal compensation.

Capacitance-to-voltage Conversion

Capacitance-to-voltage conversion is used when the output from the transducer is a variation of capacitance. The capacitance-based sensing presents multiple advantages. The capacitance varies in proportion to the distance between the armatures of the capacitor. The capacitors are sensitive to the material that resides between their electrodes. The most popular methods used to convert capacitance to voltage are similar to those used to measure resistance. However, besides these methods, more innovative principles and circuits have been created. For example, the charge amplifier circuit is used to detect small capacitance variations in the fF range.

The voltage divider uses the variable capacitor and a reference capacitor. The circuit configuration is the same as the resistance voltage divider: the only difference is that, instead of the resistors R_S and R_R , capacitors are used. Similarly, the capacitor bridge circuit configuration looks like the resistance bridge in which resistors are replaced by capacitors.

Table 6 Standard circuits

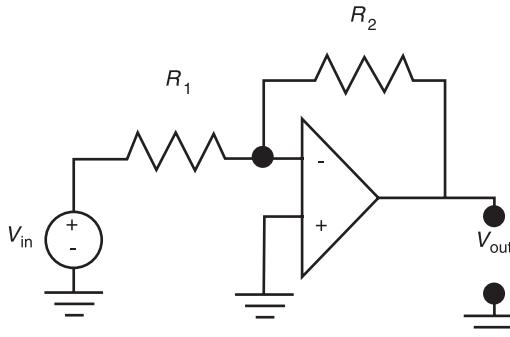

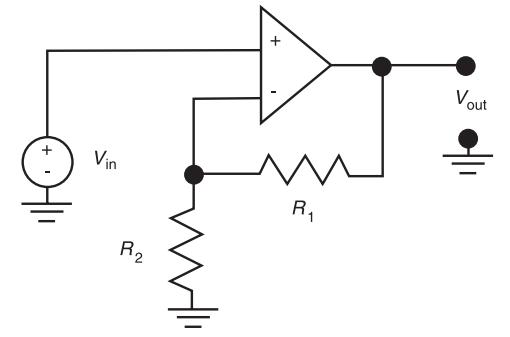

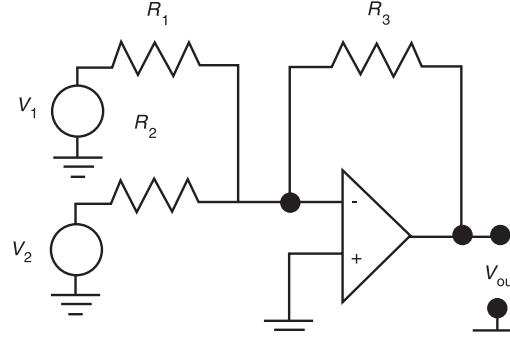

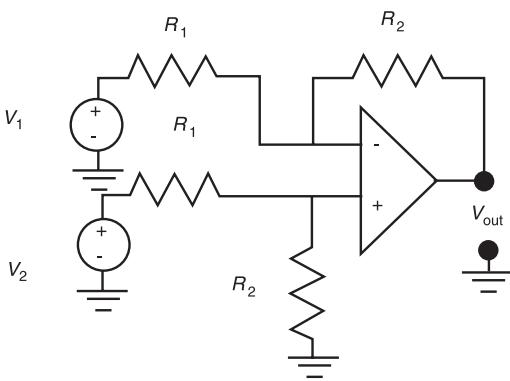

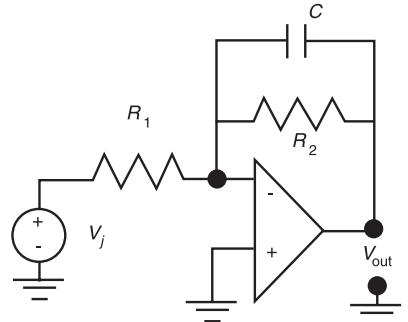

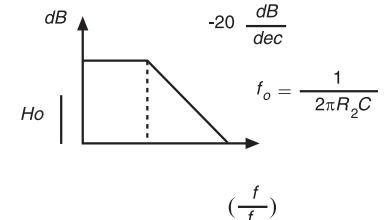

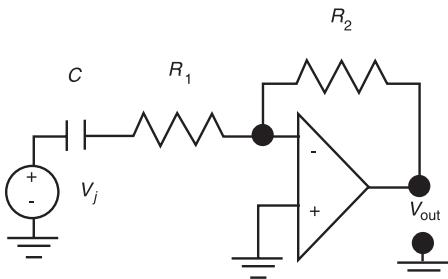

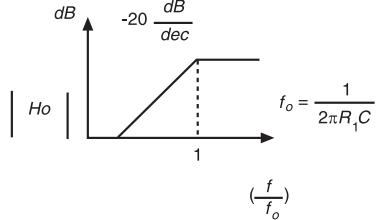

Circuit	Scheme	Input–output relationship	Characteristics
Amplifier inverter		$V_{\text{out}} = -\frac{R_2}{R_1} \cdot V_{\text{in}}$	Input Impedance $\sim R_1$ Output Impedance ~ 0
Amplifier noninverter		$V_{\text{out}} = \left(1 + \frac{R_1}{R_2}\right) \cdot V_{\text{in}}$	Input Impedance $\sim \infty$ Output Impedance ~ 0
Summing		$V_{\text{out}} = V_1 \frac{R_3}{R_1} + V_2 \frac{R_3}{R_2}$	Combines the output of arrays to sensors

Table 6 Continued

Circuit	Scheme	Input-output relationship	Characteristics
Difference	 $V_{\text{out}} = (V_2 - V_1) \cdot \frac{R_2}{R_1}$		Removes unwanted DC offset
Single-pole low-pass filter	 $A = -\frac{R_2}{R_1} \frac{1}{1 + j(f/f_o)}$	 $f_o = \frac{1}{2\pi R_2 C}$	
Single-pole high-pass filter	 $A = -\frac{R_2}{R_1} \frac{j(f/f_o)}{1 + j(f/f_o)}$	 $f_o = \frac{1}{2\pi R_1 C}$	

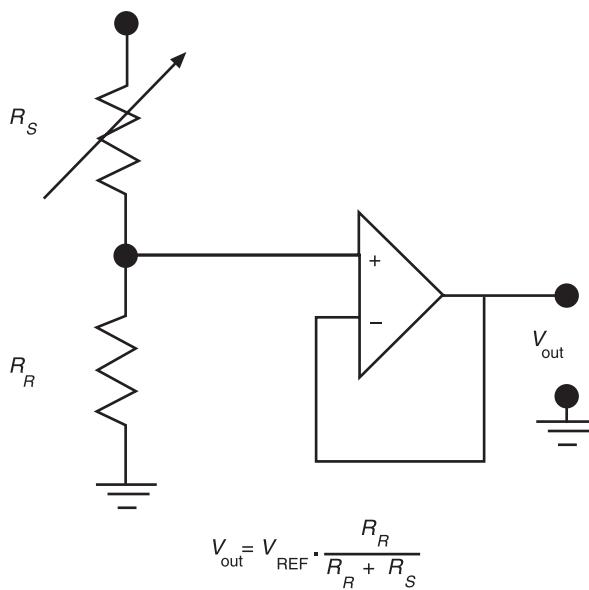

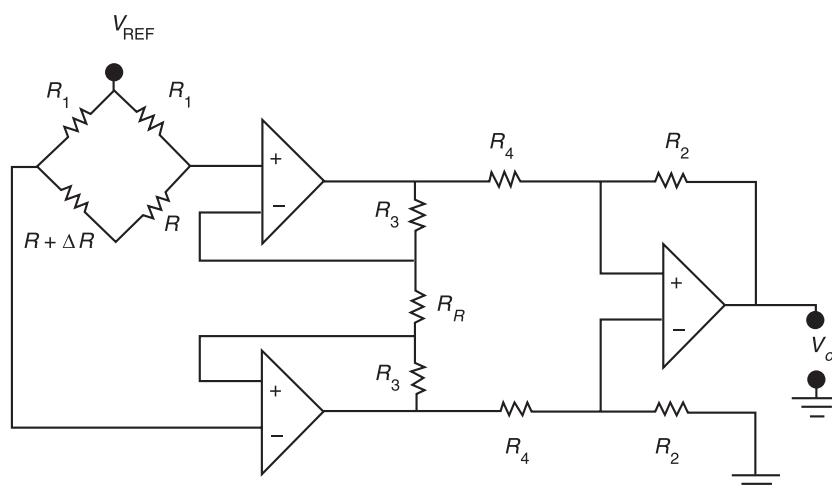

Figure 6 Resistance voltage divider measurement scheme.

The reference signal is sinusoidal, since the capacitance obstructs DC. The impedance of the capacitor is inverse in proportion to frequency. An appropriate reference frequency yields a voltage across the capacitor that is suitable for amplification. When the reference frequency is too low, the high impedance of the sensor creates high levels of noise. When the reference frequency is too high, the low impedance of the sensor allows the sensor to saturate the circuit.

The main feature of MEMS containing free-standing elements is the high natural frequency exhibited by the mechanical structure that may be strongly coupled with the electrical circuit system. MEMS perform in a very nonlinear way in dynamic characteristics. However, in a first approximation, lump mass linear models of the miniature microsystems are satisfactory. Simple formulations of the equivalent mass, stiffness, and damping are analogous with the formulations used in normal-sized systems. For a more accurate analysis of either a simple flexing structure or complex microactuators, the nonlinear phenomena must be considered and examined. They include, but are not limited to, electrostatic and electromagnetic fields, capillary forces, and interlayer mismatch stress. Analysis of the influences of nonlinear physics on the dynamics of the microstructure may be carried out using standard energy methods.

Nomenclature

A	amplitude
C	capacitance
E	Young's modulus of elasticity
g	gravitational acceleration
G	shear modulus of elasticity
h	thickness
I	inertia
L	length

$$V_o = \left(1 + 2 \frac{R_3}{R_R}\right) \left(\frac{R_2}{R_4}\right) \frac{R}{R_1 + R} \cdot \frac{\frac{\Delta R}{R}}{1 + \frac{R}{R_1} \left(1 + \frac{\Delta R}{R}\right)} V_{\text{REF}}$$

Introduction

MEMS, the acronym for Micro-Electro Mechanical Systems, represents an emerging technology through which miniature mechanical systems are built making use of the standard Integrated Circuits technologies on the same chip as the electronic circuitry. Micro-mechanical structures along with afferent electronic circuitry often perform functions with high accuracy, which cannot be accomplished by so called 'normal' sized structures. The strength of MEMS is provided through the high effectiveness of the fabrication process, which yields uniform performances for the structures at a relatively low cost, in conjunction with the low power consumption. Moreover, micro-structures may probe into phenomena deeper than actual electromechanical systems do.

Microelectromechanical systems (MEMS) are miniature mechanical devices built from silicon using solid-state technology; they contain the necessary electronic circuitry built on the same chip with the

mechanical structure. These devices are also known as microsystems or micromechatronic devices. Monocrystalline silicon is a very attractive mechanical material which, in addition to its enabling electrical properties, exhibits remarkable mechanical properties. The elastic modulus is close to that of steel while the specific mass is about three times lower. Silicon enables the parallel batch fabrication of microsystems, which yields higher reliability of the devices together with a dramatic drop in the fabrication cost. The concept of MEMS emerged from the need for miniaturization of the mechanical sensing elements, enabled by the anisotropic crystallographic etching properties of silicon and driven by the enormous progress made in integrated circuits (IC) technology over the last two decades. The field of MEMS has been acknowledged at the end of the 1980s, although the roots of silicon-based sensors and actuators go back to the 1970s.

MEMS are classified into two large functional classes: microsensors and microactuators. Microsensors are conceived as fully signal-conditioned transducers that provide the same function as the classic sensors along with their conditioning circuit board. Since the main functions of sensors are detection and measurement, they should interfere as little as possible with the environment, except for measured

physical quantity. Thus, the energy exchange between the environment and the microsensor should be minimized. Miniature transducers easily comply with these requirements.

Microactuators are conceived to convey energy to their surrounding environment. Their size limits tremendously their performance and thus, the area of application is mainly reduced due to their limited energy storage capability. Arrays of microsensors and microactuators together with implemented controls enable the creation of ‘smart matter’, which represents a natural step in the development of technology.

The first silicon-based miniature devices were produced in the early 1970s through bulk micromachining. This fabrication principle takes full advantage of batch fabrication but the minimum feature size is limited to fractions of millimeters. Besides, bulk micromachining cannot enable full implementation of the electronic circuitry with the mechanical component on the same silicon chip, using a unique processing flow. The earlier devices thus involved considerable efforts in assembling and packaging the mechanical components and the electronic conditioning circuitry. Further, the research focus has been directed towards developing a comprehensive technology to realize both the reliable electronic

circuits and robust mechanical structures integrated within a single design. Attempts to fabricate mechanical devices using modified standard IC processes were successful, so that the conditioning circuitry could be included on the same chip and fabricated during the same process flow. The surface micromachining processes yield a minimum feature size in the range of micrometers. Here, superimposing several patterned layers of conducting, insulating, and transistor-forming materials to build the structural and the sacrificial configurations along with the conditioning circuitry enables the realization of MEMS structures. After the completion of both mechanical structure and electronic circuitry, a sacrificial etching is performed to release the free-standing structure without affecting the function of the electronic circuitry. This step, called postprocessing, requires highly selective etchants and a series of precautions in order to retain the integrity of the microstructure.

The feasibility of the microactuators and micro-mechanisms has been established through a hybrid technology that enables surface micromachined MEMS based upon thicker polysilicon as the structure and SiO_2 as sacrificial films (MUMPS).

Figure 1 illustrates the difference between bulk and surface micromachining. The bulk-micromachined structures are obtained by removing the excess from

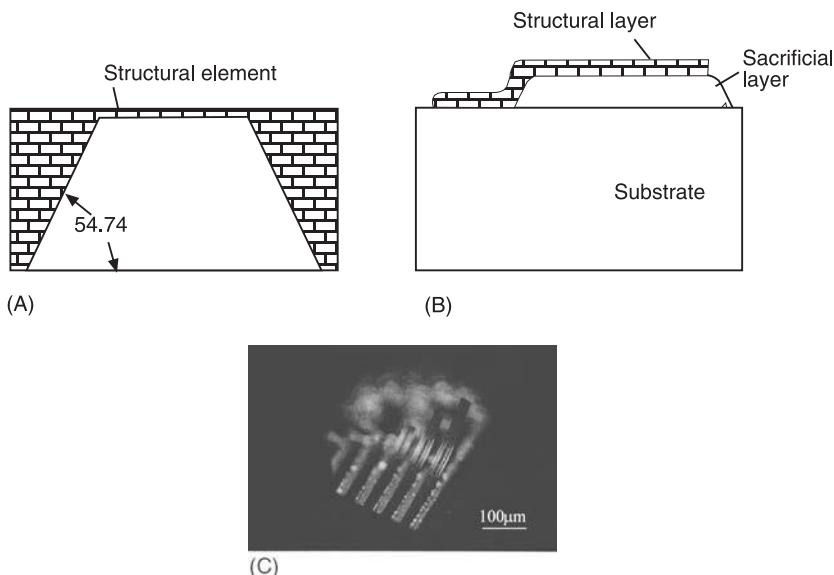

Figure 1 (A) Bulk-micromachined plate in section. The structural element is built from silicon substrate by deep crystallographic anisotropic etching. (B) Surface micromachined step-up free end beam in section. The structural element is built in the top of the sacrificial film. Postprocessing will remove the sacrificial film and release the free-standing structure. (C) Surface-micromachined microbeams released by postprocessing. Mismatching between the materials constituting the polymorphous beams induces high stress which has evolved into spectacular bending of the beam.

the substrate material, such as that shown in Figure 1A, through isotropic or anisotropic etching of the material. Surface micromachining yields microsystems enabled by the structural layers deposited and patterned in a specific sequence with the sacrificial layers. The sacrificial layers are removed during post-processing and the microstructure is released as illustrated in Figure 1B. Figure 1C shows a magnified picture of a set of micromachined cantilever beams, which are released through postprocessing etching. Thermal mismatching in thin films of various materials, which constitute the beam as a composite material, induces high stresses, resulting in a dramatic bending of the free end of the beam.

Sensors and microsensors are conceived to detect and measure electrical, chemical, magnetic, mechanical, radiant, and thermal measurands. The most common physical quantities and measurands are given in Table 1. However, mechanical microsensors are the most interesting from the point of view of vibration. They modify mechanical measurands in electrical signals, using resistive, capacitive, inductive, piezoelectric, or other physical conversion principles.

The primary sensing element is usually a simple elastic structure such as a cantilever beam, which deflects under input measurand. This deflection, although small, is related to the input measurand, which is detected and translated into an electric signal by the built-in subminiature secondary sensing devices, such as piezoresistive, piezoelectric or capacitive elements. The rendered electric signal must be well shielded from the noise of the environment for further conversion into a meaningful indication by the conditioning circuitry. The sensitivity of the sensing element to the measured signal must be high, while sensitivity to irrelevant excitations should be as low as possible. Limitations in sensitivity are related to the measured range and the maximum permitted overloading.

The force/position feedback servosensors structure is more complex, since they comprise both microsensors and microactuators. When distorted by the input signal, the sensing element is returned to its static position by actuators, which are fed by the feedback signal. The signal used to restore the position of the element is meanwhile used for measurement, as shown in Figure 2. Such a design concept, although more complex, addresses issues related to overloading and hysteresis.

Implementation of the IC technology for microsystem fabrication represents a very different concept in the sensors technology. Resolutions of $0.001\text{Å}/\text{Hz}^{1/2}$ or sensitivities in the order 10^{-10} N are usual features of such microsensors. The actual achieved precision

and the accuracy of MEMS sensors can improve up to one order of magnitude the performances of the classic sensors. The detected input signal can be further fed into the electronic circuitry, conveniently

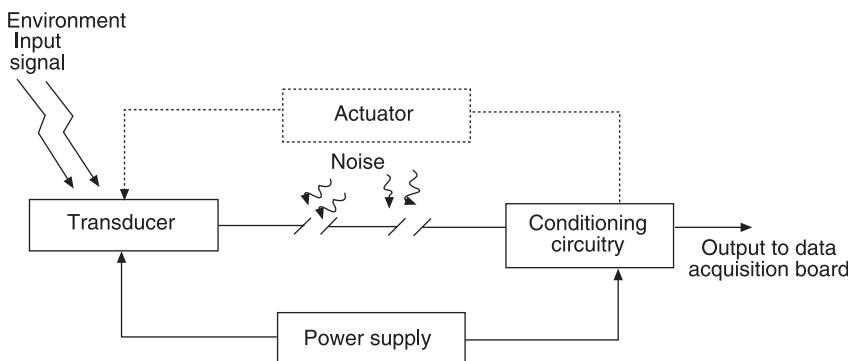

Figure 2 General configuration of a sensor. The dashed line with the feedback actuator shows the configuration of a servo sensor.

located next to the transducer, which modifies the input into a signal which matches the data acquisition system. This is usually equivalent to changing the output to a voltage. The function of the electronic circuitry extends to modifying the sensors' dynamic range to maximize accuracy, filtering the noise, and limiting the measurement spectrum.

Micromachined microactuators are conceived to convert electrostatic, electromagnetic, thermal, or fluid flow energy into mechanical rotation, translation, or oscillation. Although presently the microactuators are created for applications in which the required forces do not exceed μN range, tremendous applications in microbiology have been forecasted. Both linear and rotary microactuators have been built using bulk and surface micromachining technology, although the three-dimensional attributes of the actuators have required special technologies for high-quality vertical pattern fidelity. One main problem of the microactuators relates to the friction and wear of moving parts. The small sized pivots, the complexities associated with total control of clearances between the pivot and the bearing, and the lack of appropriate lubrication methods dramatically reduce the life of the electrostatic motor. However, IC technology has not been modified to accomplish readily assembled devices, such as hinges and articulations. Thus, the alternative technologies permit to compensate for such limitation. Elastic suspensions or levitation principles have been implemented to overcome the friction and wear in rubbing parts. Compliant mechanisms represent another option for MEMS. The compliant mechanisms allow motion through elastic deformations of one or more elements. Motion of compliant segments generally involves large-magnitude nonlinear deflections, which are difficult to predict using the linear beam theory. More accurate prediction of microstructure behavior will require multiphysics nonlinear analyses

of the miniature structures. Modeling such devices is thus quite challenging. Application of the surface-micromachined compliant multistable mechanisms on microvalves and microswitches is presently under investigation.

MEMS Materials

Microsystems manufacturing (micromachining) makes use of a large variety of materials. However, only a few are used to build the structural elements. The mechanical properties of these materials are thus of prime interest for the mechanical designer of MEMS. Although the mechanical properties of bulk materials are comprehensively known, the properties of the thin deposited films are strongly dependent on the deposition process and the deposition parameters. Table 2 provides a list of the most frequently used materials for MEMS structures together with their available relevant properties, as given in the available literature. The physical values range between broad limits, which may be attributed to excessive variations in the measurement methods employed and to the large variance in the properties of the materials. Besides, the thinly deposited films exhibit high internal compressive or tensile stresses, which may to a certain extent influence the mechanical properties of the thin structures. It has been acknowledged that the materials in thin films exhibit higher mechanical strength than the same materials in bulk state.

Apart from the mechanical properties, some materials require other special properties and conditions for the material processing, as they may not withstand subsequent processing. The active materials are specifically used to build the transducer on the measurement element, which is mostly associated with the flexing element in the mechanical microsensors. The deposition and patterning sequences rigorously

require certain standing limits for the deposited material. One should bear in mind that the same materials are used to build the IC, and thus, material selection must avoid any incompatibility problems that could jeopardize the IC performances due to the fabrication.

MEMS Fabrication Technology

MEMS fabrication mostly makes use of established IC processes. Apart from the rigid processing sequence, some new techniques have been developed and implemented to substitute for the lack of flexibility of the standard IC. They appropriately use the unconventional machining together with the standard machining processes. Thus, LIGA (deep-etch lithography, electroforming, and plastic molding), laser-assisted chemical vapor deposition (CVD), electroplating, chemical plating, and even conventional machining form the most common manufacturing techniques.

In lay terms, accomplishment of MEMS through surface micromachining is done through deposition of specific thin films (required by the IC process), patterning and etchings of the deposited material on undesired areas, followed by other successive depositions, patternings, and etchings arranged in stacks. The desired structure is thus fully completed and embedded into the consecutive layers of depositions. Postprocessing is performed to remove the sacrificial films and release the free-standing structure.

Table 3 schematically illustrates the core of the IC-for-MEMS fabrication processes. The table presents

the three main processes: deposition, patterning, and the removal of sacrificial layers. These processes are subject to considerable variations in the process parameters depending upon the technology implemented. The deposition techniques have reached performance levels that enable the deposition of films with adequate mechanical and electrical properties.

Further, Table 4 gives a list of most other common processes used to realize MEMS. As can be seen, standard machining processes are included in the list, since hybrid accomplishment of MEMS through IC and standard processes is an alternative that is still under appraisal. Some of the standard machining processes are most instrumental for packaging. Most of the standard machining processes, however, require individual manipulation of parts, which represents a bottleneck for a batch fabrication stream.

The etching process marks the postprocessing of the microstructure. Release of the free-standing structure represents a challenge, since the electronic circuitry, the contact pads, and the structure itself have to withstand the etching. The costs associated with postprocessing and packaging of MEMS often contribute to a significant increase in the cost of the MEMS. The low-cost postprocessing techniques, invariably performed outside the silicon foundry, are thus extremely desirable.

The selectivity of the etchant with respect to the passivation and structural films is of most interest in surface micromachining. Table 5 presents the most popular etching recipes for Si, glass, Si₃N₄, Al, and Au along with the corresponding etch rates.

Table 3 Description of fabrication processes for MEMS

Table 3 Continued

Process	Type and method	Sketch
E-beam lithography	Photoresist spin coating Pre-baking e-beam gun Development Post baking	<p>The diagram illustrates the E-beam lithography process. It begins with a substrate being coated with photoresist via spin coating. This is followed by a pre-baking step where the photoresist is exposed to heat. An e-beam gun then exposes the photoresist through a mask. After development, the unexposed photoresist is removed, leaving a patterned layer. Finally, a post-baking step is performed.</p>
Etching	Deep etching (crystallographic) Anisotropic – (100) silicon wafer	<p>This diagram shows deep etching on an anisotropic silicon wafer. A mask is used to expose specific areas. The etchant follows crystallographic planes, creating a V-shaped trench and a vertical hole. The angle of 54.74° is indicated between the vertical wall of the trench and the horizontal base.</p>
	Isotropic: Si wafer	<p>This diagram shows isotropic etching on a silicon wafer. A mask is used to expose the surface. The etchant removes material uniformly across the exposed areas, creating a shallow, circular cavity.</p>
	Thin film etching	<p>This diagram shows a cross-section of a thin film structure. It consists of a structural layer deposited on a sacrificial layer, which is itself on a substrate. The sacrificial layer is used as a resist during the etching process.</p>
	Sacrificial: any material etching	<p>This diagram shows the removal of a sacrificial layer. The sacrificial layer is etched away, allowing the underlying structural layer to rise and take its place, effectively releasing it from the substrate.</p>

Table 4 Alternate processes used in MEMS manufacturing

Process	Alternatives and issues
Electroforming	Electrochemical deposition (plating): contamination Anodizing: contamination Polishing: not very productive
Surface processing	Ion implantation Diffusion: high temperatures Annealing: high temperatures
Coating	Dipping: all sides are covered Spinning: high process variability Spraying: uniformity issues
Forming	Serigraphy: alignment Hydro: contamination, accuracy Drawing: high temperature or high built-in stress
Extrusion Molding	Direct/indirect: accuracy High-pressure injection Vacuum: accuracy Dipping: filling
Machining	Compression Turning: fixture Milling: high forces Drilling: chip removal Sawing
Finishing machining	Electrochemical discharge Grinding: high forces Polishing: low efficiency Lapping: low efficiency
Microcutting	Laser: low efficiency Electron beam Electrochemical discharge: contamination, minimum size
Joining	Riveting: size (microsize riveting under investigation) Screwing: size Soldering: strength Brazing: high temperature Elastic
Bonding	Anodic: high temperature and voltage Thermal: high temperature Adhesives: limited life
Welding	Laser Electron beam Electric spot: size Electrochemical
Wire bonding	Ultrasonic Thermal: high temperature

The selectivity of the anisotropic etchant versus certain crystallographic planes is responsible for the sculpturing into silicon of V or U trenches that are conveniently used to create bulk micromachined structures. Table 6 presents the most used silicon anisotropic etchants, typical etching temperature, etch rate, and selectivity.

The essential electrochemical etch reactions involve oxidation-reduction and dissolution of the oxidation products by complex etching agents. Both electrons

and hole carriers exist at the silicon surface. Oxidation of silicon atoms takes place at the anodic sites, while the oxidant is reduced at the cathodic sites. The etching mechanism can be summarized as follows:

- Injection of holes into the semiconductor $\text{Si} + 2\text{O}^{\oplus} \rightarrow \text{Si}^2$
- Attachment of hydroxyl group OH^- to Si^{2+} , e.g. $\text{Si}^{2+} + 2(\text{OH}^-) \rightarrow \text{Si}(\text{OH})_2$
- The dissociation of water $\text{H}_2\text{O} \leftrightarrow \text{OH}^- + \text{H}^+$
- Reaction of the hydrated Si with complexing agent in the solution
- Dissolution of the reacted product into etchant solution

These etching mechanisms, however, do not fully describe the crystallographic anisotropic etching of silicon, and the temperature and stress dependences or the selectivity.

More accurate etching can be carried out in reactive gases. The anisotropic etching of silicon in gas is no longer driven by the crystallographic structure. Thus, the etchant no longer follows the crystallographic direction (111), like the wet anisotropic etchants, but the cut strictly follows a perpendicular direction to the masked surface. Figure 3 illustrates isotropic and anisotropic etching. Table 7 gives the gas etchants for materials most commonly used in MEMS fabrication, together with specific etch rate and selectivity versus various masking materials.

MEMS Packaging

The basic considerations for MEMS packaging are:

- Connections to the chip for signal and power leads
- Means of cooling of the chip if necessary
- Mechanical structure to support and protect the chip
- Controlled-pressure environment to reduce the viscous damping of the flexing structure and provide access for the measurand to the sensing area

Satisfying all the requirements for a robust package has proven to be a very difficult task. The selected materials must possess compatible thermal coefficients of expansion, or the structure must comprise the means to release the resulting mechanical stress, and excess of heat.

Temperature changes may arise either from the chip operation or changes in the operating environment. The connections and the package should enable low noise transmission and a high-fidelity path for signals to and from the chip, and robustness of connections. Applications with specific considerations include, but are not limited to, operations in hostile environments, hybrid multichip packages,

Table 5 Wet etching solutions and etch rates for MEMS materials

vibration control, and direct exposure of portions of the chip to outside stimuli (i.e., light, gas, pressure, and temperature).

MEMS Design

The observations on the dynamic behavior of MEMS indicate that they do not follow the pattern of similar geometric macrostructures. The design of MEMS requires a perfect knowledge of the capabilities and drawbacks of the manufacturing processes. Both bulk and surface micromachining impose specific constraints on the design that are often reflected in the geometry of the features. Both bulk and surface MEMS could be better designed using a computer-aided design (CAD) tool which are built to include the constraints of the manufacturing process. The layout design level is usually carried out on IC-compatible design tools, which enable the design of the electronic circuitry. Simulations of the dynamics of both electronic circuitry and the mechanical structure modeled as an electronic circuit help to improve the performance of the coupled electromechanical system. The simulation uses models which are created based on analogous electrical circuit elements. A comparison of the mechanical, fluid, and thermal elements with the electrical element is given in Table 8. It is important to note that other first-order analogs are accepted and used in simulations. The selection of analogs, however, may depend on the likeness of current and voltage used in describing the mechanical physical quantities.

Table 7 The gas etchants for materials used in MEMS, etch rate, and selectivity versus Si, SiO_2 , and photoresist

Material	Etching gas	Etch rate (nm min ⁻¹)	Selectivity

One of the challenges a designer has to face in modeling is to establish the figure number of the squeeze damping and the elastic constant for the continuum beam or plate element. Attempts to express analytically the equivalent stiffness of cantilever and double-supported micromachined beams have been done, but the simple analytical expressions do not always match the experimental available data. More accurate solutions are accomplished when the finite element analysis (FEA) is used in conjunction with the appropriate material data. Nonlinear characteristics of the material or nonlinear behavior of the structure can be simulated through appropriate description of the material and elements. Sufficient accuracy can be achieved by conveniently refining the mesh. A parametric design used in conjunction with multiple variable optimization algorithms can enhance the performance of the structures. Stress-strain, modal, dynamic, thermal, electromagnetic or CFD analyses can be run once a suitable model has been conceived. The output can provide essential information that may lead to improved performance of the microstructure. Some commercial codes can perform multivariable optimization, which would ease the task of the designer.

However, an overall strategy of the entire manufacturing flow, including packaging, must be planned before the analysis is carried out. Important pieces of information such as damping of the structure reside in the environment in which the structure will work and the operating temperature. Thus, the dynamic properties will strongly be influenced by the surrounding gas/fluid in which the flexing structure performs.

Before the layout design is finalized, simulations of selected deposition and etching processes may be run to insure that critical features will be accomplished within the permitted tolerances.

Figure 4 illustrates the graphic output of a stress analysis performed on the section of a plate subjected to uniform pressure loading. Appropriate meshing yields the stress distribution across the thickness of the plate, which can further be used by the designer to establish the most appropriate location of the piezo-resistive gauges.

After prototyping, manufacturing, and testing, the models are adjusted based on the empirical data obtained from measurements. Presently, the integrated modeling of MEMS is still in its infancy, although efforts have been made to understand and model the individual manufacturing processes, such as etching, crystal growth and physical deposition. Although not explicitly stated, it is apparent that analytical models of microstructures are also used and continuously improved, as test data become available. Modeling of electromechanical-fluid-thermal systems is thus of much interest to the designer. One of the main needs at this time is to build a good microscale data bank of parameters and material properties that can be used in the modeling and design of microsystems.

Miniaturization of mechanical systems establishes a unique momentum in both classic and emerging technologies. MEMS enables a new approach in making, running, and controlling systems and processes. Micromechanical devices and systems are essentially smaller, faster, more precise, and

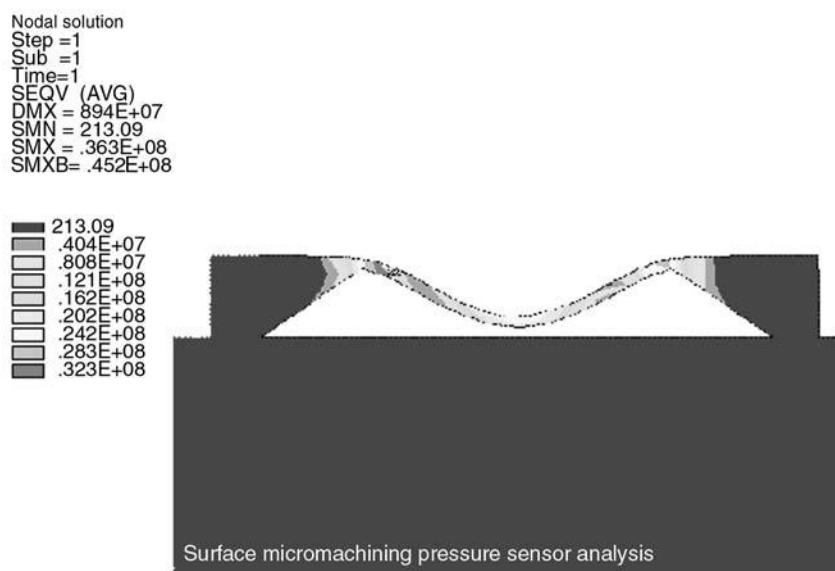

Figure 4 (see Plate 42). The output graphic file of an analysis of a silicon plate subjected to uniform distributed pressure loading.

usually less expensive than their macroscopic counterparts. The development of micromechanical systems, however, requires appropriate fabrication technologies which permit the definition of small geometry, precise dimensional control, design flexibility, interfacing with control electronics, high repeatability and reliability, high yield, and low cost.

See Plate 42.

Overview

This article introduces and explains the basic concepts of the widely-used technology which has become known as 'experimental modal analysis' or 'modal testing'. Simply put, experimental modal analysis comprises a set of experimentally-based procedures which lead to the construction of a mathematical model that can be used to describe the dynamic behavior of the test object. This model can be used on a variety of useful applications including:

1. visualization of the modes of vibration of the test structure for the purpose of gaining physical insight and an understanding of the often complex dynamic properties of real structures;
2. comparison of the actual (measured) vibration behavior of a real structure with corresponding parameters predicted from a theoretical model;
3. correcting or refining that theoretical model;

4. predicting the effects of making modifications, or predicting what modifications to introduce to change the structure's behavior;
5. predicting the behavior of structures formed by coupling two or more components together;
6. detecting damage or other changes in the integrity of a structure during its service life;
7. identification of 'unpredictable' parameters such as damping, dynamic friction effects, excitation forces from unknown sources, etc.

In effect, modal testing has been practiced for a long time but has only been formalized in the past 30 years, following the advent of computers and instrumentation capable of realizing the concepts with sufficient accuracy to warrant implementation of the ideas.

The basic sequence of steps in a modal test are:

1. measurement of the test structure's vibration response to a controlled and known excitation;
2. analysis of the resulting response functions to identify the underlying modal properties (natural frequencies and mode shapes) of the test structure;
3. construction of a mathematical model from these modal properties, suitable for the intended application.

The specific skills that are required to conduct a successful modal test include:

- a sound appreciation of the underlying theory
- measurement techniques to excite and measure the vibration response of the test structure
- signal processing techniques to define the required response function information
- data analysis methods which are capable of extracting parameters for an assumed mathematical model that can describe the observed test behavior.

Brief History of Experimental Analysis/ Modal Testing

Modal testing has been practiced at various levels for over 50 years. The earliest, and still the most common, applications of the experimental methods that are now called ‘modal testing’ or ‘experimental modal analysis’ were to validating whatever theoretical model had been constructed to predict the structure’s behavior under dynamic loading conditions – usually under steady-state excitation. Nowadays, the mathematical models in question are almost always finite element models. Probably the first documented modal testing methods date back to the 1940s when engineers charged with conducting vibration tests on aircraft structures† sought to supplement the primary test data of how and when the structure would fail under dynamic loads with intermediate observations (while the test was running) of the input forces and the resulting response levels, thereby measuring the same type of frequency response functions that we use today. These early attempts to conduct what we now recognize as modal tests were frustrated by inadequacies of the transducers and signal conditioning equipment of the day and it was a full decade later before early electronic devices, and then computers, provided the means to make and to analyze adequate measurements of the essential data. In fact, it was the widespread introduction of the digital computer and development of data analysis techniques such as the fast Fourier transform (FFT) in the 1960s that heralded the real start of modern experimental modal analysis.

The 1970s saw the development and widespread use of FFT-based signal analyzers and the associated progress of the technology necessary to process the resulting measured data by extracting the coefficients in an assumed governing mathematical model. By the 1980s, experimental modal analysis was maturing to the stage where it could be used in a routine industrial context and it was during this decade that many of the

powerful applications were developed: model updating; structural dynamic modification (SDM) and optimization methods as well as those for analyzing structures which comprise an assembly of different and often disparate components; and then later, damage detection, and identification of a range of quantities that are difficult, if not impossible, to describe theoretically.

More recent developments in the subject, in the 1990s, have seen progressive refinements in the primary techniques and applications, accompanied by a growing appreciation of the limitations associated by almost any experimental data in part by their inevitable imprecision but also, and more significantly, by their incompleteness, a feature brought about by the inescapable restrictions on the quantity and choice of what can be included in a given test. Bearing these effects in mind, and the trend towards the conduct of fewer and fewer tests, not least because of the resources and time they consume, there is now considerable interest and activity in refining modal test procedures and methods so as to optimize the whole process: to make careful selection of which parameters must be measured (and which are unimportant) and the accuracy that is required. By such an approach, the cost-effectiveness of modal tests can be considerably increased and their usefulness assured. These recent developments are often referred to as ‘test planning’ and represent a ‘full circle’ situation as regards the theoretical models that most modal tests are performed to validate: the subject theoretical models are often used in a numerical simulation of the proposed modal test in order to establish the optimum parameters for that test.

Basic Procedures Involved in a Modal Test

The sequence of steps that must be executed to conduct a modal test (the engineer having first thoroughly familiarized him/herself with the associated theory so that he/she can detect and explain any deviations of actual behavior from the expected and assumed characteristics of a linear, multi-degree-of-freedom system (MDOF)) are as follows:

1. set up the test structure in a mounting configuration which has been carefully selected and which can be controlled;
2. provide a means of exciting the structure into vibration in a controllable and measurable way. This may be by means of a nonattached device, such as an impact hammer or similar, or by an exciter which is connected firmly to the test structure. These exciters can generate the required

† At that time, ‘vibration tests’ were those conducted to simulate service loading and to determine the threshold levels that the structure could withstand before failing. They were, in effect, environmental endurance tests.

- excitation forces by several means: mechanical, electromagnetic, electrohydraulic, etc.;
3. provide a means of (transducers for) measuring the resulting response of the test structure, and to do so with the minimum of interference to the test object (often difficult to achieve);
 4. provide signal processing and analysis facilities so that the required information can be extracted from the individual measured time histories yielded by the transducers. Here, it is usually necessary to convert raw measured data in the time domain into equivalent spectra in the frequency domain, as frequency domain parameters are more commonly used to describe most vibration phenomena;
 5. subject the measured response function data to a subsequent analysis stage, often employing curve-fitting techniques, in order to construct a mathematical model of standard form (linear, MDOF system) whose dynamic properties most closely resemble those observed on the test structure.
 6. Check that the resulting model is adequate for the intended application (before releasing the test structure).

The Essential Theory

It is important in modal testing, more so than in many experimental disciplines, that the underlying theory of both the structural dynamic behavior and the various stages of signal processing and data analysis (typically, curve-fitting) is well appreciated by those who conduct such tests. There are many situations in which poor, and even very poor, results can be obtained using perfectly adequate equipment and instrumentation because these are not being used correctly: a situation which can easily arise if the understanding of the whys and wherefores of the different techniques involved is inadequate.

Much of the necessary theory can be found in more detail in other entries in this work (see **Modal analysis, experimental**, Parameter extraction methods; **Modal analysis, experimental**, Construction of models from tests). Accordingly, here we shall simply quote some of the more important expressions and formulas and indicate some of those areas that should be mastered as necessary preparation for those aspiring to conduct successful modal tests.

Having described experimental modal analysis as the process whereby a mathematical model is constructed from test data which is capable of describing the observed behavior of the test structure, it is appropriate here to define more in detail what is meant by a mathematical model. Conventionally, there are three types of mathematical model, each

of which is capable of describing the required structural dynamic behavior, but each formulating the model in a different way, based on different fundamental features.

Spatial Models

The first type of model is the spatial model which describes the distribution in space of the essential physical features of the structure – its mass or inertia, its stiffness and its damping properties. In simple terms, the spatial model is the set of mass, stiffness and damping elements which are used in describing equations of motions for the system:

$$m\ddot{x} + c\dot{x} + kx = 0$$

or

$$Mx + Cx + Kx = f$$

for the more representative MDOF system that is applicable to most real cases.

Modal Models

The second type of model is the modal model, which comprises the set of eigenvalues and eigenvectors – natural frequencies and mode shapes – that describe the individual ‘ways’ in which the structure will choose to vibrate if left to do so without any externally applied excitation, other than an initial disturbance from which it is released and allowed to vibrate. This model is defined by two matrices, ω_r^2 and Φ , containing the eigenvalues and eigenvectors, respectively.

There is a direct and algebraically simple relationship between the spatial model and the modal model which can be written for the basic undamped case as follows:

$$\Phi^T M \Phi = I$$

and:

$$\Phi^T K \Phi = \bar{\omega}_r^2$$

Response Models

The third type of model is referred to as a response model, and this consists of a set of response functions (usually but not exclusively, frequency response functions or FRFs) that relate the input/output relationships for all the degrees of freedom of the structure. The typical individual FRF from which this model is built is written as $H_{jk}(\omega)$, and is defined as the harmonic response in DOF j to a unit harmonic excitation applied in DOF k at frequency, ω . There is an important condition associated with this definition, which is that the specified excitation must be the

only excitation that is applied when the response is measured. Thus:

$$H_{jk}(\omega) = \left(\frac{X_j}{F_k} \right); \quad F_m = 0; \quad m = 1, N; \neq k$$

In fact, the complete FRF matrix, $\mathbf{H}(\omega)$, which contains the full set of individual FRFs for all j, k combinations, can be related to the preceding spatial and modal models as follows (again, shown here for the basic undamped system):

$$\mathbf{H}(\omega) = (\mathbf{K} - \omega^2 \mathbf{M})^{-1} = \Phi [(\bar{\omega}_r^2 - \omega^2)]^{-1} \Phi^T$$

From this last expression, it is possible to derive a convenient expression for the individual FRF as:

$$H_{jk}(\omega) = \sum_{r=1}^N \frac{(\phi_{jr})(\phi_{kr})}{\bar{\omega}_r^2 - \omega^2}$$

and this is the expression which forms the basis for much of modal analysis processing methods.

See **Modal analysis, experimental, Measurement techniques** for further details of this underlying theory for experimental modal analysis.

Summary of Essential Experimental Requirements

The experimental aspects of modal testing comprise two main tasks: (i) exciting the test structure into

vibration in a controlled way and (ii) measuring the excitation force(s) and the resulting response(s). These tasks embrace a series of mechanical issues of excitation devices, support of the test structure, attachment of exciters and transducers plus another set of requirements concerning the signal conditioning and processing which must be applied to the transducer outputs. A sketch of a typical set-up for conducting a modal test is shown in Figure 1, with the major elements of the system labeled appropriately.

Support of Test Structure

The first task is to decide how to support the test structure. There are essentially two choices, free-free or grounded and the selection depends on a number of factors which are determined by the eventual application of the test results. Careful consideration must be given to these and the appropriate choice must be made.

Excitation of Test Structure

Next, it is necessary to decide whether the excitation forces should be applied by an attached exciter, or by a nonattached impact device, such as a hammer. A major advantage of the former is that much more control can be applied to the excitation levels and frequency content than is possible with an impactor. On the other hand, the very attachment of the exciter to the structure introduces the risk of interfering with the structure and changing its local stiffness or mass. Care must therefore be taken to attach the exciter in a well-controlled way. The use of a hammer exciter, or equivalent, has the advantage of being

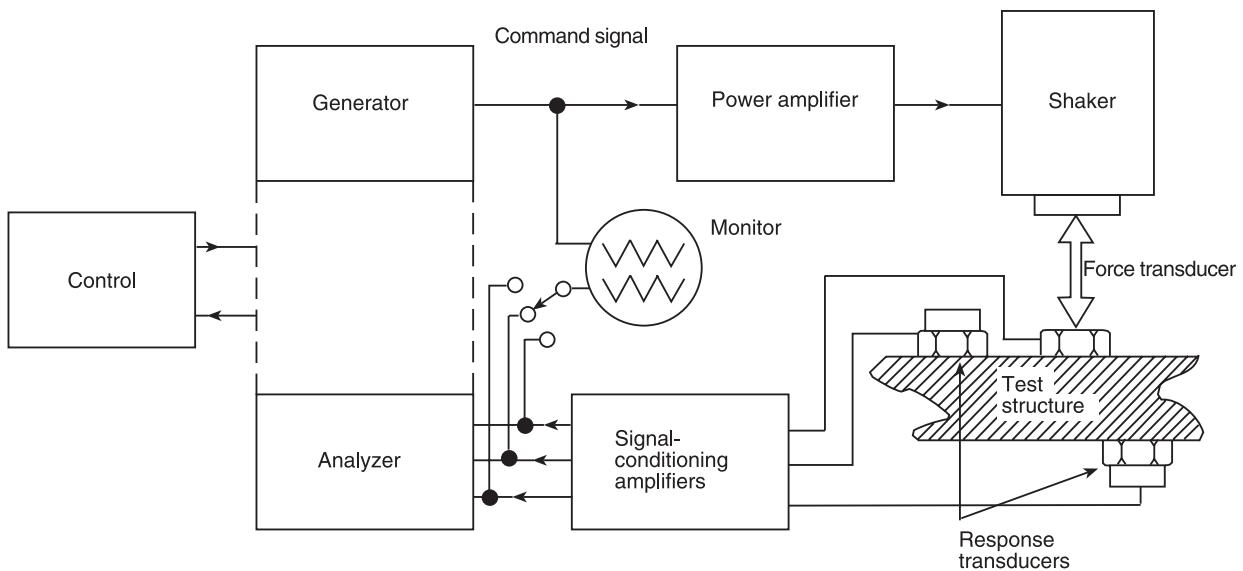

Figure 1 Typical experimental set-up for modal test.

very convenient and quick, as no attachment device is required. However, relatively little control of the excitation signal and level is possible with such an exciter and it is found that there is a relatively narrow range of structures which are well suited to impact excitation – not too lightly-damped; not too heavily-damped; linear – while those outside that set can pose problems.

The structure can be excited with almost any type of signal – sinusoidal, periodic, random, transient – and essentially the same response function will be derived from each. There has been a lot of development to determine the most effective and efficient excitation signals and the choice of the one to use in

each case needs careful consideration. Figure 2 shows some of the more popular signal types.

Transducers

A wide range of transducers are available for capturing the excitation force and resulting response levels. Many of these are piezoelectric devices, simple to use and relatively free of idiosyncratic features. Such transducers are widely available to measure force and acceleration: other transducers are also available for measuring velocity responses directly, and worth a special mention are the new generation of laser Doppler vibrometers, which offer

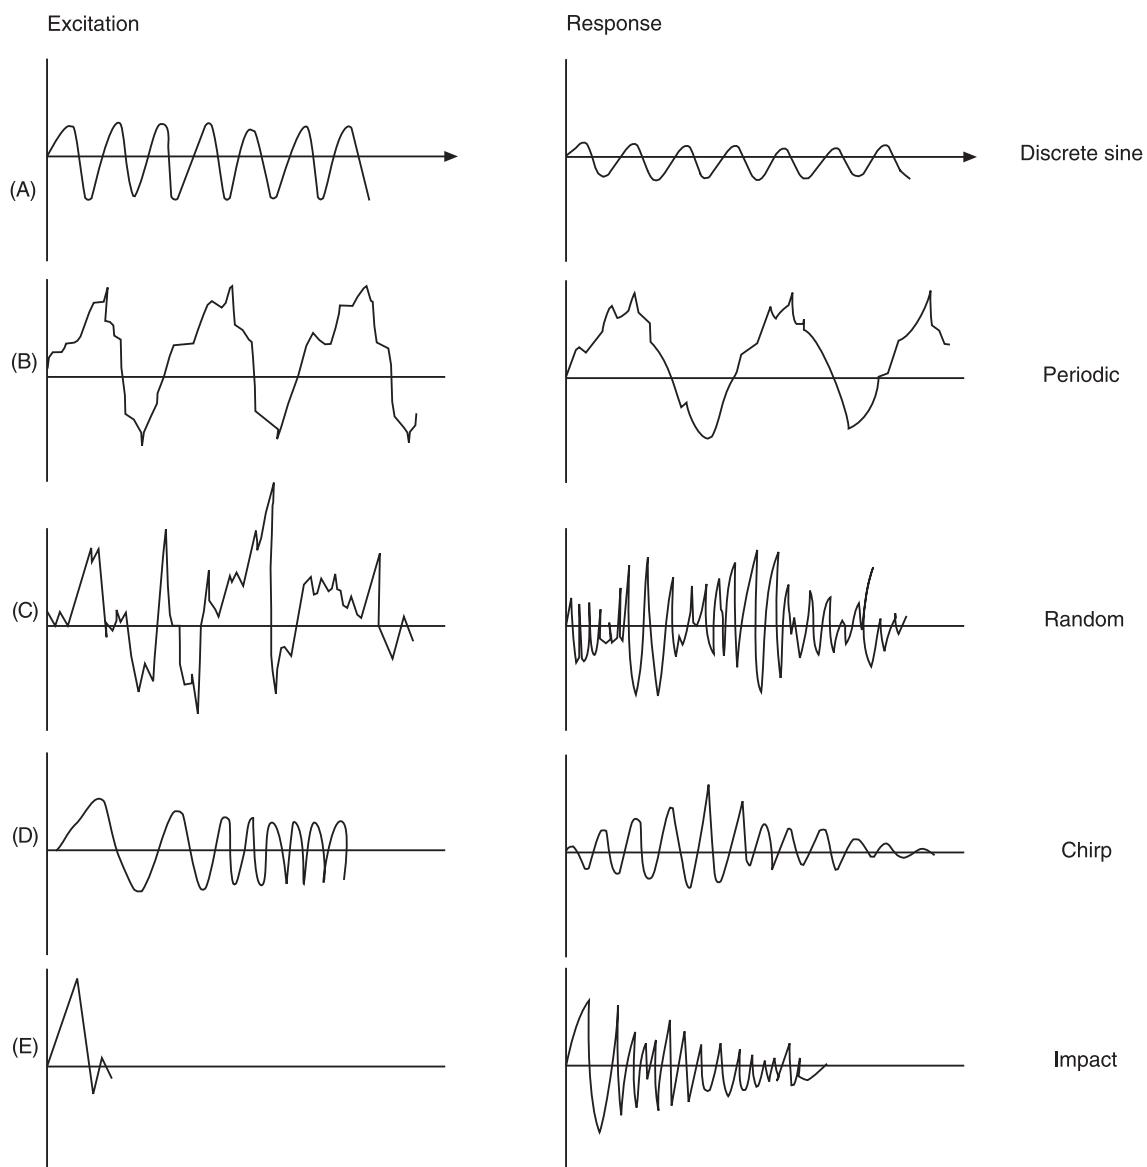

Figure 2 Popular types of excitation signal used for modal tests. (A) discrete sine; (B) periodic; (C) random; (D) transient-chirp (E) transient-impact.

advantages of being noncontacting devices, thereby minimizing interference with the behavior of the test structure.

Signal Processing

Signal processing is a major activity. It is generally required to be able to extract the individual frequency components which are present in a signal – sometimes because the original signal generating the vibration contains many components (as is the case for periodic, random or transient types of excitation), and other times because it is required to eliminate spurious components of response, introduced by noise or nonlinearities in the measuring system. These various requirements can be met with the current generation of spectrum and other frequency response analysers, often based on digital filtering and frequently employing the FFT or similar algorithms developed in the 1960s, and making signal processing very much faster than it had been hitherto. The advent of the FFT was a major development for modal testing.

The primary output from the measurement stage of a modal test consists of a series of response functions, usually – but not exclusively – FRFs, and these are yielded directly from the output of the signal processing devices (analyzers) used to treat the measured time-histories emitted from the transducers. Here, again, a thorough appreciation of the underlying theory becomes essential for the successful use of the various experimental and signal processing devices. Figure 3 illustrates some typical signals recorded during a modal test, and the resulting FRF that is produced as the ‘output’ from the measurement phase of the test.

See **Modal analysis, experimental**, Measurement techniques for details of these experimental aspects of conducting a modal test.

Summary of the Analysis of Measured Response Functions

The next stage in the modal test procedure is the analysis which is applied to the measured response functions in order to reveal the properties of the mathematical model which closely describes the behavior of the measured structure.

The first part of this stage comprises a process of ‘modal parameter extraction’ or ‘modal analysis’ in which the measured response functions are scrutinized in some detail in order to determine the underlying formulas which can be used to characterize their form. This is usually achieved by using curve-fitting procedures, where the basis of each curve is a theoretically-generated formula developed for an MDOF

system with, at the outset, unknown parameters. By applying curve-fitting procedures, least-squares or other criteria can be applied in order to determine the best-fit coefficients in these expressions such that a theoretically-regenerated curve can be constructed to pass through the measured data points with the minimum of discrepancy.

There are many implementations of this general procedure: some are simple methods that perform the analysis (curve-fit) on a very small part of the measured response function, such as in the vicinity of a single resonance on a single response curve, while others are more extensive, performing the same essential task on a much greater dataset, such as is provided by several response functions, each covering many resonances, in a single calculation. Figure 4 illustrates examples of both types of analysis – the first case (A) showing the traditional ‘circle-fit’ approach to the analysis of a single resonance on a single curve, while the second case (B) shows the result of a multicurve, multimode simultaneous analysis of over 70 FRFs in a frequency range spanning several modes.

In each case, the essential process is the same: measured response data – usually in the form of a set of measured FRFs – are subjected to an extensive curve-fitting analysis in which the reference curves are based on the formula for response functions for an MDOF system with unknown parameters. By curve fitting, best estimates for these parameters are determined and these, in turn, yield the essential modal properties – natural frequencies, damping factors and mode shapes – of the model which has been proposed. Of course, it is important that the assumed model must be of a sufficiently general form and order such that it is possible to find values for its parameters that render it capable of representing the measured behavior. There can be a problem in achieving the desired result if, for example, the model is assumed to have only 10 DOFs when the measurements clearly reflect the behavior of a system with more modes than that. Likewise, conflicts will arise if the assumed model is linear while the measured data reflect the behavior of a structure which is noticeably nonlinear in its characteristic. In this respect, it is important to check that the results of the curve-fitting, modal analysis, process are not only the ‘best-fit’ results in a least squares sense, but also that they are good results. These two criteria are not automatically satisfied simultaneously.

For full details of the various methods for extracting modal parameters estimates for a structure from analysis of measured response functions, see **Modal analysis, experimental**, Parameter extraction methods.

Construction of the Mathematical Model

The final step in the analysis of measured data is that of combining all the detailed results from the parameter extraction procedures, and using these to con-

struct the mathematical model which is the objective of the whole exercise. In effect, once the modal parameter extraction exercise is completed, the elements for a modal model have been obtained, and a mathematical model of this type is, theoretically, available.

However, there are complications that can arise in practice because of the fact that the measured data, and the resulting modal parameters that have been extracted, are not only imprecise – any measured data are liable to contain errors – but are generally incomplete. It is simply not practical to measure at all the DOFs and even less so to measure over a frequency range that captures all the modes. Thus, any model which is constructed from a practical modal test will be restricted to one which represents the behavior of only a limited number of modes and with these defined at just a small number of DOFs.

While these limitations which result from the inevitable incompleteness of the measured data are not particularly problematic when considering the modes of the structure, they can become a problem when seeking to convert the measured modal model into a spatial (mass-stiffness) model or to a response model. The equations given above which define the interrelationships between these three types of model can be seen to become inapplicable if the description in the original model is not complete – even if the data which are included are fully accurate. This presents something of a problem for some applications as several of the more popular ones really require the derived model to be in spatial or response form (see **Modal analysis, experimental, Applications**). For a full discussion of the issues which arise in constructing a suitable model from the measured and analyzed vibration data, see **Modal analysis, experimental: Construction of models from tests**.

Introduction

The experimental determination of natural frequencies, mode shapes, and damping ratios is called experimental modal analysis and is based on vibration measurements that fall within the general designation of modal testing. The objective of this form of vibration testing is to acquire sets of frequency response functions (FRFs) that are sufficiently accurate and extensive, in both the frequency and spatial domains, to enable analysis and extraction of the dynamic properties for all the required modes of vibration of the structure. Prior knowledge of areas such as vibration analysis, instrumentation, signal processing, and modal identification, to state just a few, is required to understand modal testing.

The basic aim of modal testing is to obtain FRFs relating output vibration responses at a number of coordinates of interest, usually under the form of accelerations (or velocities, or displacements), to input vibration excitations, usually under the form of driving forces, applied at a given coordinate.

Basic Measurement System

In order to perform modal testing a number of hardware components must be available. These components may be interfaced with a host computer allowing for coordination of the operation of the overall system and enhancing the data-processing capabilities, if adequate software is available. The hardware components are schematically represented in **Figure 1**, which shows a typical set-up for a measurement system. Basically, there are three main measurement mechanisms:

- the excitation mechanism
- the sensing mechanism
- the data acquisition and processing mechanism

Adequate selection of an experimental modal analysis system is not an easy task and requires good understanding of the underlying theory.

The Excitation Mechanism

The excitation mechanism is constituted by a system which provides the input motion to the structure under analysis, generally under the form of a driving force $f(t)$ applied at a given coordinate. There are many variants for this system, their choice depending on several factors such as the desired input, accessibility, and physical properties of the test structure. Basically there are fixed excitors and non-fixed excitors.

The fixed exciter, also known as shaker, is usually an electromagnetic or electrohydraulic vibrator, driven by a power amplifier (Figure 2). The excitation signals, in these cases, are generated by a signal generator and can be chosen from a variety of different possibilities (stepped-sine, swept sine, impulse, random, etc.), to match the requirements of the structure under test.

This type of excitation mechanism may be easily controlled both in frequency and amplitude and therefore offers the best overall accuracy. However, it also has some disadvantages, such as the need for the exciter to be connected to the test structure. Despite the use of connecting devices (named push-rods, drive rods, or stingers) designed to reduce the attachment consequences, there are always some constraining effects and mass loading of the structure.

Conventional electromagnetic or electrohydraulic excitors vary in size and their choice depends on the structure under test. The main characteristics to take

Figure 2 Example of electromagnetic exciter and matching power amplifier.

into consideration are force level, displacement level, and frequency range. The objective is for the exciter to provide inputs large enough to result in easily measured responses. The applied excitation force is commonly measured by means of a load cell (known as force transducer) which is located at the end of the stinger and is rigidly connected to the test structure (Figure 3).

The nonfixed exciter, known as an impulse or impact hammer, is a very popular alternative to fixed systems. It consists of a hammer with a force transducer attached to its head (Figure 4). The most important advantage of these excitation systems is that they do not need a signal generator and a power amplifier and nothing is attached to the structure. Hence, the excitation system does not affect the dynamics of the test structure.

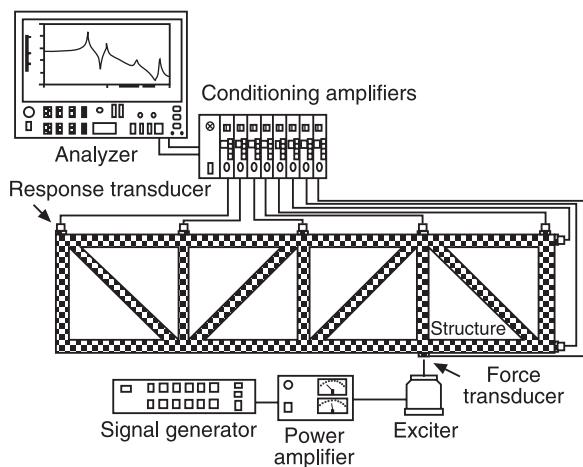

Figure 1 Typical measurement set-up.

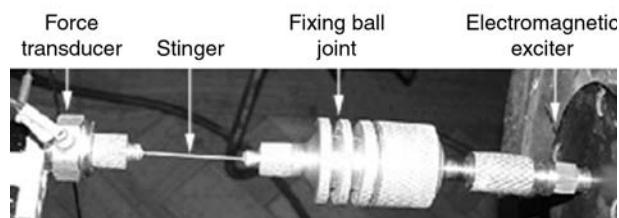

Figure 3 (see Plate 44) Shaker connected to test structure.

Figure 4 Impact hammer with force transducer and soft head.

The range of frequencies covered by a hammer depends on the hammer mass and on how hard its impacting head is (note that the mass and stiffness of the impacted structure also contribute to define this range). Furthermore, the mass and therefore the size of the hammer, together with the velocity of the impact, dictate the amplitude of the impact force. Impact hammers concentrate the total input excitation energy in a very short period of time, producing an almost flat force spectrum over a wide frequency range. Problems may arise due to local deformations and nonlinearities.

Preloading a structure and suddenly releasing it, exciting with acoustic energy (using a loudspeaker) or with a magnetic device, are other alternative nonfixed excitation possibilities. The problem with most of these cases (except in the preload/release alternative) is that the exciting force cannot be measured.

The Sensing Mechanism

The sensing mechanism is, basically, constituted by sensing devices known as transducers. There is a large variety of such devices: the most commonly used in experimental modal analysis are the piezoelectric transducers either for measuring force excitation (force transducers), as exemplified in Figure 5, or for measuring acceleration response (accelerometers), as exemplified in Figure 6. The transducers generate electrical signals that are proportional to the physical parameters one wants to measure.

Most of the time, the electrical signals generated by the transducers are not amenable to direct measurement and processing. Such a problem, which is usually related to the signals being very weak and to electric impedance mismatch, is solved by the use of conditioning amplifiers. These devices are usually considered as part of the transducers and therefore of the sensing mechanism (some transducers actually incorporate the basic conditioning electronics).

The choice of transducers is based on maximum force or maximum motion response, frequency range (which depends on the load), size (and therefore mass), and sensitivity.

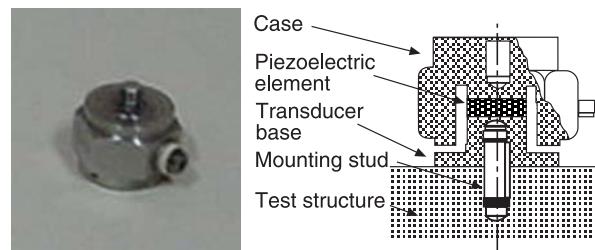

Figure 5 Example of piezoelectric force transducer and schematic representation of their cross-section.

Most transducers used in modal analysis have to be fixed to the structure under test and, thus, they may affect the measured dynamic response. This is especially true in the case of small lightweight structures. A common alternative is to use a contactless motion transducer, such as a laser vibrometer. This is a velocity transducer based on detection of the Doppler frequency shift of a laser beam light scattered from the moving surface.

Data Acquisition and Processing Mechanism

The basic objective of the data acquisition and processing mechanism is to measure the signals developed by the sensing mechanism, and to ascertain the magnitudes and phases of the excitation forces and responses. There are very sophisticated devices for this purpose, called analyzers, that incorporate many functions and even include the signal generation component. The most common analyzers are based on the fast Fourier transform (FFT) algorithm and provide direct measurement of the FRFs. They are known as spectrum analyzers or FFT analyzers. Basically, they convert the analog time domain signals generated by the transducers into digital-frequency domain information that can be subsequently processed with digital computers. Multichannel FFT analyzers (Figure 7) are a normal component of any modal analysis laboratory.

Due to the rapid development of computers, there is nowadays a tendency for the computer to replace the analyzer, provided it incorporates adequate software and a data acquisition board. More sophisticated systems are based on personal computers (PCs) or workstations with an acquisition front-end module. These solutions have the additional advantage of allowing for storage and data processing without having to go through the intermediate steps of data transfer. If based on a portable computer (lap-top), these systems may easily be carried to the test site.

The PC-based systems are usually cheap. However, one must be careful in choosing the data acquisition

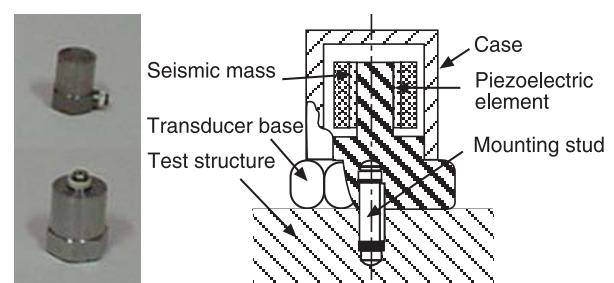

Figure 6 Example of piezoelectric accelerometers and schematic representation of their cross-section.

Figure 7 Example of multichannel FFT analyzer.

plug-in boards: Sampling rate, analog-to-digital conversion (ADC) accuracy, frequency range, filter characteristics, and zoom capabilities are some of the characteristics to take into consideration.

Understanding the principles behind signal acquisition and processing is very important for anyone involved with the use of modal analysis test equipment. The validity and accuracy of the experimental results may strongly depend on the knowledge and experience of the equipment user.

Excitation Methods and Measurement

There are various excitation signals that are commonly used in experimental modal analysis. They may be classified as single-frequency and broadband excitation signals, and each technique incorporates several different methods. Although each method has specific advantages and disadvantages, selection of a testing technique is often based (unfortunately) on the type of equipment and expertise available rather than on its suitability for a particular job.

Single-Frequency Excitation

Stepped sine and swept sine are the two types of single-frequency excitation signals commonly used.

In the stepped sine testing technique, a shaker is used to excite the structure sinusoidally at a single, precisely controlled frequency. The structure is allowed to settle under this excitation, to remove any transient effects. Steady state measurements are then made of the magnitude and phase relationship between the input force and the response at the precise excitation frequency for any desired response location. Division of the response by the force input gives the value of the FRF at that particular frequency. The excitation frequency is then changed by a small increment and the measurement process is repeated once the structure has settled at the new

frequency. Thus, the FRF can be constructed for any frequency range.

One of the advantages of the stepped-sine testing technique is the large signal-to-noise ratio for all the force and response measurements. Furthermore, the input ranges for the force and response signals can be adjusted automatically for each excitation frequency point, and this allows the best possible use of the measuring equipment. This technique is especially adequate to investigate nonlinear behavior.

In the swept-sine testing technique, a shaker is used to excite the structure with a sine signal whose frequency varies slowly and continuously along the test frequency range. Sets of simultaneous measurements of the excitation signal and response signals are then taken at a given rate. The frequency of the sine signal allows a low rate of change, assuming that each set of measurements correspond to virtually steady state characteristics, i.e., that the technique sinusoidally excites the structure for each set of measurements at virtually one single frequency.

Though similar, swept sine techniques are faster than stepped sine techniques. However, since there is a continuous rate of frequency shift, accuracy is affected.

Broadband Excitation

In broadband testing, the structure is excited with a signal containing energy over a wide range of frequencies simultaneously. The time domain force and response signals are filtered, digitized and then passed through a Fourier analysis process to transform the time domain information to frequency domain spectra. By appropriate combination of the force and response spectra, the required FRFs for the structure can be derived.

Broadband excitation techniques may be classified as nonperiodic (purely random), periodic (pseudo-random, periodic random, and periodic chirp) and transient (burst random, burst chirp, and impact). Random, periodic random and impact are probably the most commonly used types of broadband excitation signals.

The pure random excitation signal is a nonperiodic stochastic signal with a Gaussian probability distribution. For a linear system, a Gaussian input will produce a Gaussian output. Since the peak-to-root mean square ratio of the output is relatively small, the random-type excitation does not cause undue problems with excitation of nonlinear structures and easily averages out noncoherent noise. However, because the force and response signals are random, a weighting function (e.g. Hanning window) must be applied to these signals before the discrete Fourier

transform (DFT) is performed, otherwise the mathematical assumptions of periodicity in the measurement time frame are invalid.

The force and response signals from the transducers contain energy at all frequencies. Because the measurement time frame is of a finite length, the Fourier analysis produces spectra that are discrete, rather than continuous, functions. Therefore, there is a 'spreading' of energy from the continuous spectra into adjacent spectral lines producing a phenomenon known as 'leakage'. The use of adequate weighting functions (windows) reduces the above-mentioned 'spreading'.

Periodic random excitation is a special form of periodic excitation, similar to pseudo-random, that has several benefits for signal processing. Although called 'random' it is not random in the true sense of the word. Within a time period equal to the analysis time frame, the signal is random, but the same signal is then repeated continuously. Usually, the signals are generated inside the data acquisition equipment in the frequency domain. The spectrum of a periodic random signal consists of discrete frequencies at integer multiples of the frequency resolution used by the DFT. Once the measurement frequency range and number of frequency lines have been selected, a flat excitation frequency spectrum may be generated by setting the magnitude of all spectral lines to the same value. The phases of the spectral components are then randomized. By use of the inverse Fourier transform (IFT), this frequency domain spectrum is transformed into the time domain to produce a random-like excitation signal in the analysis time frame. As a consequence of generating the signal in this way, it is exactly periodic in the analysis time frame, and both the force and response signals will be periodic in the analysis time frame also.

Provided that the excitation is applied to the structure more than once, so that any start-up transients have had sufficient time to decay, there is no requirement for any window function to be applied to this type of data. These signals only contain energy at the precise spectral component frequencies of the analysis and, therefore, there are no leakage problems when periodic random excitation signals are used. Furthermore, the signal-to-noise ratios for the measured force and response signals are much better than they would be with pure random excitation because there is no superfluous energy contained in the excitation.

The impact excitation is based on an input transient deterministic signal consisting of a pulse lasting for only a very small part of the sampling period. The shape, width, and amplitude of the pulse determine the frequency content of the force spectrum.

Impact excitation is usually obtained with impact hammers. The shape and amplitude of the impact signal determine the level of the force spectrum. The base-band frequency span is controlled by the width of the impact signal. The maximum frequency is inversely proportional to the width of the pulse signal.

Multipoint Testing

In tests on large complicated structures, with numerous joints and nonlinearities, the vibration energy is quickly dissipated within the structure. This may indicate that the use of multipoint testing is preferable to a series of single-point tests. By the use of multipoint excitation, the energy can be fed into the structure more uniformly than with single-point excitation and the response amplitudes at various locations can be kept much closer to those found in operation. Energy is supplied to the structure by several shakers, and so smaller and cheaper shakers can be used than would be necessary for single-point testing. Furthermore, the effects of nonlinearities, which may occur with excessive single-point forcing, can be substantially reduced. Since all the shakers are connected to the structure before the start of the test, systematic errors, resulting from repositioning the shaker during a series of single-point tests, do not occur. The influence of the shakers on the structure is not removed; it just remains constant throughout the whole of the test program. Simultaneous measurement of multiple columns of the FRF matrix means that the overall test time is shortened. There is less opportunity for structural changes (with time, temperature, or humidity) to affect the measured results.

Multipoint testing may be expensive in terms of suitable test control hardware and software that are required. Also, the process for extracting the FRFs is more complicated than for a single-input test.

The most commonly-used multiple shaker technique is known as multipoint random (MPR). For all multipoint excitation techniques, more sophisticated computer programs are necessary to extract the standard FRFs from the measured data.

To comply with the mathematical assumptions made in the analysis, it is important that the excitation inputs to the structure are purely random and uncorrelated. Although it is possible to ensure that the excitation signals driving the shakers are uncorrelated, it does not necessarily follow that the excitation force signals are uncorrelated. At the resonance frequencies, in particular, it is found that the motion of the structure tends to correlate the multiple forcing inputs. This can lead to degradation in the quality of the derived FRFs at the resonance frequencies.

Special types of multipoint excitation methods are known as ‘phase resonance methods’ (also known as ‘tuned-sinusoidal’ or ‘force appropriation methods’) and these rely on the ability to excite a single mode of vibration by the use of multiple shakers with independently variable force levels. All the shakers produce sinusoidal excitations at the same frequency and are either in-phase or out-of-phase with a reference source.

The excitation set-up in the ‘normal mode’ technique effectively cancels the damping in the structure the exciting forces are distributed such that each energy sink is canceled by a corresponding energy source and single real modes can be excited. In this condition of normal-mode vibration, the excitation frequency is the undamped natural frequency of the mode. The response at all the points on the structure is in quadrature with the excitation forces, and the structural responses relate directly to the mode shape vector.

The previous method provides the ability to measure real normal modes (for direct comparison with finite element results) and the ability to investigate nonlinear behavior. The main difficulties are the selection of excitation locations, the tuning of the force pattern, and the choice of the excitation frequency. The complete process has to be repeated for each different mode and consequently the testing time can be lengthy.

Calibration

The values measured by the test equipment represent electrical voltages and therefore it is necessary to obtain a calibration factor which translates these values into units of acceleration and force.

Though transducer manufacturers generally provide reliable calibration information, the use of their quoted sensitivities may not be accurate enough since they can change with time and environmental conditions. In addition, the transducers may have suffered some kind of damage due to rough handling or other extreme conditions and, although still working, may have lost their response linearity. Finally, the remaining units in the measurement chain (amplifiers, filters, signal conditioners, cable lengths, etc.) may change, albeit slightly, the overall sensitivity. It is therefore good practice to recalibrate the transducers before performing a test, preferably using the same measuring set-up that will be used in the test program.

Various transducer calibration techniques are available to the test engineer. The simplest and most common calibration procedure is the classical back-to-back method that compares the accelerometer to be calibrated with a reference accelerometer. This

entails keeping a special reference transducer that offers a high level of linearity and stability. Another simple calibration procedure is based on the use of small hand-held calibrators that most manufacturers commercialize. In this case, the calibration is performed at one frequency only and, therefore, a flat frequency response of the transducer over the frequency band of interest is assumed.

When measuring FRF data, one is concerned with the motion/force ratio and not with the individual values of any of these quantities. This fact allows the use of a simple and straightforward technique which provides an accurate calibration of the transducers, including the influence of the remaining units of the measurement chain. The technique requires only the use of a simple rigid structure, such as a steel block, together with the equipment that is going to be used for the accelerance measurements.

For each accelerometer to be used, it is necessary to make a calibration test involving simultaneously the accelerometer and the force transducer. Applying a time-varying force to a solid block of known mass (which can be accurately measured), measuring the corresponding acceleration response, and computing the accelerance through a specified frequency range, one obtains a value in units of volt/volt which corresponds to $1/m$, where m is the mass of the block (which may include the added transducers masses). Thus, the measured accelerance will be a constant value proportional to the block mass, within a frequency range for which the block behaves as a rigid body. This calibration technique does not use the individual transducers sensitivity values and must be performed for each pair of accelerometers/force transducers.

Support Conditions

The support conditions of the structure under test are an important part of the test set-up. They must be well defined and experimentally repeatable if the results of the measurements are to reflect the properties of the structure without undue influence from the support. For test of components *in situ*, exact definition of the boundary conditions may be problematic but, nevertheless, tests should be considered to prove the repeatability of the installation. When the aim of the test is to determine the dynamic characteristics of a system under operating conditions, the test boundary conditions should be as close as possible to the operating conditions.

When testing in the laboratory, the most frequently used boundary conditions are grounded or free conditions. It is almost impossible for either of these two conditions to be achieved in practice. The most

difficult to achieve is the grounded condition as the structure will always have some movement at the grounding point (usually rotation). Free conditions are easier to achieve, although there will always be some small restraints.

For a structure to be really free, it should be suspended (floating) in the air, free in space with no holding points whatsoever. Such a situation is commonly designated as ‘free-free’, ‘freely supported’ or ‘ungrounded’ and is clearly impossible. However, simulation of free-free conditions can be closely approximated. It suffices to suspend or support the structure using very flexible (also designated as soft) springs so that the resonance frequencies of the mass of the structure on the stiffness of the supports or suspension devices are very low and far away from the frequency range of interest.

Pretest Decisions and Checks

Performing modal analysis tests is a time-consuming task involving qualified operators and delicate equipment. As a consequence, it is an expensive task. Thus, great care should be taken in preparing the test set-ups and in performing a number of checks prior to starting the real tests. All available previous knowledge about the system under test should be taken into consideration. In addition, it may be important to have accurate information about the aim of the tests, the required data, and the required accuracy of the measured data.

Parameters that must be carefully defined include, among others, the frequency range of interest, the selection of the transducer (response and excitation) locations, the selection of the suspension locations (when adequate), and the type of excitation to be used.

A large number of transducers on a structure sometimes leads to mistakes related to the correct identification of their location and values of the calibration factors when introducing the information into the analyzing system. Such mistakes may completely destroy the validity of the final measured data unless discovered in time and rectified.

Common problems that may be overlooked are related to broken leads, badly connected cables, badly attached transducers, and even pieces of equipment that are not powered (signals do show even in these cases). Careful checks will avoid most of these problems. An oscilloscope may be a valuable piece of hardware for this purpose.

Another type of verification, which is very important, is related to the efficiency of the inputs. In case of random-type excitation, the autopower spectrum of the input should be observed in order to verify if it

maintains about the same level over the test frequency range, though it may be noisy. In case of impact excitation, the input autopower spectrum should be clean and flat up to the maximum frequency of interest.

Validation of Measurements

One of the problems facing the test engineer is an inability to ascertain the quality of the measured data. Throughout the complete modal test, checks should be made to assess this quality. There are several techniques in general use that can provide an indication of the quality of the measured data, e.g. repeatability, reciprocity, and coherence.

Almost always, repeatability and reciprocity checks are done by comparing sets of FRF curves to see if there are any major differences. The comparisons are made significantly easier if difference function curves (Δ FRFs) are plotted for the sets of data.

Repeatability checks are performed by repeating some measurements and comparing the results with previously measured curves. These checks assess the stability of the structural characteristics over a period of time. It is usually assumed that the structure does not change with time or as a result of the excitation itself but there are a number of practical effects, such as bolt slackening, fretting, change of temperature and humidity, etc., that can alter the characteristics of a structure.

Reciprocity checks are based on Maxwell's rule of reciprocity. The FRF matrix is symmetric and this property can be used as a check on the quality of the measured data. In fact, for a linear conservative system, the FRF measured for a force at location j and a response at location i should correspond directly to the FRF measured for a force at location i and response at location j .

Where a multiple single-input test (various separate single-input tests with the shaker located at a different position for each test) strategy is used, the reciprocity check can give an indication of shaker and accelerometer loading effects on the structure. The positions of the shaker and accelerometer are reversed in multiple single-input reciprocity checks. If the shaker and accelerometer have negligible effect on the structure, then there should be good reciprocity. If the shaker and accelerometer have a significant loading effect on the structure, then the effects in the two configurations will be different and the reciprocity check will reveal any differences between the FRFs.

Nowadays, almost all spectrum analyzers incorporate the calculation of the coherence, which is nothing but a correlation coefficient that measures the degree of consistency of all averages of the FRF evaluated by

the analyzer. A coherence equal to 1 indicates that each average is exactly the same. Low coherence values indicate a significant variance on the averages and, therefore, poor data quality. Usually, low-frequency regions and regions close to resonances and antiresonances yield low coherence values. The reason for this is poor performance of many transducers at low frequencies and low signal-to-noise ratios close to resonances and antiresonances.

Introduction

The measurement of frequency response functions (FRFs; see **Modal analysis, experimental**, Basic principles), impulse response functions (IRFs), or simply free decay responses (either of these constitute the response model) may not be enough for the envisaged subsequent applications in modal analysis. Most of the time it is necessary to build a modal model and sometimes a spatial model (see **Modal analysis, experimental**, Construction of models from tests). The modal model comprises the so-called modal parameters, which are the natural frequencies, damping ratios, and mode shapes (amplitudes and phases). The natural frequencies and damping ratios are characteristics of the structure with its boundary constraints and are therefore related to the poles of the transfer

function, whereas the modal constants, amplitudes and phases (coming from the mode shapes or vice versa) depend on the locations where the responses and forces are taken and are related to the residues of the transfer function.

Methods that estimate the modal parameters, or the poles and residues to which they are closely connected, from measured responses are called indirect methods (of system identification). They allow for the construction of the modal model. The spatial model is composed of the mass, stiffness, and damping matrices of the system. Methods that evaluate those matrices are called direct methods, as they go directly from the response model to the spatial model without computing the modal parameters.

All methods that allow for the identification of the dynamic properties (or parameters) from measurements made on a real structure or machine are called Parameter extraction methods and are the subject of this article.

Classification of Methods

There are many different methods to extract the modal parameters from measurements made on a structure. The main division between them is in the domain in which the experimental responses are treated. With respect to this, there are time-domain and frequency-domain methods. The first methods to appear, around 60 years ago, were very simple and fundamentally in the frequency domain. The main objective was to determine the resonance frequencies. At the time, modal testing was known as resonance testing.

In both time and frequency domains, there are indirect and direct methods. Within a given frequency range where measurements have been taken, there are usually various resonances. Most methods allow for the extraction of the dynamic properties taking into account all the resonances simultaneously. They are called multi-degree-of-freedom (MDOF) methods. However, there are some indirect methods in the frequency domain that can estimate the modal parameters by making a separate and progressive analysis around each resonance until the whole frequency range is covered. These are called single-degree-of-freedom (SDOF) methods.

A last classification has to do with the number of time histories (or IRFs) or FRFs that are processed at the same time. If only one FRF relating one input to one output is being analyzed, the method is called a single-input single-output one (SISO); if a method simultaneously takes data from various FRFs representing different responses due to a single input location, it is called single-input multi-output (SIMO);

when FRFs relating various outputs and inputs are considered in the analysis, the method is called multi-input multi-output (MIMO). Figure 1 illustrates the general classification of methods.

Time-domain Methods

Within the indirect methods, probably the best known ones in the time domain are the complex exponential method, which is an SISO method, and its extended versions, the least-squares complex exponential (SIMO) and polyreference complex exponential (MIMO) methods. Also very well known are the Ibrahim time domain (SIMO) and the eigensystem realization algorithm (MIMO) methods.

Within the category of direct methods the main techniques are the autoregressive moving average (SIMO) and the direct system parameter identification (MIMO).

To understand how these methods work, a brief explanation of the complex exponential and Ibrahim time domain methods is given next.

The Complex Exponential Method

This method takes the IRF, and assumes that it can be described by a series of complex exponentials:

$$h_{jk}(t) = \sum_{r=1}^{2N} {}_r A_{jk} e^{s_r t} \quad [1]$$

where ${}_r A_{jk}$ is the residue of mode r , related to the complex modal constant $s_r = -\omega_r \xi_r + i\omega_r \sqrt{(1 - \xi_r^2)}$ and ω_r and ξ_r are the natural frequency and viscous damping ratio of mode r , respectively.

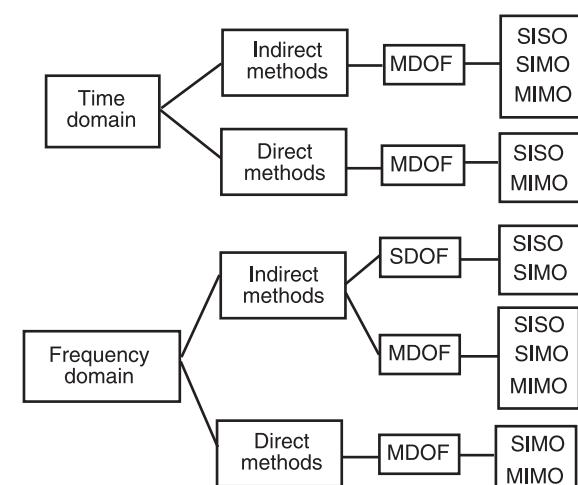

Figure 1 Classification of parameter extraction methods.

Eqn [1] is the inverse Fourier transform of the corresponding FRF:

$$H_{jk}(\omega) = \sum_{r=1}^{2N} \frac{{}_r A_{jk}}{\omega_r \xi_r + i(\omega - \omega_r \sqrt{(1 - \xi_r^2)})} \quad [2]$$

From eqn [1], by taking L equally-spaced time intervals and simplifying the notation, one has:

$$\begin{aligned} b_0 &= h(0) = \sum_{r=1}^{2N} A_r \\ b_1 &= h(\Delta t) = \sum_{r=1}^{2N} A_r V_r \\ &\vdots \quad \vdots \quad \vdots \\ b_L &= h(L\Delta t) = \sum_{r=1}^{2N} A_r V_r^L \end{aligned} \quad [3]$$

where A_r is an abbreviation for ${}_r A_{jk}$ and where $V_r = \exp(s_r \Delta t)$. As the roots, s_r , for an underdamped system occur in complex conjugate pairs, so also do the variables, V_r , and thus there must exist a polynomial with real coefficients, β , such that:

$$\beta_0 + \beta_1 V_r + \beta_2 V_r^2 + \cdots + \beta_L V_r^L = 0 \quad [4]$$

It is possible to show that, for each V_r , $\sum_{i=0}^L \beta_i b_i = 0$. From this, taking the appropriate number of data points, the values of β can be obtained. Then, V_r are calculated from eqn [4] and so the natural frequencies and damping ratios are determined. From eqn [3], the values of the residues are easy to calculate, and from these, so are the modal constants. The above method is not iterative, and so no initial estimates for the modal parameters are necessary. The uncertainty lies in determining the correct number of participating modes. To determine that quantity, an iterative procedure is used, varying the number of assumed modes. When the error between the real measurements and the synthesized ones has a minimum, the correct number of modes is determined.

The Ibrahim Time Domain Method

This method, an example of a SIMO approach, uses free responses instead of IRFs. For a system with N DOFs, the free response of the structure at a point i and for the instant of time t_i can be expressed as a summation of the individual responses of each mode:

$$x_i(t_j) = \sum_{r=1}^{2N} \psi_{ir} e^{s_r t_j} \quad [5]$$

where ψ_{ir} is the i th component of the complex eigenvector Ψ_r . Considering q response locations and L time instants leads to an expression of the type:

$$\mathbf{X}_{(q \times L)} = \Psi_{(q \times 2N)} \Lambda_{(2N \times L)} \quad [6]$$

where Λ is composed of the various $e^{s_r t_j}$ elements. Considering a second set of L data points, shifted one interval Δt with respect to the first, it is possible to write a similar expression:

$$\hat{\mathbf{X}}_{(q \times L)} = \hat{\Psi}_{(q \times 2N)} \Lambda_{(2N \times L)} \quad [7]$$

Defining \mathbf{A}_S of order q such that $\mathbf{A}_S \Psi = \hat{\Psi}$ leads to $\mathbf{A}_S \mathbf{X} = \hat{\mathbf{X}}$, from which one can calculate \mathbf{A}_S in a least-squares sense. As each vector $\hat{\Psi}_r = \Psi_r e^{s_r \Delta t}$, a standard eigenproblem is obtained:

$$[\mathbf{A}_S - e^{s_r \Delta t} \mathbf{I}] \Psi_r = 0 \quad [8]$$

From the eigenvalues and eigenvectors, the modal parameters are evaluated. The difficulty here is to determine the order q of the problem, as the system will have as many resonances as the number of chosen responses, q , and this is quite an arbitrary choice. If q is higher than the true number of resonances, some of the solutions of eqn [8] will not be physically meaningful, they will just be computational solutions which are a priori difficult to distinguish from the genuine ones. The quality of the results can be checked using the modal confidence factor, based on repetition of the calculations in different time interval shifts: the expected value of $\hat{\Psi}_r$ from $\hat{\Psi}_r = \Psi_r e^{s_r \Delta t}$ is then compared with the calculated value of $\hat{\Psi}_r$ in the following time interval.

Frequency-domain Methods

There are many different frequency-domain parameter extraction methods. Here, the following will be addressed: the circle-fitting method (SDOF, SISO), the rational fraction polynomial (MDOF, SISO), and the identification of structural system parameters method (MDOF, SIMO), which is a direct method.

The Circle-Fitting Method

This is one of the simplest and most popular methods in the frequency domain category. The receptance

FRF of an N degree-of-freedom system with hysteretic damping is given by the following expression:

$$H_{jk}(\omega) = \sum_{r=1}^N \frac{{}_r C_{jk}}{\omega_r^2 - \omega^2 + i\eta_r \omega_r^2} \quad [9]$$

where η_r and ${}_r C_{jk} = (C_r e^{i\phi_r})_{jk}$ are the hysteretic damping loss factor and the complex modal constant associated with mode r , respectively. Expression [9] is the equivalent of eqn [2], which referred to viscous damping. In this method, each mode is treated separately and the contribution of the neighboring modes to the particular one under study is assumed to be a constant, eqn [9] is therefore approximated by:

$$H_{jk}(\omega) \approx \frac{{}_r C_{jk}}{\omega_r^2 - \omega^2 + i\eta_r \omega_r^2} + {}_r D_{jk} \quad [10]$$

where ${}_r D_{jk}$ is a complex constant associated with mode r . It can be shown that the Nyquist plot (real part versus imaginary part) of $1/(\omega_r^2 - \omega^2 + i\eta_r \omega_r^2)$ is a circle. From eqn [10], it is clear that the multiplication by the complex constant ${}_r C_{jk}$ means a magnification or reduction of the circle radius, as well as a rotation. ${}_r D_{jk}$ corresponds to a simple translation of the whole circle.

When representing the measured data in a Nyquist plot, the complete curve will not be an exact circle around each natural frequency, but eqn [10] tells us that the curve will approach a circle around those frequencies, as illustrated in Figure 2.

The modal parameters associated with mode r are derived from fitting a circle to the frequency response

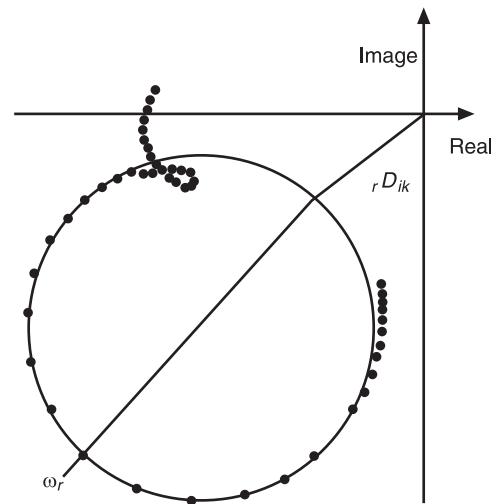

Figure 2 Nyquist plot of the receptance, showing the SDOF circle-fit approach.

curve near each natural frequency, ω_r . This objective is achieved through the use of a least-squares technique. Once the circle centre coordinates and radius are known, the natural frequency can be estimated, as it occurs where the angular frequency spacing has its highest value. The damping factor is evaluated from a generalized version of the half-power points formula. From the diameter of the circle and its position, the complex modal constant is calculated. As the process continues to the next resonance peak, the effect of the previously-identified modes is subtracted, in order to enhance the mode one is dealing with at each time.

The Rational Fraction Polynomial Method

In this method, the FRF is expressed in terms of a ratio of two polynomials (in place of the summation of simple fractions) as:

$$H(\omega) = \frac{\sum_{k=0}^{2N-1} a_k(i\omega)^k}{\sum_{k=0}^{2N} b_k(i\omega)^k} \quad [11]$$

Defining a linearized error function between the measured FRF values and the model, and minimizing it, a linear system of equations is obtained, from which the coefficients a_k and b_k are evaluated. As such a system is usually ill-conditioned, the problem is reformulated in terms of orthogonal polynomials. Knowing the resulting coefficients, the modal parameters are retrieved. A global version of this method also exists, i.e. its SIMO version, where several FRFs are taken into account simultaneously.

The Identification of Structural System Parameters Method

This is a direct method, i.e., it provides the system matrices (\mathbf{K} , \mathbf{M} and \mathbf{C}) which constitute the spatial model directly, from the response model (the FRFs), without computing the modal parameters. The general idea, common to all direct methods, is to take the dynamic equilibrium equation and write it for various frequency data points, in order to form an over-determined system of equations, from which the system matrices are computed. Such a system will look like:

$$\begin{aligned} [-\omega_1^2 \mathbf{M} + i\omega_1 \mathbf{C} + \mathbf{K}] \bar{\mathbf{Y}}_1 &= \mathbf{F} \\ [-\omega_2^2 \mathbf{M} + i\omega_2 \mathbf{C} + \mathbf{K}] \bar{\mathbf{Y}}_2 &= \mathbf{F} \\ &\vdots \quad \vdots \\ [-\omega_L^2 \mathbf{M} + i\omega_L \mathbf{C} + \mathbf{K}] \bar{\mathbf{Y}}_L &= \mathbf{F} \end{aligned} \quad [12]$$

where $\bar{\mathbf{Y}}_i$ is the vector of complex response ampli-

tudes, at frequency ω_i , which is the frequency data point, varying from 1 to L .

The Unified Matrix Polynomial Approach

The unified matrix polynomial approach (UMPA) is a method that shows that a considerable number of methods in both time and frequency domains are just particular cases of a more general polynomial formulation. That work helps us to understand better the similarities amongst most of the existing techniques, giving a more general panorama on the subject, and it contributes to a deeper knowledge of the philosophy of parameter extraction methods.

Methods to Check the Quality of Extracted Parameters

Almost every method has its own check for the quality of the obtained parameters. As mentioned before, in the complex exponential method, the correct number of modes is determined when the error between the measured and synthesized FRFs has a steep drop. In the Ibrahim time domain method, as already explained, the modal confidence factor is used, repeating the calculations in different time intervals. In the rational fraction polynomial method it is also usual to make the calculations taking each time a different set of data points and checking for the repeatability and variation of the results. In the identification of structural system parameters method, the singular value decomposition technique is usually employed to determine the effective number of degrees-of-freedom.

Another very popular method nowadays is the so-called stabilization chart. Some tolerance values are assigned *a priori* to each modal parameter (as a percentage) and the calculations are repeated taking each time a different number of modes. The chart then shows the progress of the results, indicating (by the display of a symbol) close to each peak which modal parameters have stabilized along the various iterations. Other methods for quality checking are the so-called mode indicator functions (MIFs) that indicate not only the number of existing modes, but also their relative incidence, by displaying the physical magnitude of each one and natural frequency. They can also detect repeated modes and are based on calculation of the singular value decomposition of the FRF matrix at each spectral line.

Construction of models from tests

Introduction

Any real structure possesses an infinite number of degrees-of-freedom. In very simple cases, like a single beam of homogeneous isotropic material and constant cross-section, it is possible to derive an analytical solution enabling the calculation of all natural frequencies and mode shapes. In more general cases, such a solution cannot be found and therefore the modeling must be based either on a numerical study or on experimental tests undertaken on the real structure. In either case, it is necessary to decide on the number of degrees-of-freedom one must choose, so that the final model represents the reality as accurately as possible, i.e., the dynamic behavior of the structure under some loading conditions is well predicted when compared with its real behavior in service.

The decision on the appropriate number of degrees-of-freedom is called discretization, as we go from a continuous situation to a discrete one. Such a decision

has to be balanced, taking into account the objectives of the study and also the available calculation power. For instance, to evaluate the dynamic behavior of a vehicle in order to assess the passengers' comfort, it may be irrelevant to discretize the whole structure in thousands of degrees-of-freedom. A few dozen may be enough.

Building a theoretical model of a structure based on a numerical approach, usually through a finite element discretization, is not a big problem nowadays, especially if the structure is a lightly damped one: the resulting stiffness and mass matrices are – most of the time – adequate to represent its real behavior with sufficient accuracy, at least over a limited frequency range. However, if the frequency range is considerably large, it may be important to consider more complicated theories or elements with higher complexity. In any case, a numerical model is never perfect and in general it is necessary to validate (see **Model updating and validating**) it with experimental tests and, in most situations, to correct it or update it using those tests as a reference. There are specific methods, known as updating techniques, to achieve the most correct model. The important issue here is to have accurate experimental results. The following presents some issues related to the construction of models from experimental results, and how these models relate to theoretically-derived ones.

Construction of a model from experimental results

Response Models vs Spatial Models

Let us consider a structure whose behavior can be well represented, for our application, by a four-degrees-of-freedom model as shown in Figure 1. It is therefore assumed that the dynamic behavior of the

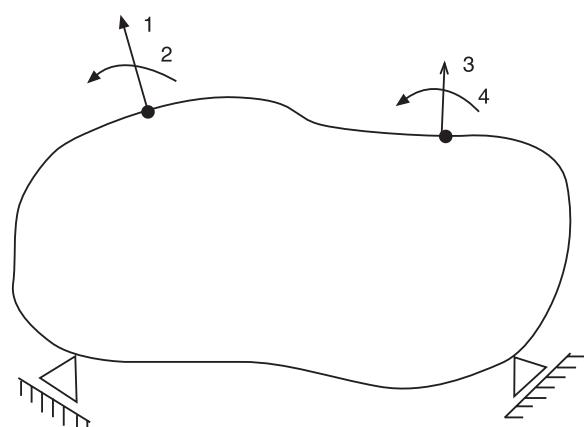

Figure 1 Real structure characterized by coordinates 1–4.

system is described with enough accuracy for our purposes using only those four-degrees-of-freedom. It is also known from the study of the single-degree-of-freedom system that the function which most conveniently reflects the behavior of that system is the particular version of the transfer function, known as a frequency response function (FRF), relating the obtained harmonic output to a given harmonic input. If F is the input, X the output and H the FRF, $X = HF$. For a system discretized by N degrees-of-freedom, the FRF properties can be contained in an $N \times N$ FRF matrix relating the amplitudes of the input and output:

$$\begin{matrix} X \\ (N \times 1) \end{matrix} = \begin{matrix} H \\ N \times N \end{matrix} \begin{matrix} F \\ (N \times 1) \end{matrix} \quad [1]$$

For the example of Figure 1, eqn [1] turns into:

$$\begin{matrix} X_1 \\ X_2 \\ X_3 \\ X_4 \end{matrix} = \begin{bmatrix} H_{11} & H_{12} & H_{13} & H_{14} \\ H_{21} & H_{22} & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33} & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44} \end{bmatrix} \begin{matrix} F_1 \\ F_2 \\ F_3 \\ F_4 \end{matrix} \quad [2]$$

where X_2 and X_4 are, in fact, rotational responses (angles) and F_2 and F_4 are moments.

It is worth noting that the FRF matrix is generally symmetric, due to Maxwell's reciprocity theorem, i.e., the response at degree-of-freedom (DOF) i due to an input at DOF j is equal to the response at DOF j when the same input happens at coordinate i .

The response model is available once the FRFs in \mathbf{H} have been measured.

Equivalent to eqn [1] is the following inverse relationship:

$$\mathbf{F} = \mathbf{H}^{-1} \mathbf{X} \quad [3]$$

or:

$$\mathbf{F} = \mathbf{Z} \mathbf{X} \quad [4]$$

where \mathbf{Z} is called the dynamic stiffness matrix, which for an undamped system (the damped case will be discussed later) is:

$$\mathbf{Z} = \mathbf{K} - \omega^2 \mathbf{M} \quad [5]$$

where \mathbf{K} and \mathbf{M} are the stiffness and mass matrices, respectively, and ω is the frequency of the applied forces. If the model is represented in terms of \mathbf{K} and \mathbf{M} (and of the damping matrix if this is to be considered), it is called the spatial model.

Expanding [4] in accordance to the given example, it follows that:

$$\begin{matrix} F_1 \\ F_2 \\ F_3 \\ F_4 \end{matrix} = \begin{bmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} \\ Z_{21} & Z_{22} & Z_{23} & Z_{24} \\ Z_{31} & Z_{32} & Z_{33} & Z_{34} \\ Z_{41} & Z_{42} & Z_{43} & Z_{44} \end{bmatrix} \begin{matrix} X_1 \\ X_2 \\ X_3 \\ X_4 \end{matrix} \quad [6]$$

Apparently, it would be easier to measure \mathbf{Z} directly, from which one could evaluate \mathbf{K} and \mathbf{M} to obtain the spatial model directly. However, it is \mathbf{H} that is measured in practice and then \mathbf{Z} must be derived from: $\mathbf{Z} = \mathbf{H}^{-1}$. Let us see why this is the correct procedure to calculate \mathbf{Z} . First of all, it is clear that $Z_{ij} \neq H_{ij}^{-1}$; retrieving [6], the first equation is given by:

$$F_1 = Z_{11}X_1 + Z_{12}X_2 + Z_{13}X_3 + Z_{14}X_4 \quad [7]$$

Consider, for example, the interpretation of Z_{12} . The individual dynamic stiffness coefficient, Z_{12} , is the force F_1 when $X_2 = 1$ and $X_1 = X_3 = X_4 = 0$. In theory, this is obvious, but in practice it simply cannot be achieved, as it implies that X_1 , X_3 and X_4 should be blocked, something impossible to achieve in an experimental set up. In contrast, from [2], the first equation is:

$$X_1 = H_{11}F_1 + H_{12}F_2 + H_{13}F_3 + H_{14}F_4 \quad [8]$$

It is very easy to calculate H_{12} , for example, as H_{12} equals X_1 when $F_2 = 1$ and $F_1 = F_3 = F_4 = 0$, or $H_{12} = X_1|_{F_1, F_3, F_4=0}$. Therefore, to calculate matrix \mathbf{H} it is sufficient to apply a force at one point at a time, and to measure all the responses. After knowing \mathbf{H} , it is possible to calculate \mathbf{Z} from its inverse (\mathbf{H}^{-1}). Note that as \mathbf{Z} and \mathbf{H} are both functions of frequency, and so the inverse has to be taken at each frequency point along the frequency range of interest, i.e., there will be as many inversions as frequency data points.

At this point, there is a conclusion: in practice, the system is characterized by the response model.

The Modal Model and its Relationship to the Spatial and Response Models

The undamped equilibrium equation for free vibration of an N -degree-of-freedom system leads to a generalized eigenvalue and eigenvector problem:

$$[\mathbf{K} - \omega^2 \mathbf{M}] \boldsymbol{\Phi} = \mathbf{0} \quad [9]$$

This provides a set of N natural frequencies, ω_r , and N mass-normalized mode shapes, $\boldsymbol{\Phi}_r$. From the orthogonality properties for mass-normalized mode shapes, it is known that:

$$\Phi^T M \Phi = I \quad [10a]$$

$$\Phi^T K \Phi = \omega_r^2 \quad [10b]$$

where Φ is the modal matrix whose columns are the mass-normalized mode shapes and ω_r^2 is a diagonal matrix composed of the squares of the natural frequencies. When the model is characterized in terms of ω_r^2 and Φ , it is called the modal model. Therefore, from knowledge of K and M (the spatial model) it is possible to obtain the modal model. The opposite is also possible, as from [10a] and [10b]:

$$M = \Phi^{-T} \Phi^{-1} \quad [11a]$$

$$K = \Phi^{-T} \omega_r^2 \Phi^{-1} \quad [11b]$$

Therefore, one can derive the modal model from the spatial model and vice-versa.

To calculate Z from H along the frequency range of interest may imply a considerable computational effort, due to the inversions referred to at the end of the previous section. An alternative approach consists of expressing Z in terms of the modal parameters – natural frequencies and mode shapes.

As $Z = K - \omega^2 M$, upon substitution of [11a] and [11b], it follows that:

$$Z = \Phi^{-T} \omega_r^2 \Phi^{-1} - \omega^2 \Phi^{-T} \Phi^{-1} \quad [12]$$

or:

$$Z = \Phi^{-T} (\omega_r^2 - \omega^2) \Phi^{-1} \quad [13]$$

Clearly, from [13]:

$$H = Z^{-1} = \Phi (\omega_r^2 - \omega^2)^{-1} \Phi^T \quad [14]$$

and one has a direct relationship between the modal and response models. Note that eqn [13] only requires the inverse of the modal matrix, which is trivial as it is diagonal. Thus, along the frequency range it is no longer necessary to invert a matrix at each frequency point.

It is now clear how the three models are interrelated. However, it is not so clear as to which model to use, when or why. Figure 2 illustrates this point for an N -degree-of-freedom system. Note that there are two main routes. On the one hand, there is the theoretical route, where the starting point is the analytical or numerical solution, establishing the spatial model; then, through an eigensolution, the natural frequen-

cies and mode shapes are obtained, constituting the modal model; finally, the response model may be evaluated. On the other hand, there is the experimental route, where the departure point is the response model, formed by the relevant measured FRFs; through an identification process, which is an inverse problem, the modal model is built; using the orthogonality relationships, the spatial model may be recovered.

The necessity of permutation among the three models is to bring together the theoretical and experimental results for comparison, validation or updating objectives. Although quite illustrative, Figure 2 may look too optimistic, as one may think that everything is perfect, all models are (more or less) easily interrelated and one can readily move from one to the other in any sense. In practice, problems may arise. In what follows, some of those problems are mentioned.

Damped Systems and Complex Modes

Any real structure is dissipative. The dissipation of energy is modeled through a damping term that in most cases in structural dynamics is either the hysteretic damping model (also called structural damping: forces proportional to the displacements but in phase with velocity) or the viscous damping model (forces proportional to the velocities). If the structure is very lightly damped, then the undamped model may be a good approximation. If that is not the case, then a damping matrix must be defined, together with the stiffness and mass matrices. The equilibrium equation becomes, for the viscous damping case, as follows:

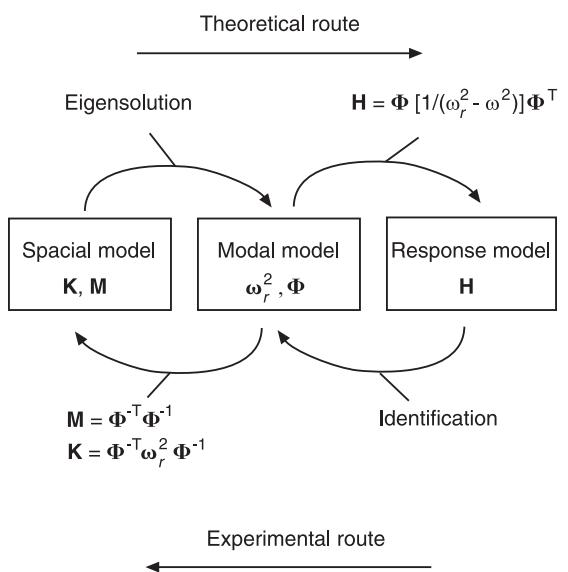

Figure 2 Interrelation among dynamic models.

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f} \quad [15]$$

and for the hysteretic damping case, as:

$$\mathbf{M}\ddot{\mathbf{x}} + i\mathbf{D}\mathbf{x} + \mathbf{K}\mathbf{x} = \mathbf{f} \quad [16]$$

Matrices \mathbf{M} , \mathbf{K} and \mathbf{C} (or \mathbf{D}) now constitute the spatial model in the damped case.

Except for very special cases (for instance, if the viscous damping matrix can be defined as a linear combination of the mass and stiffness matrices), the result of the associated eigenproblem is a set of complex natural frequencies and complex mode shapes, which define in that case the modal model. Although not so easy as the undamped case, passing from the spatial to the modal model and to the response model (the theoretical route) is not a problem. The big problem in that case is how to define the damping matrix. That is why in a pure analytical or numerical approach we only have a description of the system in terms of \mathbf{K} and \mathbf{M} , i.e., the numerical solution is the undamped one.

To model the damping, one needs to follow the experimental route where, through adequate identification methods, we are able to go from the measured response model to the modal model, with information about the natural frequencies, damping factors and complex mode shapes. For instance, in the hysteretic damping case, each FRF can be shown to relate to the modal model through the following expression:

$$H_{kj} = \sum_{r=1}^N \frac{\phi_{rk}\phi_{rj}}{\omega_r^2 - \omega^2 + i\eta_r\omega_r^2} \quad [17]$$

where H_{kj} is the measured FRF relating the response at coordinate k with the input force at coordinate j , N is the number of degrees-of-freedom, ϕ_{rk} and ϕ_{rj} the mode shape elements k and j of mode r (complex in general), ω_r the natural frequency and η_r the damping ratio of mode r .

The problem is that in many cases one wishes to validate the theoretical model or even to update it and on the one hand there is a set of real modes coming from the numerical solution, on the other hand a set of complex modes. This gives rise to an old problem: how to relate complex modes to real (or normal) modes? How to pass from one to the other? How to measure the complexity of the modes? The problem of having in practice considerably complex modes may be difficult to address. In some cases, linear transformations between real and complex modes are made, where the real modes are used as a basis to expand complex modes. These approximations,

however, should be used with great care, as they are bound to produce erroneous or misleading results. Fortunately, in many applications, the complexity of the modes is not so high and even not genuine, i.e., it can result from other problems that have not been carefully addressed, such as the existence of aliasing, leakage, measurement noise, nonlinearity, identification errors, etc. Careful measurement procedures can significantly reduce the degree of false complexity indicated in measured mode shapes.

Turning to the issue of going from the measured response model to the modal model, we saw that eqn [17] is the kind of expression we often use as a basis for the identification of the modal properties of a system. While the damping ratios and natural frequencies are global properties of the system, i.e., they have the same values no matter which FRF H_{kj} is considered, the mode-shapes have a local nature, as each point has its own amplitude (and phase) (this is why most of the identification techniques proceed in two steps: first, the calculation of the global properties and second, the evaluation of the local ones). In the limit, we would appear to need only one FRF to obtain ω_r and η_r but all the FRFs to estimate ϕ_{rk} and ϕ_{rj} . In fact, neither of these two extremes are used. For the natural frequency and damping ratio we usually take more than just a single FRF, as variations always occur and experience advises to take a set of FRFs to obtain a kind of ‘average result’. For the mode-shapes, not all the FRFs are necessary, because there are some inter-relationships that hold true and reduce the number of responses that need to be measured. If one measures a point FRF (excitation and measurement at the same DOF), say H_{kk} , the numerator of [17] becomes $(\phi_{rk})^2$ and ϕ_{rk} is therefore evaluated. Measuring a transfer FRF, H_{kj} , allows for the calculation of the product $\phi_{rk}\phi_{rj}$, known as a modal constant of mode r . As ϕ_{rk} is already known, we obtain ϕ_{rj} . As a consequence, it is not necessary anymore to measure H_{jj} , as its numerator (ϕ_{rk}^2) can now be computed. The implication of such properties of the mode-shape components, known as consistency properties, is that we only need to measure one column (or one row) of the FRF matrix \mathbf{H} to obtain the whole mode-shape (or modal) matrix.

It is often recommended to measure more than a single column, to obtain some redundant data to improve our confidence in the results, especially when we suspect the existence of repeated natural frequencies. Theoretically, based on the consistency properties, we could even obtain the whole FRF matrix. For instance, for a 3×3 , FRF matrix, let us suppose we measured H_{11} , H_{21} and H_{31} . Due to the symmetry of the matrix, we already know H_{12} and

H_{13} . So, we miss H_{22} , H_{23} ($=H_{32}$) and H_{33} . Due to the consistency properties, with H_{11} and H_{12} we could recover H_{22} ; with H_{11} and H_{13} , we would obtain H_{33} ; with H_{22} and H_{33} , we would obtain H_{23} .

Unfortunately, the evaluation of unmeasured FRFs based on a single column (or row) of the FRF matrix is not so straightforward as it seems, due to the incompleteness of the model in terms of frequency range, as we will see next.

Complete and Incomplete Models

To ensure clarity of exposition, the undamped case is used once more. The issue of moving to and from the different spatial, modal and response models is not the real problem, even when taking the experimental route, provided that appropriate methods are used. Probably the greatest problem of all is the incompleteness of the models obtained from the experimental tests. From the numerical solution, one has a model with N -degrees-of-freedom, which in some applications can be of the order of 10^4 or even more. Assuming that this N is representative of the behavior of the structure, the model with matrices of order N will be considered as the complete one. In contrast, from the experimental point of view, it is not usually possible to measure all the coordinate motion responses, or to apply all force excitations. Normally, only a few dozen degrees-of-freedom are measured. The system is therefore a reduced or incomplete one by comparison with the theoretical version.

Another ‘source’ of incompleteness is related to the measured frequency range. Only a few modes are covered and are therefore ‘identifiable’ from tests, in contrast with the theoretical model. To identify in an accurate way the modes within the frequency range of interest, one has to take account of the influence of the modes outside that range, the so-called low- and high-frequency residuals.

This sort of incompleteness precludes the exact evaluation of the complete FRF matrix from measurements of a single column, as explained before, since the residual mode-shapes do not verify the consistency properties. So, as in practice this is always the case, we cannot effectively reconstruct unmeasured FRFs, but can only use such properties to estimate unmeasured mode-shapes within the frequency range of interest.

If the incompleteness has only to do with the lack of measured coordinates, the relation between the modal and response models given by eqn [14] becomes:

$$\mathbf{H} = \begin{pmatrix} \Phi & \\ (n \times n) & (n \times N) \end{pmatrix} \begin{pmatrix} \omega_r^2 - \omega^2 & \\ N \times N & \end{pmatrix}^{-1} \begin{pmatrix} \Phi^T & \\ & (N \times n) \end{pmatrix} \quad [18]$$

where $n < N$ is the number of measured coordinates. If the incompleteness is also in the number of modes available, say $m < N$, eqn [18] becomes:

$$\mathbf{H} = \begin{pmatrix} \Phi & \\ (n \times n) & (n \times m) \end{pmatrix} \begin{pmatrix} \omega_r^2 - \omega^2 & \\ m \times m & \end{pmatrix}^{-1} \begin{pmatrix} \Phi^T & \\ & (m \times n) \end{pmatrix} \quad [19]$$

Note that for \mathbf{H} to be of full rank the number of retained modes must be equal or larger than the number of coordinates, i.e., $m \geq n$. Inverting [18] or [19] produces a reduced stiffness matrix \mathbf{Z}^R .

In the case where $n = m$, expressions [11a] and [11b] can be used to go from the modal to the spatial model, where all matrices are $n \times n$. \mathbf{M} and \mathbf{K} are in that case reduced mass and stiffness matrices. As already mentioned, it is often necessary to bring together the experimental and theoretical models, for validation or updating purposes, for example. As the order of magnitude of both models is very different, the comparison between the two is only possible either by a condensation of the theoretical model or by expansion of the experimental one. In either case, there are several techniques available.

For the condensation of \mathbf{K} or \mathbf{M} , the most used method is that known as Guyan reduction: suppose one wishes to represent an N -degree-of-freedom system only through p (primary) coordinates, corresponding to the dimension of the experiments. The remaining $s (= N - p)$ coordinates are called secondary (or slave) and in those it is supposed that there are no applied forces. In a static case, where $\mathbf{KX} = \mathbf{F}$, \mathbf{K} is partitioned so that:

$$\begin{bmatrix} \mathbf{K}_{pp} & \mathbf{K}_{ps} \\ \mathbf{K}_{sp} & \mathbf{K}_{ss} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_p \\ \mathbf{x}_s \end{Bmatrix} = \begin{Bmatrix} \mathbf{f}_p \\ \mathbf{0} \end{Bmatrix} \quad [20]$$

The objective is to obtain a condensed (or reduced) \mathbf{K}^R matrix referred to the p coordinates, i.e.,

$$\mathbf{K}^R \mathbf{x}_p = \mathbf{f}_p \quad [21]$$

Eliminating \mathbf{x}_s in [20], it follows that:

$$\mathbf{K}^R = \mathbf{K}_{pp} - \mathbf{K}_{ps} \mathbf{K}_{ss}^{-1} \mathbf{K}_{sp} \quad [22]$$

A similar formula can be found for the reduced mass matrix.

For the expansion process, the most used technique is that known as Kidder’s expansion, although several interpolation alternatives are also possible. Kidder’s expansion is somehow the reverse of the Guyan reduction, although normally used together with the

mass matrix. From the partitioned free vibration equilibrium equation, it follows that:

$$\left[\begin{bmatrix} \mathbf{K}_{pp} & \mathbf{K}_{ps} \\ \mathbf{K}_{sp} & \mathbf{K}_{ss} \end{bmatrix} - \omega_r^2 \begin{bmatrix} \mathbf{M}_{pp} & \mathbf{M}_{ps} \\ \mathbf{M}_{sp} & \mathbf{M}_{ss} \end{bmatrix} \right] \begin{Bmatrix} \boldsymbol{\Phi}_p \\ \boldsymbol{\Phi}_s \end{Bmatrix}_r = \begin{Bmatrix} \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad [23]$$

where $(\boldsymbol{\Phi}_p)_r$ are the known (measured) coordinate amplitudes and $(\boldsymbol{\Phi}_s)_r$ the unmeasured ones, for each mode, r . It is possible to show that:

$$(\boldsymbol{\Phi}_s)_r = -[\mathbf{K}_{ss} - \omega_r^2 \mathbf{M}_{ss}]^{-1} [\mathbf{K}_{sp} - \omega_r^2 \mathbf{M}_{sp}] (\boldsymbol{\Phi}_p)_r \quad [24]$$

Whenever trying to compare both theoretical and experimental models, several authors advise the use of expansion instead of condensation, so that most of the information in the theoretical model is preserved.

qualitative, primarily visual, way and those which use the models in a quantitative, numerical way. The first set of applications is primarily concerned with relatively practical, troubleshooting, problem-solving activities and, historically, constitutes the original purpose of most early modal tests. More recently, as the quality and reliability of the derived models have improved, several more ambitious applications have emerged in which the models are used for numerical predictions of various alternative configurations or scenarios to the test set-up. These include:

- comparisons of theoretically- and experimentally-derived models with a view to improving the analytical model (model ‘validation’ or ‘updating’);
- structural modification and optimization activities;
- structural assembly analysis;
- operating conditions response prediction and force determination; and
- measurement of dynamic properties of complex materials and structures, including for damage detection purposes.

The following sections provide an introduction to these applications, discussing the main requirements and limitations of each.

It should be noted at the outset that different applications make use of the derived mathematical model in different forms: spatial, modal or response. The troubleshooting applications generally use the derived models in their original format – as modal models. The model validation and updating applications use both modal and spatial models: modal models for the initial comparisons and spatial models at the stage when modeling errors are sought, and corrections to the original model are introduced. Structural modification and assembly applications generally rely more on response models, as do the applications concerned with operating response and excitation analysis.

Applications

Introduction

This final article in the series on experimental modal analysis is concerned with the applications to which the mathematical models derived from the test data are to be put. These applications fall into two categories: those which use the resulting models in a

Troubleshooting

In troubleshooting applications, the engineer is generally interested in obtaining visual displays of the individual modes of vibration, or even of the operating deflection shapes ('modes', but not 'normal modes'). By inspection of these mode shapes, it is often possible to develop an appreciation and physical understanding of exactly how, and why, the structure is vibrating. A skilled engineer can often diagnose troublesome vibration conditions from such a visual inspection of the structure's modes and, eventually, prescribe appropriate modifications or other corrective actions. However, all this inspection and interpretation is done in an essentially qualitative

way, and relatively few computations (if, indeed, any at all) are involved.

Theoretical Model Validation

Probably the single most practiced application of modal testing is that of validating a theoretical model using measured data. ‘Validation’ means checking that an already-available theoretical model (usually, a finite element model) is in fact ‘valid’. By this we mean that the model is capable of predicting the actual dynamic behavior of the test structured to an acceptable accuracy. The last qualification is important because it is not realistic to expect the theoretical model to be absolutely correct.

The various phases of model validation can be listed as follows:

- Comparison
- Correlation
- Verification
- Reconciliation
- Error location or ‘localization’
- Model updating or ‘correction’

and it will be helpful to explain each of these in a few words:

- ‘Comparison’ is the passive process of setting measured and predicted results side by side and observing their similarities and differences.
- ‘Correlation’ is the ensuing step of quantifying these differences in order to assess the extent of the comparison. A number of standard numerical indicators are widely used in this process.
- ‘Verification’ is a procedure which should be carried out before any attempt is made to explain and correct for the differences which have been observed between the test-derived model and its analytical counterpart. Verification is the process of determining whether a given model is capable of describing the behavior of the subject structure, if all the individual model parameters are assigned the correct values. A model may not be verified if it lacks certain features or freedoms which are present in the actual structure since, in this case, no amount of parameter correction can compensate for the errors embedded in the basic model.
- ‘Reconciliation’ refers to the sometime delicate task of establishing reasons for the observed differences between measurement and prediction. These differences can arise either because of inaccurate models, or because of imperfect measurements, and the necessary corrective action is, of course, different in the two cases. A third explanation is also

frequently-encountered: the actual structure under test might not conform precisely to the specification (or drawings) upon which the theoretical model will have been based.

- ‘Error location’ is the very difficult task of establishing which elements or parts of the model contain the errors (whether these be errors in the theoretical model or in the test data). This is made difficult because of the usually heavily underdetermined nature of the analysis: there will be many more parameters with potential errors in the model than there are independent measured data from the modal test with which to locate them.
- ‘Updating’ is the final step in the complete validation process: it is the computation of the necessary changes to be introduced to the parameters which have been identified as containing the errors.

Comparison and Correlation of Vibration Properties

The most common form of analysis-test comparison is of the modal properties. Plots of measured vs predicted natural frequencies, such as that shown in **Figure 1A** and side-by-side comparisons of mode shapes, shown in **Figure 1B**, are fairly standard displays. It is also possible to compare measured with predicted frequency response functions (FRFs), but these are generally more difficult to interpret (**Figure 1C**). An alternative way of displaying the mode shape comparison in **Figure 1B** is to plot the values of the respective eigenvectors (the deflected mode shape display is simply one way of plotting the elements in a mode shape vector), test vs analysis, such as the example shown in **Figure 1D**.

The plot of natural frequencies in **Figure 1A** can be used to obtain a quantitative measure of the agreement between test and analysis, principally by determining the slope of the straight line drawn through the plotted points. This should be unity and any deviation in this slope, accompanied by minimal scatter of the points, suggests strongly that there is simply an error in some global property, such as modulus or density, but that the basic model is in close agreement with the measurements. If, on the other hand, the points are markedly scattered about the best-fit line, then that suggests a poor correlation between test and prediction. However, it is necessary to exercise some caution in this type of comparison: a point should only be plotted on the graph in **Figure 1A** after it has been established that the shape of the mode corresponding to the measured natural frequency matches closely that of the mode which

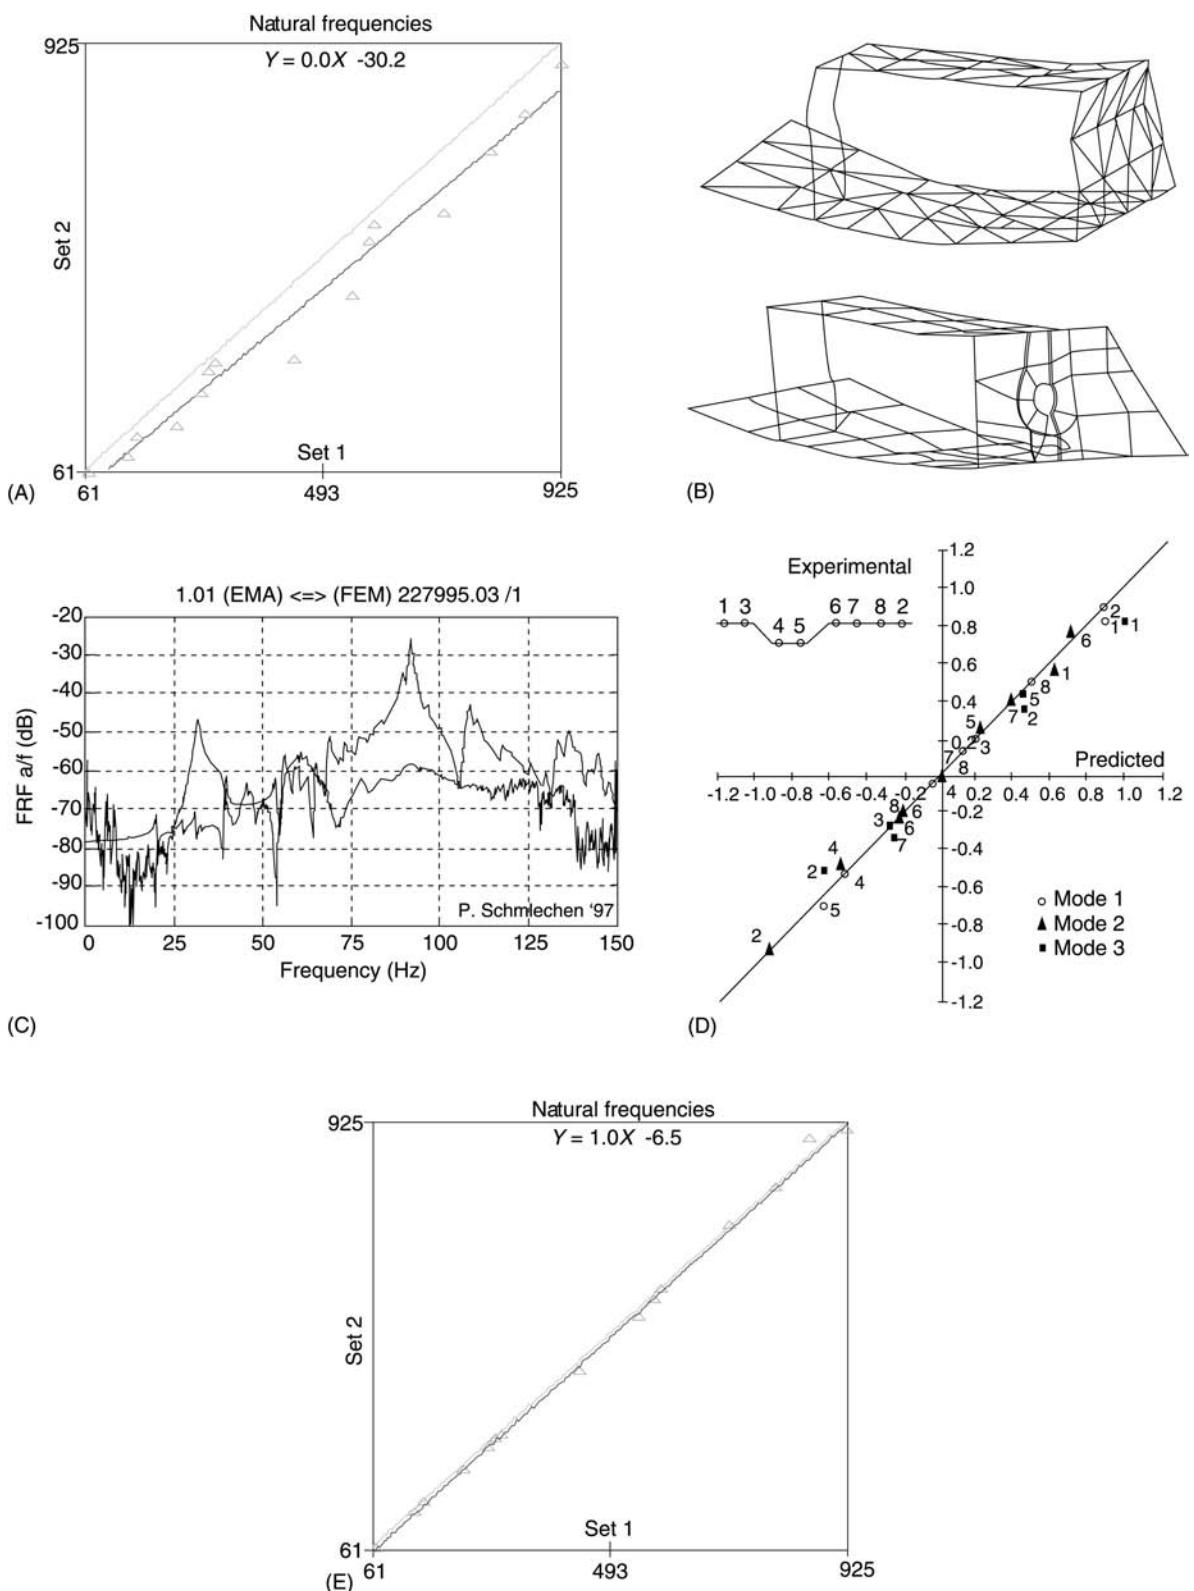

Figure 1 (A) Plot of measured vs predicted natural frequencies. (B) Measured and predicted mode shapes. (C) Measured and predicted FRFs. (D) Comparison of mode shape vectors. (E) A more reliable plot of measured vs predicted natural frequencies.

corresponds to the relevant predicted natural frequency. It is not valid to plot the natural frequency of, say, a torsion mode against a predicted natural frequency of a bending mode – just because they happen to have similar frequency values. In fact, it is essential that correlated mode pairs are identified prior to constructing a lot such as that shown in **Figure 1A** and this can only be achieved by a systematic analysis of the mode shapes of the experimental and theoretical modes.

The necessary systematic comparison between two mode shapes (such as measured vs predicted) can be made based on the plot shown in **Figure 1D** which shows the corresponding elements from the two vectors plotted one against the other. In the ideal case, all such points should lie on a straight line of slope ± 1 . If they lie close to a straight line of a different slope, this indicates very similar mode shapes, but different scaling, in the two cases. From such a plot two average parameters can be extracted: the slope of the best-fit straight line drawn through the points (known as the ‘modal scale factor’, MSF) and the scatter of those points about that line (known as the ‘mode shape correlation coefficient’ or ‘modal assurance criterion’, MAC). The relevant formulae for these two quantities are:

$$\text{MSF}(X, A) = \frac{\sum_{j=1}^n (\psi_X)_j (\psi_A)_j^*}{\sum_{j=1}^n (\psi_A)_j (\psi_A)_j^*}$$

and

$$\text{MAC}(A, X) = \frac{|\psi_X^T \psi_A|^2}{(\psi_X^T \psi_X)(\psi_A^T \psi_A)}$$

respectively. If two sets of eigenvectors are compared, say measured modes vs predicted modes, then a matrix of MAC coefficients can be produced, and can be displayed in several ways, including a table of numerical values (**Figure 2A**) or a diagram (**Figure 2B**).

From the diagram in **Figure 2B**, it can be seen that the correlated modes (those with a MAC exceeding 80%) do not correspond exactly with a direct sequential comparison. Thus the natural frequency of test mode 1 (SET 1) should not be compared numerically with the natural frequency of analysis mode 1 (SET 2) because they do not relate to the same basic mode, as determined by the shapes. The first valid comparison that can be made is between test mode 1 (SET 1) and analysis mode 2 (SET 2). Then, 2;3, 3;4, 5;5, 6;6, ... Once this pairing has been completed, the natural

frequency plot can be redrawn this time making a more reliable comparison between test and analysis, see **Figure 1E**. Clearly, the earlier plot in **Figure 1A** of uncorrelated modes is misrepresentative of the true degree of correlation between test and analysis.

The MAC correlation function is widely used as the first level of quantitative comparison between two sets of modal data. The diagrams and tables shown in **Figure 2** can, however, become confused as a result of incompleteness of the measured mode shape data. To check for such problems, it is possible to compute an AUTOMAC, in which a set of eigenvectors are correlated with themselves. The result of such a computation should be a simple diagonal matrix, indicating that each mode shape vector correlates only with itself. If anything different is found, then it must be concluded that the modes are described by an insufficient number of degrees of freedom (DOFs) or points – a situation which can occur all too easily in experimental situations where the number of measured points is usually severely restricted for reasons of resource. Examples of both situations are shown in **Figures 2C** and **2D**, which show the same data plotted using 102 measured DOFs in **Figure 2C**, but only 30 DOFs in **Figure 2D**.

The most recent format for plotting all these data is shown in **Figure 2E**, in which the natural frequency plots of **Figure 1**, and the mode shape correlation in the MAC and AUTOMAC diagrams in **Figure 2**, are combined into a single plot that contains all the relevant information referred to as the FMAC.

Model Updating and Error Localization

The Basic Principle of Model Updating

Correlation constitutes the essential prerequisite for model updating, or correction. In model updating, the concern here is with the logical conclusion of comparison or correlation: namely, the discovery and correction of errors in the theoretical model (although it is also possible that the reasons for the two sets of data to differ might not always lie in the theoretical model: it is possible that certain of the measured data might contain errors). However, whether the actual errors reside in the theoretical model or in the test data, the task is essentially the same: to find the regions of the model/structure where the causes of the less-than-perfect correlation are located. Once these regions have been identified, then detailed examination of the specific data usually reveals which model contains the errors. If they are found to be in the measured data, then a partial re-test is the ideal solution, although if this is not feasible,

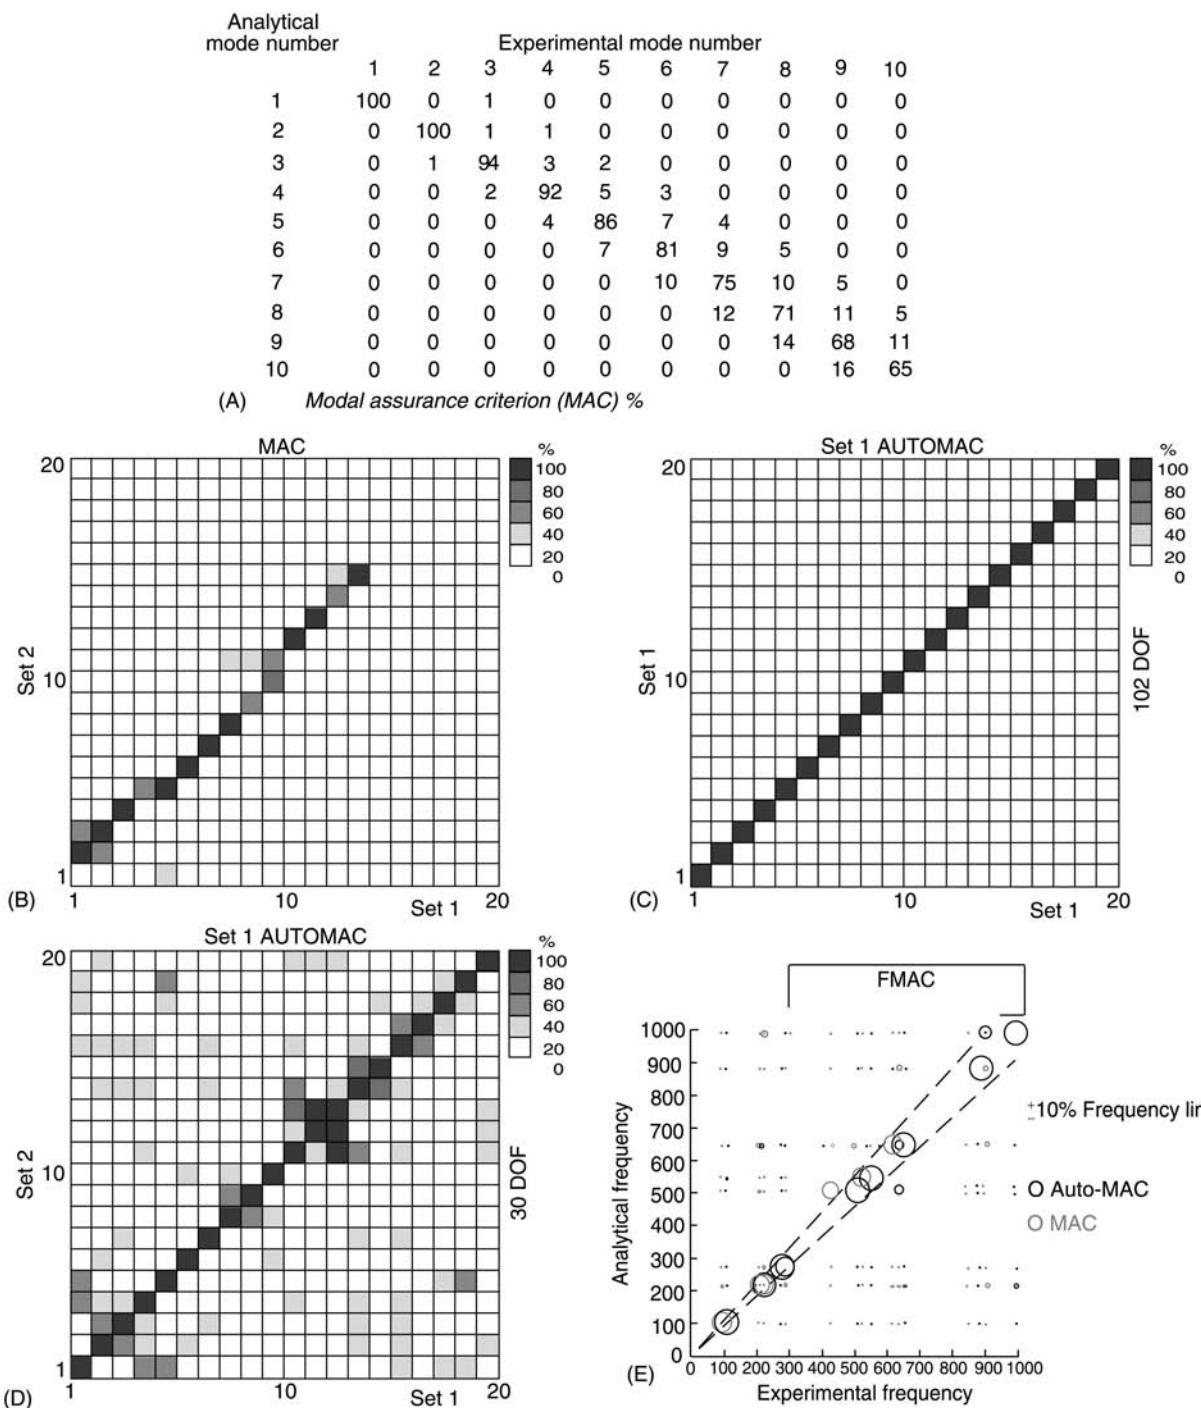

Figure 2 (See Plate 46). (A) Correlation of test and analysis. (A) MAC table; (B) MAC diagram; (C) AutoMAC – many DOFs; (D) AutoMAC – reduced DOFs; (E) FMAC plot.

then the offending data need to be eliminated from the whole validation process. If, on the other hand, the errors are believed to be contained in the theoretical model, then it is necessary to determine what adjustments to the numerical values of the critical model parameters are required in order to bring the

theoretical model predictions closer into line with the measured data.

The algorithms and procedures to carry out the tasks summarized in the above paragraph are rather complex, and cannot be covered in an introductory article such as this. However, there is a complete

entry devoted to the topic of model updating and the interested reader is directed there for a more complete description (see **Model updating and validating**). This section simply discusses some of the more practical considerations.

The Processes Involved in Model Updating

Essentially, what is required in the process of updating (or ‘refining’, or ‘correcting’) a theoretical model is to identify changes that need to be made to the individual elements in the mass and stiffness coefficients in the spatial model. This is often translated into the requirement to update or correct elements in the mass and stiffness matrices which constitute the numerical representation of the spatial model.

Verification The updating task comprises one introductory and two active stages. Before embarking on an updating exercise, it is important to determine the extent to which the two models (experimental and analytical) are different as there is little point in seeking to correct for discrepancies that lie within the measurement uncertainty that must be applied to the test data. At the same time, it is also necessary to establish that the analytical model is capable of representing the measured behavior, even when numerical adjustment of its various parameters has been undertaken. In fact, satisfying this condition is by no means a foregone conclusion: if the theoretical model is too simple, and contains only a few DOFs while the actual test structure is complex and has many active DOFs, then it is clear that no amount of adjusting such a theoretical model can render it capable of replicating the behavior of a much more complicated structure. In this respect, the theoretical model which is to be updated must first be ‘verified’ as being intrinsically capable of describing the structure’s dynamic behavior. Only then is it appropriate to search for the parameters in the model which need to be adjusted, and then to introduce the appropriate numerical changes to those parameters.

Error location Once this precondition is satisfied, the first of the two main updating tasks is to locate those regions or elements in the model which need to be adjusted. This is, in fact, the most difficult task and it is made so by the fact that the measured data that are to be used to perform this task are not only inaccurate (as are all measured data) but – and more importantly – they are generally heavily incomplete. In most modal tests on real structures, practical considerations mean that only a relatively small number of modes of vibration are measured, and these are defined at only a small number of DOFs,

as compared with the total number of DOFs in the theoretical model. As a result, the error location problem is heavily underdetermined, which means that it is almost impossible to obtain a unique solution – many ‘solutions’ are generally found – and those which are obtained may well be ill-conditioned because of the inadequacy of the measured data.

Model adjustment Nevertheless, there are several algorithms that seek to identify the most critical of the parameters in the model and, once identified, the second task is relatively straightforward – generally using some optimization criteria, a ‘best’ set of individual correction factors for the identified erroneous elements can be determined. This process, also, suffers from the underdetermination feature referred to above and care must usually be exercised not to allow model parameters to be modified to a degree which cannot be justified from a physical point of view. This is very important because, in many cases, a satisfactory match between measured data and predictions from an updated model can be achieved at the expense of realism in the adjusted theoretical model. Such a situation constitutes a numerical solution, but not a reasonable one from a physical or practical viewpoint. Any updated model must be able to pass a test of ‘reasonableness’ in its numerical parameters.

Algorithms for Model Updating

There have been many algorithms proposed for the task of updating a theoretical model, but only two or three survive. The most popular one is an iterative one which is based on the sensitivity properties of the subject model; sensitivity to small changes in individual mass or stiffness elements in that model. Figure 3 illustrates a typical updating session spanning some 10 iterations, showing: (a) the current degree of correlation (MAC matrix); (b) the evolution of the selected parameters being updated; (c) the evolution of the MAC values for the correlated mode pairs and (d) the discrepancies between measured and predicted natural frequencies (one of the primary indicators of agreement between two models). However, not all updating sessions are as classical as the one illustrated here.

Structural Modification and Structural Assembly Analysis

The next important application for a modal test-derived model of a structure is a family of methods which are referred to as ‘modification’ and ‘assembly’ methods. Although these two families of applications appear to be quite distinct, in fact they share the same

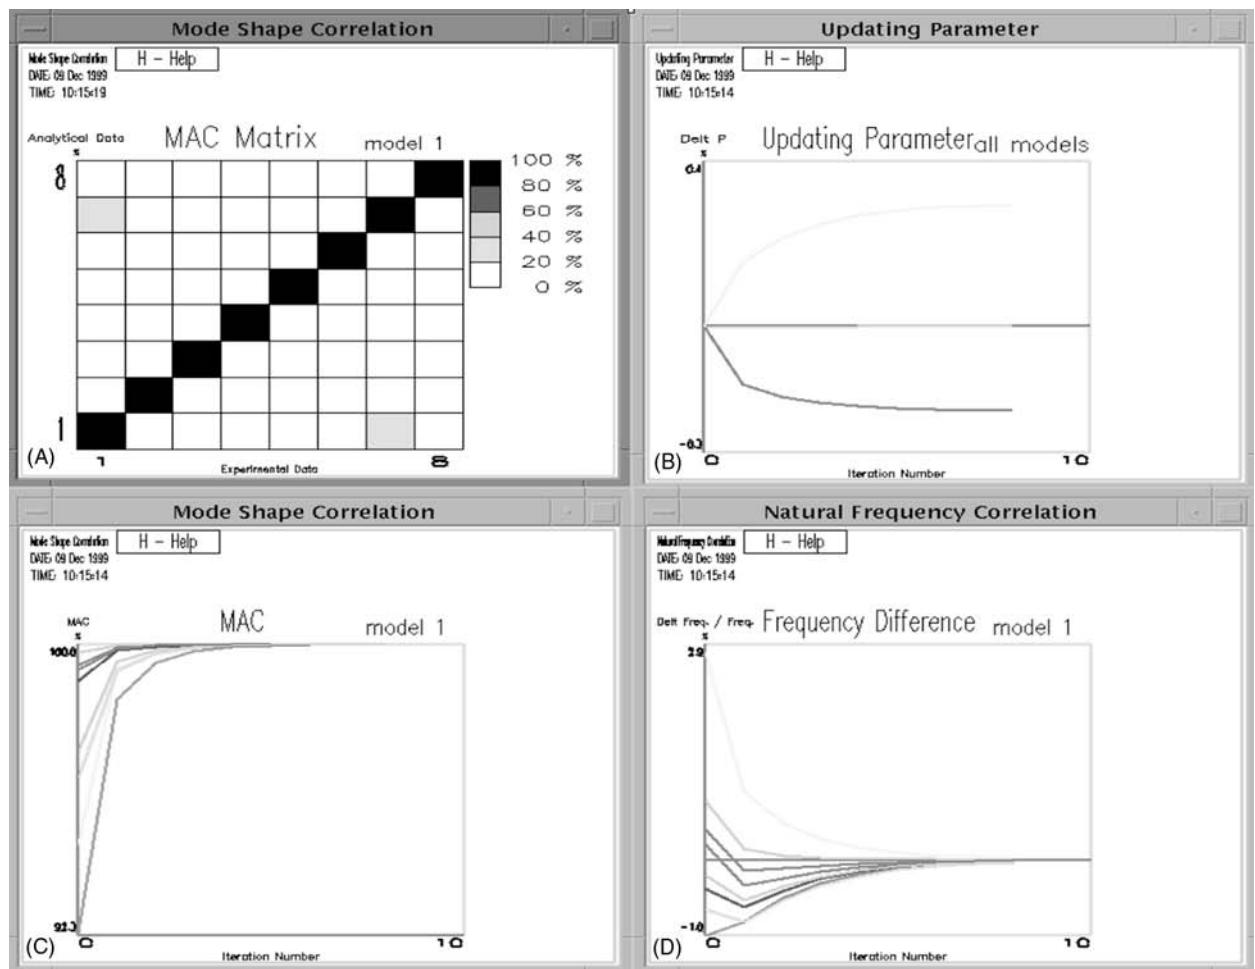

Figure 3 (See Plate 49). Example of evolution of model updating session. (A) Current MAC matrix; (B) evolution of updated parameters; (C) evolution of MAC values for correlated model pairs; (D) evolution of natural frequency discrepancies.

analytical techniques and processes. Indeed, it is quite reasonable to visualize a ‘modification’ as a simple case of one substructure being connected to the main test structure to form an ‘assembled structure’.

The Three Specific Applications

There are three well-defined versions of this class of problem. The first – simple structural modification – seeks to answer the following question: ‘if we have obtained a modal model of a particular test structure using modal testing techniques, can we readily predict (without the need for further tests) how those dynamic properties would change if a specified modification was introduced to the original test structure?’

The second application is an inverse version of the first, and can be summarized by the question: ‘given a mathematical model derived from measurements on the test structure, how can we ascertain

what modifications need to be made to that structure in order to change its vibration properties to some prescribed values?’

The third of these applications is more ambitious. If there are a number of components which will be combined, or coupled, to form a structural assembly, how can the dynamics of that assembly be forecast from a prior knowledge of the dynamics of each component structure individually? In other words, ‘if we have a mathematical model of each separate component, (how) can we predict the dynamics of the assembly formed by coupling those components together, even before that assembly is realized physically?’

This last demand actually subsumes the first and second, and it can be seen that the generic application is structural assembly or structural coupling, and this is described pictorially in **Figure 4** which shows one component (A , with N_A DOFs) connected in a particular way to another component (B , with N_B DOFs)

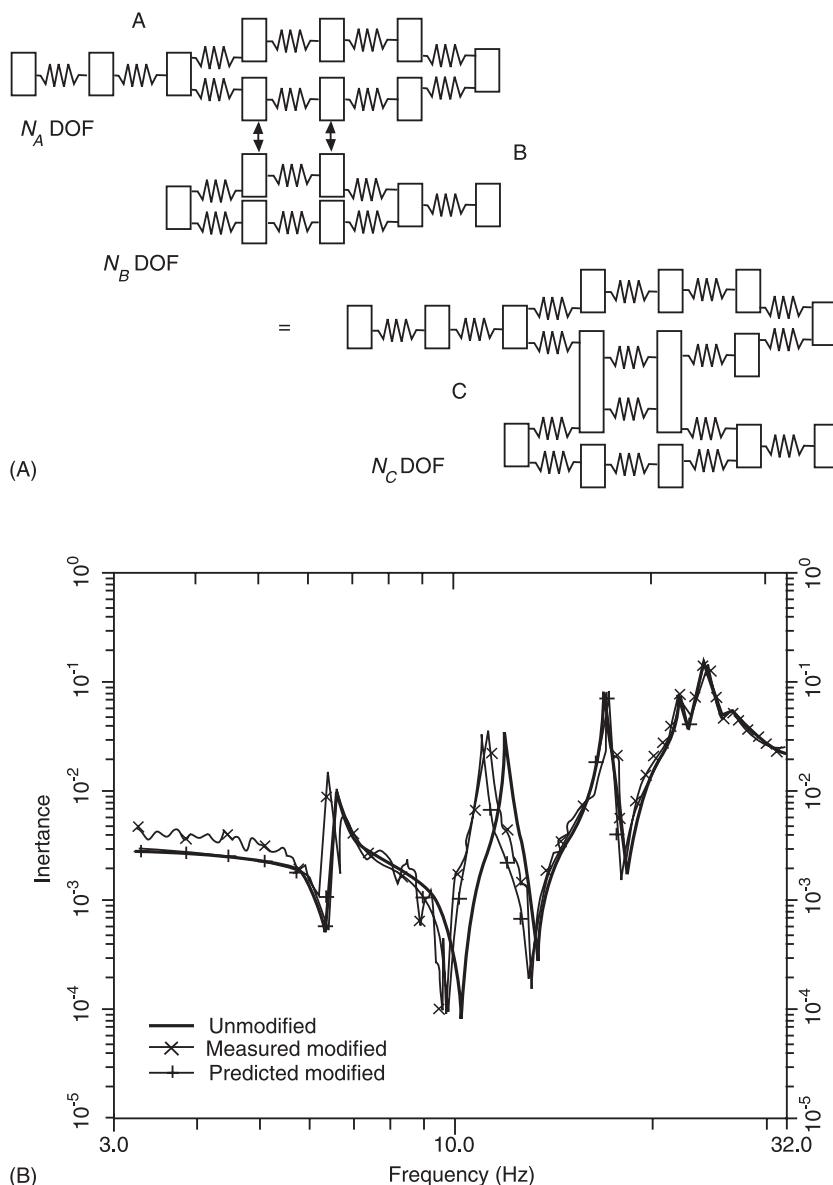

Figure 4 (A) Schematic illustration of a structural assembly formed by combining components A and B to form C; (B) practical application of structural modification.

so as to form a coupled structure, C (or structural assembly), with N_C DOFs. (It should be noted that N_C is not simply $N_A + N_B$.)

The methodology of structural assembly analysis seeks to provide a reliable prediction of the dynamic properties of the complete assembly (C) given the corresponding properties of each component individually. Thus, if we have a modal model for each of the components, A and B as separate structures, perhaps from a modal test on each, then we seek to predict the modal model for the assembly, C. Alternatively, if a response model exists for each of the component structures individually, then it may be preferred to derive a response model for the

assembly. Both approaches are possible and are routinely made. Once again, a full discussion is not practical in this section, but there is a separate article on structural modification to which the reader who seeks more detail is directed (see **Structural dynamic modulations**).

It will suffice here to discuss some of the implications of using such analysis tools as can be found in that companion article in a practical situation. While the essential formulas and algorithms to undertake the required predictions are relatively simply stated, their successful implementation in practice is often difficult. This fact can be traced to the same issues as mentioned in the previous paragraphs: partly to the

imprecision but mostly to the incompleteness of the test data used to construct (limited, incomplete) models for the individual components. In this case, the incompleteness comes in two respects. First, there is the inevitable restriction to the frequency range over which tests are conducted, and modal properties are extracted. This range is usually curtailed by the structure itself because, at higher frequencies, the modes tend to become closer and closer together with the result that they eventually become indistinguishable in the response functions that are measured and analyzed to extract the required modal properties. The second restriction arises because not all the DOFs which are active in the connection interface can generally be measured, and so some are omitted from the component models, frequently with severe consequences on the resulting application. Most common amongst this category are the rotation DOFs which are notoriously difficult to measure, yet are clearly important participants in the coupled structure interactions.

As with the earlier example of model updating, care must be exercised here when seeking to exploit these advanced and potentially powerful applications in practice. Nevertheless, when such care is judiciously applied, very useful results can be obtained and considerable further testing can be avoided.

Response Prediction and Force Determination

Next, we describe two applications which are once again linked by virtue of the common underlying mathematics used in each case, even though the physical context can be quite different in the two cases.

Operating Response Levels

One obvious application of a modal-test derived model of a structure is to use that model to predict how the test structure would respond if subjected to any or many of a range of different excitations ('different' to that used for the modal test), usually referred to as 'operating' excitations, and thus to 'operating' responses. Interest might well be focussed on using the model to simulate excitations which are either multiple, and thus difficult to apply directly to the actual test piece, or at high forcing levels, thereby carrying a risk of damaging the structure. In both cases, the test-derived model can be used to make such predictions with a high degree of reliability and at a fraction of the cost that would be incurred to obtain the same results by direct testing.

The basic theory of the method can be illustrated by the specific case of single-harmonic (but multi-

point) excitation, for which the equation that yields the response, \mathbf{X} , in terms of a specified excitation, \mathbf{F} , is:

$$\mathbf{X}_{n_1 \times 1} e^{i\omega t} = \mathbf{H}_{n_2 \times n_1}(\omega) \mathbf{F}_{n_1 \times 1} e^{i\omega t}$$

The required elements in the FRF matrix, $\mathbf{H}(\omega)$, can be derived from the modal model by the familiar formula:

$$\mathbf{H}_{n_2 \times n_1}(\omega) = \mathbf{\Phi}_{n_2 \times m} (\lambda_r^2 - \omega^2)^{-1}_{m \times m} \mathbf{\Phi}_{m \times n_1}^T$$

Thus it can be seen how knowledge of the structure's modal properties can be used to predict that structure's response to an arbitrary set of harmonic excitation forces, \mathbf{F} , such as are experienced under service or operating conditions. Indeed, the type of response vector that has been derived here is often referred to as an operating deflection shape, or ODS. Clearly, by invoking one of several versions of Fourier analysis, the illustrated example of harmonic excitation and response can be extended to almost any type of vibration: periodic, random, transient, etc.

Determination of Unknown Excitation Forces from Measured Responses

The preceding technique of operating response analysis, based on the modal test-derived model, is generally very reliable. Care must be taken, as always, to ensure that the model used is complete enough for the task, and that means that a sufficient number of modes, m , is used so that the elements in the FRF matrix are accurate. However, the computation is generally well-conditioned.

There is an obvious extension of the foregoing approach in the form of the inverse formulation which sets out to determine the excitation force vector, which is supposed to be unknown in this application, using knowledge of the operating response levels, which can be more readily measured in a service environment than can the excitation forces.

The theoretical principle of the approach seems straightforward enough. It is the inverse of the above formula for response prediction and can be written as:

$$\mathbf{F}_{n_1 \times 1} e^{i\omega t} = \mathbf{H}_{n_1 \times n_2}^{-1}(\omega) \mathbf{X}_{n_2 \times 1} e^{i\omega t}$$

However, there is an obvious problem in using this equation because of the need to invert the rectangular FRF matrix, $\mathbf{H}(\omega)$. In fact, it is necessary to use the generalized inverse to proceed with this expression, and we can write:

$$\mathbf{F}_{n_1 \times 1} = \mathbf{H}_{n_1 \times n_2}^+(\omega) \mathbf{X}_{n_2 \times 1}$$

where the generalized inverse is defined as

$$\mathbf{H}^+(\omega) = (\mathbf{H}^T(\omega)\mathbf{H}(\omega))^{-1}\mathbf{H}^T(\omega)$$

Although these expressions provide us with a means to solve the problem, and to determine the unknown force vector, \mathbf{F} , from knowledge of the measured operating response vector, \mathbf{X} , there are latent problems because of the under or overdetermination of the problem. These two conditions lead to multiple or nonunique solutions, coupled with the prospect of numerical ill-condition of the matrices involved. Needless to say, great care must be taken when implementing this innocuous formula: it may well be that an impossible solution is being sought. Experience shows that force determination is very much more difficult to apply successfully than its partner, response prediction.

Other Applications

There are a range of other applications to which the results of modal tests are being put. One recent and potentially important use is to damage detection. In this application, techniques relate to those used in model updating are employed; not for test against theory, but for test against test (generally on different occasions), where observed differences between the behaviour on day 1 and that on day N are studied for signs of structural changes that might herald incipient damage to a part of the structure. The need to 'locate' the sources for any such discrepancies becomes of paramount importance because it can be local damage that brings about these changes and it is the location of just that damage that is the primary objective of the application.

Advanced modal testing methods are also increasingly used to discover and to characterize nonlinear behavior of materials or structures. There are many situations where recourse must be made to test data in order to be able to characterize many nonmetallic materials in finite element (FE) models. Similarly, modal testing is being used more in the difficult

arena of rotating machinery dynamics, where the rotation of certain components in the structure introduces significant complications of both a theoretical and a practical nature. Performing tests on rotating objects is an extremely challenging task, and the underlying theory is made significantly more complex by the loss of reciprocity, by the existence of two sets of axes and by the complicating effects such as gyroscopic and other forces.

In summary, a number of applications for modal test-derived models of structures have been discussed briefly. The first of these applications – troubleshooting – was largely of a quantitative nature, but the others are all firmly quantitative. They seek to use the test-derived model to perform computations of the effects, consequences or implications of the data that have been acquired during the modal test.

Definition of Mode of Vibration

A mode of vibration can be defined as a way of vibrating, or a pattern of vibration, when applied to a system or structure that has several points with different amplitudes of deflection. A mode of vibration

comprises two distinct elements: first, a time variation of the vibration and, second, a spatial variation of the amplitude of the motion across the structure. The time variation defines the frequency of oscillations together with any associated rate of decay or growth. The spatial variation defines the different vibration amplitudes from one point on the structure to the next. The underlying expression that defines a vibration mode can be written as:

$$\mathbf{x}(t) = \mathbf{X}e^{st}$$

or:

$$x(y, t) = X(y)e^{st} \quad [1]$$

depending upon whether the system is discrete, described by a finite number of specific degrees of freedom (Figure 1A), or continuous, in which case the motion is defined by a continuous function of position, as illustrated in Figure 1B. In these expressions, the coefficient s represents the time-dependent property while the vector \mathbf{X} or the function $X(y)$ represents the spatial dependence of the vibration mode. Throughout this entry, it will be convenient to focus discussion on the former of these two expressions, the discrete version, as this is the one in more widespread use. However, it should be noted that all properties are common to both discrete and continuous versions.

Types of Vibration Mode

There are basically two types of vibration mode:

- free vibration modes and
- forced vibration modes

Modes of the first category, by far the more common, are sometimes called ‘normal’ or ‘natural’ modes (both names are equivalent), and those of the second category are sometimes referred to as ‘operating

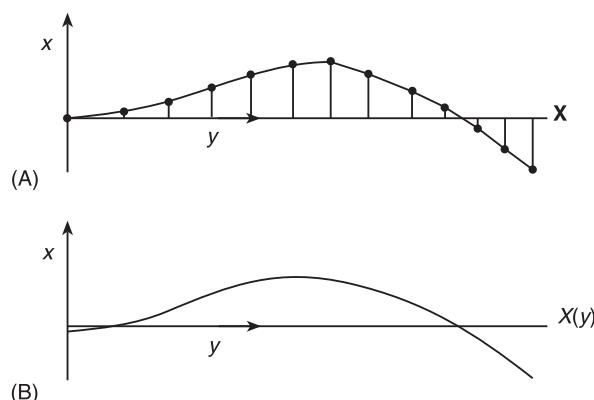

Figure 1 (A) Discrete and (B) continuous systems.

deflection shapes’. As the names imply, these two types of mode relate to fundamentally different types of vibration. Free vibration modes describe the motion that takes place in a system that is free of any external excitation or forcing. They are therefore determined completely by the properties of the system or structure itself. Forced vibration modes, on the other hand, are influenced by the nature of the external excitation that generates the motion and are thus a reflection of both the system’s parameters and the external forces.

Essential Features of a Vibration Mode

The time-dependent component of a vibration mode is often referred to as the modal frequency and is represented by a complex quantity, s , appearing in the term e^{st} in the above expressions. The modal frequency is independent of spatial location of the vibration description and is called a global parameter, as a result of this feature. If s is imaginary ($s=i\omega$), then the motion is purely oscillatory at frequency ω , as illustrated by Figure 2A. If s is complex, then there is a combination of oscillation and exponential decay or growth, the latter alternatives following the sign of a ,

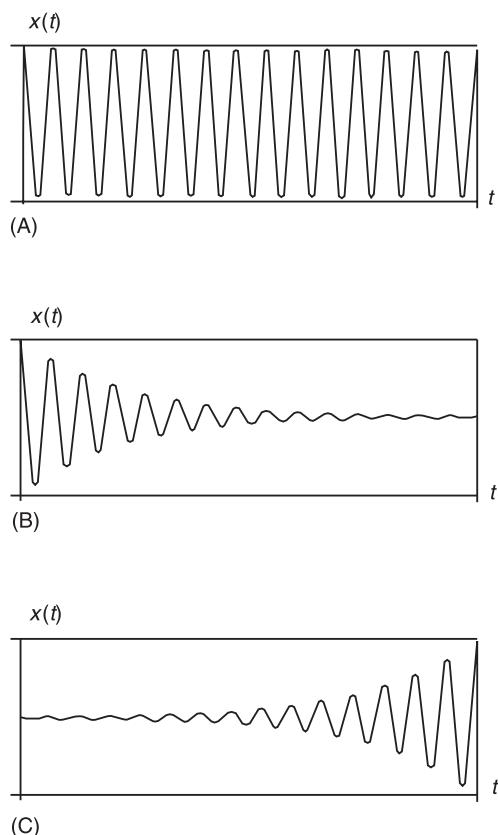

Figure 2 (A) $a = 0$; (B) $a < 0$; (C) $a > 0$.

the real part of s : if a is negative, then the oscillation decays and the system is stable (Figure 2B); if a is positive, then the oscillation grows and the system is said to be unstable (Figure 2C). If s is real, then the motion is nonoscillatory and consists simply of an exponential decay or growth.

The spatially-dependent component is usually referred to as the modal vector or mode shape and is represented by a vector of discrete amplitudes or by a continuous function, both of which are independent of time. The elements or coefficients that make up the mode shape may be real or complex quantities. In a real mode shape, all elements or parts of the system are vibrating exactly in or out of phase with each other. In consequence, all points reach their maximum deflections at the same instant(s) in time, and pass through their undeformed positions simultaneously. The resulting vibration is often described as constituting a standing wave as a result of the appearance of such a type of motion, and is illustrated in Figure 3.

In a complex mode shape, each part of the system vibrates with its own phase, which is not necessarily exactly in phase or out of phase with the other parts. As a result, each point on the structure reaches its own maximum excursion at different instants in time compared with its neighbors and, similarly, passes through its undeformed or zero position at different instants to the other points. The resulting motion in a complex mode is said to have the appearance of a traveling wave type of movement, as illustrated in Figure 4 (although the full impact of a complex mode can only really be appreciated by viewing an animated display).

Free Vibration Modes

Origins of Free Vibration Modes

The free vibration modes represent the inherent vibration properties of the system or structure under discussion. They are usually referred to as the normal or natural modes of the structure and, although in some places a distinction may be drawn between these two different names, here they are taken as

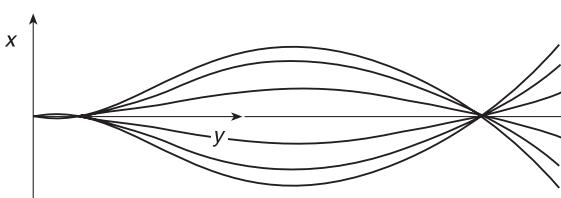

Figure 3 Standing wave (real mode).

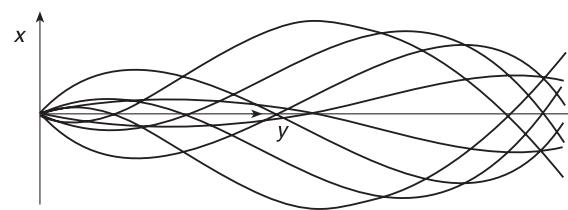

Figure 4 Traveling wave (complex mode).

being synonymous. The normal modes are the natural modes of vibration.

The normal modes are obtained from solution of the equations of motion for the system under discussion for the case of zero external excitation, i.e., the solution to the homogeneous equations of motion. The equations of motion may be written in various forms, depending upon the exact nature of the system, and these include:

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} &= \mathbf{0} \\ \mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} &= \mathbf{0} \\ \mathbf{M}\ddot{\mathbf{x}} + (\mathbf{K} + i\mathbf{D})\mathbf{x} &= \mathbf{0} \end{aligned} \quad [2]$$

where \mathbf{M} , \mathbf{C} , \mathbf{D} , and \mathbf{K} are the system mass, damping, and stiffness matrices, respectively. In these various cases, the solutions are

$$\begin{aligned} \mathbf{x}(t) &= \boldsymbol{\psi}_r e^{i\omega_r t} \\ \mathbf{x}(t) &= \boldsymbol{\psi}_r e^{s_r t} \\ \mathbf{x}(t) &= \boldsymbol{\psi}_r e^{i\omega_r(1+i\eta_r)t} \end{aligned} \quad [3]$$

respectively, where ω_r and η_r are real, s_r is complex, and $\boldsymbol{\psi}_r$ may be real or complex depending upon the exact nature of the system. Thus we see that the free vibration modes can be real or complex and it is important to be able to explain and to understand the significance of the differences between the different types of mode which may be encountered in different systems.

The specific values of the modal frequency that refer to individual modes, ω_r or s_r , have a variety of different names. In some situations they are referred to as the poles or roots or characteristic values of the system equations, this term arising from the underlying mathematics. Sometimes they are referred to as the eigenvalues of the system, based on the German for characteristic value, although strictly, the eigenvalue is the square of the modal frequency. In their general form, they are complex and the two parts – real and imaginary – determine both the oscillatory and the decay/growth features of the time response of motion in that vibration mode, as previously explained. The oscillatory part is usually called the

natural frequency of the mode, while the real part contains the damping factor. In other situations, however, the whole term is referred to as the complex natural frequency, it being understood that there are two parts with the significance just defined. When analyzing undamped systems, the analysis usually delivers values of ω_r^2 directly, and these values (the squares of the natural frequencies) are then called the eigenvalues of the system.

The corresponding mode shape vectors are frequently referred to as the eigenvectors, the origin of this name being the same as that for eigenvalue. It can be seen from the solution to the equations of motion that there is an arbitrary scaling factor applicable to the mode shape vectors, Ψ_r , which follows from the observation that if Ψ_r is a solution to the equation of motion, then so too is $A\Psi_r$, where A is a scaling factor. This means that a normal mode shape vector cannot be defined absolutely, but only as a set of relative amplitudes, or deflections, and this is an inherent feature of these properties of the free vibration modes. We shall see below that there is one particular scaling factor which it is convenient to use for further applications that refer to the mode shape vectors, but we shall leave further discussion of this point until then. This arbitrariness is not a feature that is present in forced vibration modes.

Orthogonality Properties of Normal Modes

The parameters that make up the full set of free vibration modes of a system or structure possess certain properties that are very useful for dynamic analysis in general. These are referred to as the orthogonality properties and it is appropriate to explain something of their origin and significance.

The essential orthogonality property is a relationship between the mode shape vectors of two different modes and is usually expressed in the form:

$$\Psi_q^T M \Psi_r = 0 \quad [4a]$$

and:

$$\Psi_q^T K \Psi_r = 0 \quad [4b]$$

There are some conditions for the validity of this relationship, the most important of which are that in this form it refers only to undamped systems and, further, that $\omega_r^2 \neq \omega_q^2$, for the two modes in question. If this latter condition is met (and the case where it is not satisfied is discussed below), then these two mode shape vectors are said to be orthogonal to each other and, provided that neither mode has the same natural frequency as any other mode in the set for that

system, they are unique, save for the arbitrary scaling constant mentioned above.

If we consider the corresponding expressions where r and s are identical, we shall find both to be nonzero such that:

$$\Psi_q^T M \Psi_r = m_r \neq 0 \quad [5a]$$

and:

$$\Psi_q^T K \Psi_r = k_r \neq 0 \quad [5b]$$

These two quantities, m_r and k_r , are sometimes referred to as the modal mass and the modal stiffness, or generalized mass and generalized stiffness, and are related through the corresponding natural frequency by the simple relationship: $\omega_r^2 = k_r/m_r$. However, it must be noted that the modal mass and modal stiffness parameters defined in this way are not unique: they depend directly on the scaling of the mode shape vector. Nevertheless, this feature provides a means of defining a ‘reference’ version of the mode shape vector for each mode, by specifying a scaling factor that has a particular property of interest. It is possible to scale or multiply each mode shape vector, such as Ψ_r , by a constant, A_r , to create a particular (but equally valid) mode shape vector, $\Phi_r = A_r \Psi_r$, such that the modal mass is unity when computed using this new vector:

$$\Phi_q^T M \Phi_r = 1 = A_r^2 \Psi_q^T M \Psi_r \quad [6a]$$

For this scaled vector, Φ_r , referred to as the mass-normalized mode shape vector for mode r , the second orthogonality expression yields the useful result that the value of the modal stiffness computed using it reverts to the eigenvalue, or square of the natural frequency:

$$\Phi_r^T K \Phi_r = \omega_r^2 \quad [6b]$$

If the condition that $\omega_r^2 \neq \omega_q^2$ is not satisfied, and there are two modes of vibration with identical natural frequencies, then a more complicated situation exists. In such cases, it can be stated that any combination of the two mode shape vectors presented is also a valid mode shape vector; in other words, there is no unique mode shape corresponding to that particular natural frequency. However, not all such mode shape vectors (constructed from any combination of the original two) will be orthogonal to each other: only certain combinations will have this property, but these combinations will certainly exist.

If the system is damped, then the orthogonality conditions become more complex, as do the mode shape vectors and the eigenvalues themselves. In the case of structural, or hysteretic, damping, as described by the equations of motion shown in the third of equations [2], essentially the same orthogonality equations apply with the sole difference that the mode shape vectors, ψ_r or ϕ_r , and thus the modal mass and stiffness expressions, are now all complex quantities. In the case of general viscous damping (described by the second of equations of motion in eqn [2]), the expressions corresponding to the standard orthogonality equations in [5] are:

$$(s_r + s_q)\psi_q^T \mathbf{M} \psi_r + \psi_q^T \mathbf{K} \psi_r = 0$$

and:

$$s_r s_q \psi_q^T \mathbf{M} \psi_r - \psi_q^T \mathbf{K} \psi_r = 0$$

[7]

which are clearly more complicated than the previous set.

In the most general cases, where symmetry of the system matrices cannot be assured, the situation becomes yet more complicated because the mathematics of the equations of motion gives rise to two sets of eigenvectors, the left-hand (LH) eigenvectors and the right-hand (RH) eigenvectors, only one set of which can realistically be related to mode shapes in the context discussed here. The orthogonality expressions for such cases involve a combination of LH and RH eigenvectors. Reference should be made to a detailed treatise on the mathematics of this type of case for a full description of the analysis. Suffice it to state here that all such systems possess a set of vibration modes with complex natural frequencies (roots) and complex mode shape vectors.

Real Normal Modes and Complex Normal Modes

Basically, the modal frequency (or eigenvalue) will be complex if the system contains damping of any type. As a result, all positively damped systems are expected to exhibit decaying as well as oscillatory motion. (Likewise, systems with ‘negative’ damping exhibit exponentially growing oscillations.)

Origins of complex mode shapes

However, when we turn our attention to the mode shapes, we find a more complicated set of rules. The mode shapes, the modal vectors ψ_r , can contain real or complex elements depending on the exact nature of the damping effects. Except for the special case where all the elements in a vector have exactly the same degree of complexity (i.e., all have the same phase angle, or angles separated by 180°), modes with complex vectors are called complex modes and it is of interest to determine when such modes will exist, and the cause or interpretation of the complexity.

Visualization of complex modes can be difficult and one style of presentation is illustrated in Figure 5, which shows Argand diagram plots of the individual elements in three different vectors of different degrees of complexity.

If the system is undamped, so that \mathbf{C} or \mathbf{D} in eqn [2] is zero, then the mode shape vectors, ψ_r , are all real. If the system has a particular distribution of damping such that \mathbf{C} or \mathbf{D} can be expressed as a linear combination of the mass and stiffness matrices, i.e., if:

$$\mathbf{C}, \mathbf{D} = \beta \mathbf{M} + \gamma \mathbf{K} \quad [8]$$

then the system is said to be proportionally damped and it can be shown that the mode shape vectors for such a system are still real.

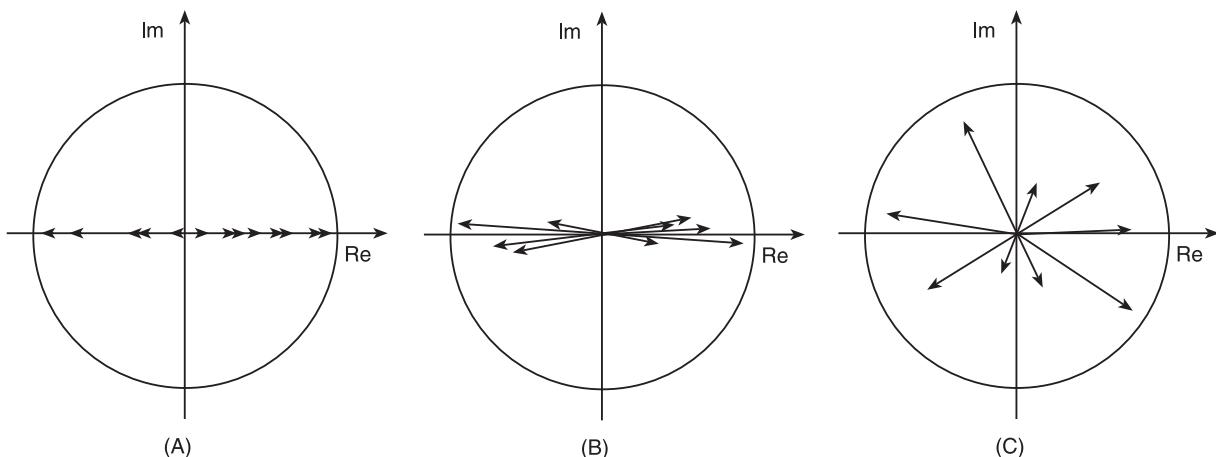

Figure 5 Plots of complex model shapes: (A) \mathbf{X} is real; (B) \mathbf{X} is slightly complex; (C) \mathbf{X} is very complex.

If the system has damping that exhibits a more general distribution than the special case of proportional damping, so that:

$$\mathbf{C}, \mathbf{D} \neq \beta\mathbf{M} + \gamma\mathbf{K}$$

or, more generally, if: [9]

$$(\mathbf{M}^{-1}\mathbf{K})(\mathbf{M}^{-1}\mathbf{C}, \mathbf{D}) \neq (\mathbf{M}^{-1}\mathbf{C}, \mathbf{D})(\mathbf{M}^{-1}\mathbf{K})$$

then the mode shapes, ψ_r , will be complex.

Complex modes can also be caused by other effects, one of the most common of which is the gyroscopic terms that exist in rotating structures. These terms, which arise from Coriolis accelerations, together with some others that are found in rotor/stator interactions in rotating machines, can have the effect of making the mode shapes complex even in situations where there is no damping. This last effect is important and can be identified as the consequence of losing the symmetry of one of the system matrices. In the case of a simple undamped rotating system with mass and stiffness properties only, the velocity-dependent matrix created by the inclusion of gyroscopic terms is skew-symmetric and it is this feature that gives rise to a system with real eigenvalues (i.e., purely oscillatory natural frequencies) and complex eigenvectors (complex mode shapes).

Extraction of real modes from complex modes

One of the topics related to complex modes is the difficulty encountered when comparing normal modes from one source (such as an FE model) with those from another (such as a modal test) when the modes in one set are real while those in the other set are complex. Although such a comparison could provide valuable information about the damping in the structure that is clearly missing from the undamped model, in fact such comparisons are usually made to validate or to correct the representation of the essential features of mass and stiffness in the simpler model. In these cases, the damping information contained in the complex normal modes is of secondary importance and so it is often required to extract the corresponding real modes (sometimes referred to as the ‘undamped system normal modes’) from the provided complex modes. Such a complex-to-real conversion, or ‘realization’ process, is in effect an attempt to remove the non-proportional damping effects from the more complete model to reveal what the vibration modes would be if these effects were absent altogether.

Several algorithms have been proposed for this task, although none is exact in the practical situation where the mode vectors are incomplete, i.e., where

only a subset of the elements in the vector are known. It will be seen in the following section dealing with forced vibration modes how certain excitation patterns can be defined to bring about special mono-mode response characteristics, and this same process can be used to estimate the undamped system normal modes from a model that is described in terms of its damped normal modes, but this is the best that can be achieved for this complex-to-real transformation.

Forced Vibration Modes

The second category of vibration mode is that referred to as a forced vibration mode. As the name implies, this is the description of the pattern (‘mode’) of vibration present in a structure when it is subjected to external excitation forces. The term is confined to cases where the excitation itself can be represented by an expression of the form:

$$\mathbf{f}(t) = \sum_{q=1}^Q \mathbf{F}_q e^{i\omega_q t}$$

or: [10]

$$f(y, t) = \sum_{q=1}^Q F_q(y) e^{i\omega_q t}$$

which means that the set of individual excitation forces all share the same multi-harmonic time dependence, a condition that is commonplace in forced vibration but not universally the case. It is a feature of this type of excitation that there will be a steady-state response which has the form:

$$\mathbf{x}(t) = \sum_{q=1}^Q \mathbf{X}_q e^{i\omega_q t}$$

or: [11]

$$x(y, t) = \sum_{q=1}^Q X_q(y) e^{i\omega_q t}$$

Each term in the series of [11] represents a forced vibration mode for that system, and is clearly as much a function of the excitation forces as it is of the system properties. As before, it will be convenient to discuss the features of a forced vibration mode based on the first of these two variants – the discrete, rather than the continuous version – with the assurance that the same features will apply to the latter case as well. Thus we shall examine in more detail the elemental forced vibration mode form [11a], namely \mathbf{X}_q . This is a vector, as are the previous expressions for the free or

normal modes of the system. However, the solution to the equations of motion in this case of forced vibration yields a response vector that is unique and that harbors no undefined scaling factor, as was the case for free vibration modes. Thus, the forced vibration mode shape vector is simply \mathbf{X}_q , and this vector may be complex or real, depending upon the specific details of the excitation and the system. In general, it will be complex and it can be shown that this vector can be expressed in terms of the normal modes of the system using the simple modal summation, or superposition, equation:

$$\mathbf{X}_q = \sum_{r=1}^N \gamma_r \boldsymbol{\psi}_r \quad [12]$$

where the coefficients, γ_r , are strongly dependent upon the frequency of the excitation relative to the natural frequencies of the system (as well as the forcing levels) and may themselves be complex. In particular, it is found that when the frequency of excitation, ω_q , approaches one of the system's natural frequencies, ω_r , then the corresponding coefficient, γ_r , becomes very large so that the forced vibration mode shape, \mathbf{X}_q (also referred to as an operating deflection shape) may be heavily influenced by the normal mode shape of the nearby mode, $\boldsymbol{\psi}_r$ and thereby provide a good approximation to that free vibration mode. However, excitation at a natural frequency does not guarantee that the forced vibration mode that is generated is necessarily close to the corresponding free vibration mode shape.

For each structure, or system, there are a set of forced vibration mode shapes of special interest. These are the forced vibration modes that have the particular feature that they are real, in the sense that all the elements in each such vector have exactly the same phase as (or 180° different from) each other.

These forced vibration modes have particular interest in the type of test where the objective is to excite vibration in a single (pure) mode – the so-called appropriation tests. For these tests, it is necessary to determine the vector of forces, \mathbf{F}_q , required to produce this mono-mode response condition, and this is achieved by finding a real (i.e., mono-phase) excitation force vector, $\hat{\mathbf{F}}_q$, which will generate a similarly mono-phase response vector, $\hat{\mathbf{X}}_q$ although the phase, θ_f , of the elements of $\hat{\mathbf{F}}_q$ and that, θ_x , of the elements of $\hat{\mathbf{X}}_q$ are not identical. It can be shown that for a given frequency of excitation there is one of these mono-phased forced vibration vectors for each mode of vibration of the structure. It can also be seen that these vectors vary with the excitation frequency. The case of greatest interest is that where the phase difference between the mono-phased force vector and the corresponding response vector ($\theta_x - \theta_f$) is exactly 90° . At this condition, the excitation frequency, ω_q , corresponds exactly to one of the natural frequencies of the undamped version of the system in question, and the forced vibration mode, $\hat{\mathbf{X}}_q$, corresponds exactly to one of the undamped system's normal mode shape vectors which, of course, is real.

Introduction

Despite the high degree of sophistication of today's structural dynamic analysis using the finite element

(FE) method (see **Finite element methods**), practical applications often reveal considerable discrepancies between analytical predictions and test results. The classical way to reduce these discrepancies is to modify by trial and error the assumptions made for the mechanical idealizations and the parameters of the analytical model until the correlation of analytical predictions and experimental results satisfies practical requirements. For complex FE models, this trial-and-error approach turns out to be very

time-consuming and sometimes is simply not feasible. Some effort has therefore been spent in the development of computational procedures to update the parameters of analytical models using dynamic test data.

The FE model of an elastodynamic structure is governed by the equation of motion in the time domain in the form (see **Finite element methods**):

$$\mathbf{M}\ddot{\mathbf{y}}(t) + \mathbf{C}\dot{\mathbf{y}}(t) + \mathbf{K}\mathbf{y}(t) = \mathbf{f}(t) \quad [1a]$$

or, after Fourier transformation (see **Transform methods**) into the frequency domain by $\mathbf{y}(\omega) = F[\mathbf{y}(t)]$ in the form:

$$\mathbf{K}\mathbf{y}(j\omega) = \mathbf{f}(j\omega) \quad [1b]$$

where:

$$\hat{\mathbf{K}} = -\omega^2 \mathbf{M} + \mathbf{K} + j\omega \mathbf{C}$$

denotes the dynamic stiffness matrix. The system matrices \mathbf{M} , \mathbf{K} , and \mathbf{C} of order (N, N) represent the mass, stiffness, and viscous damping matrix. ω is the excitation frequency, \mathbf{f} the excitation force vector, and \mathbf{y} is the response vector (t = time, $j = \sqrt{-1}$). The solution of eqn [1b] yields the frequency response:

$$\mathbf{y}(j\omega) = \mathbf{H}(j\omega)\mathbf{f}(j\omega) \quad [2a]$$

where $\mathbf{H}(j\omega) = \mathbf{K}^{-1}(j\omega)$ represents the frequency response function (FRF) matrix.

The undamped eigenfrequencies, ω_n , and eigenvectors, φ (also called natural frequencies and normal modes, respectively), are calculated from the undamped eigenequation (see **Eigenvalue analysis**):

$$(-\omega_n^2 \mathbf{M} + \mathbf{K})\varphi = 0 \quad [2b]$$

Before using such models for subsequent model updating, the user must be aware of the modeling uncertainties arising from three main sources:

1. Idealization errors resulting from the assumptions made to characterize the mechanical behavior of the physical structure. Typical errors of this type result from:

- simplifications of the structure: for example, when a plate is treated like a beam, which may or may not be erroneous depending on the length-to-width ratio of the plate and the frequency range to be covered;
- inaccurate assignment of mass properties, for example, when distributed masses are modeled

with too few lumped masses or when an existing eccentricity of a lumped mass is disregarded;

- when the FE formulation used neglects particular properties, for example, when the influence of transverse shear deformation or warping due to torsion in beam elements is neglected;
- errors in the connectivity of the mesh, i.e., some elements are not connected or are connected to a wrong node;
- erroneous modeling of boundary conditions, for example, when an elastic foundation is assumed to be rigid;
- erroneous modeling of joints, for example, when an elastic connection is assumed to be rigid (clamped) or when an eccentricity of a beam or a plate connection possibly existing in the real structure is disregarded;
- erroneous assumptions for the external loads;
- erroneous geometrical shape assumptions;
- a nonlinear structure assumed to behave linearly.

2. Discretization errors introduced by numerical methods like those inherent in the FE method, for example:

- discretization errors when the FE mesh is too coarse (not fully converged modal data in the frequency range of interest);
- truncation errors in order reduction methods like static condensation (see **Finite element methods**);
- poor convergence and apparent stiffness increase due to the element's shape sensitivity (see **Finite element methods**).

Since errors of types (1) and (2) are related to the mathematical structure of the model, they are also called model structure errors.

3. Erroneous assumptions for model parameters, for example:

- material parameters such as Young's modulus or mass density;
- cross-section properties of beams such as area moments of inertia;
- shell/plate thicknesses;
- spring stiffnesses; or
- nonstructural masses

The parameters can affect one element or a group of elements with the same properties, i.e., a single parameter may be assigned to a substructure.

Computational procedures for model updating are generally restricted to the correction of model parameters. When the model includes model structure

errors or when the selected correction parameters were not assigned correctly to the real source and location of the errors, then the model is called inconsistent because it is not consistent with the physics. Models of this kind may only be updated in the sense that the deviations between test and analysis are minimized. However, the parameters in this case will generally lose their physical meaning after updating. A typical result of updating such inconsistent models will be that while they may be capable of reproducing the test data they may not be useful to predict the system behavior beyond the frequency range used in the updating, or to predict the effects of structural modifications or to serve as a substructure model to be assembled into an overall structural model.

The aim of all structural analyses to predict the structural response can only be achieved if all three kinds of modeling errors are minimized with respect to the given purpose of the structural analysis. Models which fulfill these requirements are called valid models. Model quality must therefore be assessed in three steps:

- Step 1: initial assessment of idealization and numerical method errors (model structure errors) prior to parameter updating;
- Step 2: correlation of analytical model predictions and test results and selection of correction parameters; and
- Step 3: computational parameter updating and final assessment of model quality.

In this article basic procedures for computational updating of analytical model parameters are summarized. These procedures have been investigated thoroughly in the past with respect to:

- the numerical estimation techniques for solving the updating equations;
- the type of residuals formed by the test/analysis differences to be minimized;
- inconsistent assumptions related to the model structure and the parameterization in conjunction with the requirements to be posed on the initial analysis model;
- the influence of test data deficiencies resulting from incomplete test data where the number of measurement degrees-of-freedom (DOFs) is less than the number of analytical DOFs and from unavoidable random and (small) systematic measurement errors.

The residuals described here are formed by force and response equation errors, by eigenfrequency, antire-

sonance and mode shape errors, and by frequency response errors. An experimental frame structure is used in this article to illustrate a practical application of model updating and validating.

Mathematical Background of Parameter Identification

Parameter identification techniques aim at fitting the parameters of a given initial analytical model in such a way that the model behavior corresponds as closely as possible to the measured behavior. The parameters identified represent estimated values rather than true values since the test data are unavoidably polluted by unknown random and systematic errors. Also, the mathematical structure of the initial analysis is not unique and depends on the idealizations made by the analyst for the real structure. The method of extended weighted least-squares (LS) is summarized below since it represents the most important technique for parameter estimation.

The first step in parameter identification is the definition of a residual containing the difference between analytical and measured structural behavior, for example, the difference between analytical and measured eigenfrequencies. The weighted LS technique requires the definition of a weighting matrix, \mathbf{W}_v , which accounts for the importance of each individual term in the residual vector, $\boldsymbol{\epsilon}$:

$$\boldsymbol{\epsilon}_w = \mathbf{W}_v \boldsymbol{\epsilon} = \mathbf{W}_v (\mathbf{v}_M - \mathbf{v}(\mathbf{p})) \quad [3]$$

where \mathbf{v}_M represents the measured and $\mathbf{v}(\mathbf{p})$ the corresponding analytical vector which is a function of the parameter vector, $\mathbf{p} = [\dots p_i \dots]^T (i = 1 \dots n_p = \text{number of correction parameters})$. The weighted squared sum of the residual vector yields the objective function:

$$J = \boldsymbol{\epsilon}_w^T \boldsymbol{\epsilon}_w = \boldsymbol{\epsilon}^T \mathbf{W} \boldsymbol{\epsilon} \rightarrow \min \quad \mathbf{W} = \mathbf{W}_v^T \mathbf{W}_v \quad [4]$$

whose minimization yields the unknown parameters. In general, the model vector, \mathbf{v} , represents a nonlinear function of the parameters resulting in a nonlinear minimization problem. One of the techniques for solving this nonlinear optimization problem is to expand the model vector into a Taylor series truncated after the linear term as follows:

$$\mathbf{v}(\mathbf{p}) = \mathbf{v}_a + \mathbf{G} \Delta \mathbf{p} \quad [5]$$

where $\mathbf{v}_a = \mathbf{v}|_{\mathbf{p}=\mathbf{p}_a}$ represents the model vector at the linearization point $\mathbf{p} = \mathbf{p}_a$. $\mathbf{G} = (\partial \mathbf{v} / \partial \mathbf{p})|_{\mathbf{p}=\mathbf{p}_a}$ represents the sensitivity matrix of order (m, n_p) with

m = number of measurements and n_p = number of parameters. $\Delta\mathbf{p} = \mathbf{p} - \mathbf{p}_a$ represents the vector of the parameter changes. The index, a , denotes the linearization point. Eqn [5] introduced into eqn [3] yields the linear residual:

$$\boldsymbol{\varepsilon}_w = \mathbf{W}_v \boldsymbol{\varepsilon} = \mathbf{W}_v(\mathbf{r}_a - \mathbf{G}\Delta\mathbf{p}) \quad [6]$$

where $\mathbf{r}_a = \mathbf{v}_M - \mathbf{v}_a$ contains the residual at the linearization point. Of course, this formulation includes the special case when the model vector is a linear function of the parameters leading to a constant sensitivity matrix. The stepwise calculated minimum of the objective function with respect to the parameter changes is obtained from the derivative of the objection function, $\partial J/\partial\Delta\mathbf{p} = 0$, yielding the linear system of equations:

$$\mathbf{W}_v \mathbf{G} \Delta\mathbf{p} = \mathbf{W}_v \mathbf{r}_a \quad [7]$$

with the solution:

$$\Delta\mathbf{p} = (\mathbf{G}^T \mathbf{W} \mathbf{G})^{-1} \mathbf{G}^T \mathbf{W} \mathbf{r}_a = \mathbf{Z}^T \mathbf{r}_a \quad [8]$$

The condition of the sensitivity matrix, \mathbf{G} , plays an important role in the accuracy and the uniqueness of the solution. It is clear that in the case when fewer measured data than parameters are available ($m < n_p$), eqn [7] leads to an underdetermined system whose solution is not unique. Even if a minimum norm or a minimum parameter change solution is selected, the resulting parameters will in general not retain their physical meaning. In parameter updating, the number of measurements should always be made larger than the number of parameters ($m > n_p$), which yields over-determined equation systems. Instead of decomposing $\mathbf{G}^T \mathbf{W} \mathbf{G}$ in eqn [8], the numerical solution of the overdetermined system [7] is preferably done via QR or singular value decomposition (see **Linear algebra**).

Assuming that the sensitivity matrix, \mathbf{G} , is not polluted by measurement errors, it can be shown that the statistical expectation values of the solution equal the true values. The inversion of $\mathbf{G}^T \mathbf{W} \mathbf{G}$ in eqn [8] tends to magnify the error of the parameter estimates when the parameter sensitivities are small and when the sensitivity matrix is ill-conditioned.

The classical weighted LS method, described above, can be extended in cases where it is difficult to obtain a convergent solution because of an ill-conditioned sensitivity matrix. After introducing the linearization in eqn [5], the objective function [4] can be extended by the requirement that the parameter changes $\Delta\mathbf{p}$ shall be kept minimal:

$$J(\Delta\mathbf{p}) = \boldsymbol{\varepsilon}^T \mathbf{W} \boldsymbol{\varepsilon} + \Delta\mathbf{p}^T \mathbf{W}_p \Delta\mathbf{p} \rightarrow \min \quad [9]$$

When the parameters are unbounded, the minimization [9], now with respect to the parameter changes, $\Delta\mathbf{p}$, yields the following linear problem to be solved within each iteration step, which represents the linearization point:

$$(\mathbf{G}^T \mathbf{W} \mathbf{G} + \mathbf{W}_p) \Delta\mathbf{p} = \mathbf{G}^T \mathbf{W} \mathbf{r}_a \quad [10]$$

Of course, any other mathematical minimization technique could also be applied, in particular when the parameters are constrained by upper and lower bounds. Where $\mathbf{W}_p = 0$, the solution of eqn [9] represents the standard weighted LS solution; otherwise the solution is affected by the choice of the weighting matrix, \mathbf{W}_p .

Definition of Updating Parameters

The starting point for updating is the selection of those model parameters defining the type and location of the parameters to be updated in the equation of motion [1] of the FE elastodynamic model. In the most popular approach, the system matrices are updated by substructure matrices according to:

$$\begin{aligned} \mathbf{K} &= \mathbf{K}_A + \sum_i \alpha_i \mathbf{K}_i, & \mathbf{M} &= \mathbf{M}_A + \sum_j \beta_j \mathbf{M}_j, & \text{and} \\ \mathbf{C} &= \mathbf{C}_A + \sum_k \gamma_k \mathbf{C}_k & & & [11a - c] \end{aligned}$$

where α_i , β_j , and γ_k denote the unknown correction (design) parameters assembled in the parameter vector $\mathbf{p} = [\dots \alpha_i \dots \beta_j \dots \gamma_k \dots]^T$, \mathbf{K}_A , \mathbf{M}_A , \mathbf{C}_A denote the analytical (initial) stiffness, mass, and damping matrices, and \mathbf{K}_i , \mathbf{M}_j , \mathbf{C}_k represent the assumed correction substructure matrices (elements or element groups) defining source and location of modeling error.

The correction submatrices defined above can be related to the first derivatives of the updated matrices with respect to a physical or geometrical model parameter:

$$\begin{aligned} \mathbf{K}_i &= \alpha_A \partial \mathbf{K} / \partial \alpha_i, & \mathbf{M}_j &= \beta_A \partial \mathbf{M} / \partial \beta_j, & \text{and} \\ \mathbf{C}_k &= \gamma_A \partial \mathbf{C} / \partial \gamma_k & & & [12] \end{aligned}$$

These derivatives are constant, as in the case of a beam element, with α representing Young's modulus

where the stiffness matrix is a linear function of the modulus. The derivatives need not be constant, as in the case when α represents the shear modulus of a Timoshenko beam where the stiffness matrix terms are nonlinear functions of the shear modulus. α_A , β_A , and γ_A denote the initial parameters used to make the parameter changes dimensionless. Other parametrizations related to generalized elements or substructures have also been reported in the literature.

The success of parameter updating is governed not only by the skill of the analyst to assume an appropriate initial analysis model but also by the ability to assume the right source and location of the erroneous parameters to be corrected.

Definition of Test/Analysis Residuals

Another important assumption the analyst has to make is the choice of residuals formed by differences in the predicted analytical and the measured behavior. In the present article we have considered the following residuals which have been applied most often in the past:

- eigenvalues and antiresonances
- mode shapes
- (weighted) input forces and
- FRF

The linearized undamped eigenvalue residuals, ε_λ , are defined by the differences between measured (index M) and analytical undamped eigenvalues at the linearization point:

$$\varepsilon_\lambda = \lambda_M - \lambda_a = \mathbf{r}_{\lambda a} - \mathbf{G}_\lambda \Delta \mathbf{p} \quad (\lambda = \omega_n^2) \quad [13a]$$

where:

$$\mathbf{r}_\lambda = \lambda_M - \lambda_a \quad [13b]$$

is the residual vector containing test/analysis differences of eigenvalues.

$$\begin{aligned} \mathbf{G}_\lambda &= [\dots \partial \lambda / \partial p_s \dots] \\ &= [\dots \partial \lambda / \partial \alpha_i \dots \partial \lambda / \partial \beta_j \dots] \Big|_{\alpha=\alpha_a, \beta=\beta_a} \end{aligned} \quad [13c]$$

is the sensitivity matrix at linearization point and $\Delta \mathbf{p} = [\dots \Delta \alpha_i \dots \Delta \beta_j \dots]^T$ is the vector of parameter changes.

If the undamped problem is considered, \mathbf{G}_λ can be calculated by differentiation of the undamped eigenvalue eqn [2b] and by substituting the parame-

trization of eqns [11] or [12], which yields the sensitivity expressions:

$$\partial \lambda / \partial \alpha_i = \boldsymbol{\varphi}^T \mathbf{K}_i \boldsymbol{\varphi} \quad [14a]$$

and:

$$\partial \lambda / \partial \beta_j = -\lambda \boldsymbol{\varphi}^T \mathbf{M}_j \boldsymbol{\varphi} \quad [14b]$$

with respect to the i th stiffness and the j th mass parameter. ($\boldsymbol{\varphi}$ = real normal mode normalized to unit modal mass.)

Antiresonances

Antiresonances (see **Resonance and antiresonance**) may also be included in the residual. These appear as zeros in the (undamped) FRFs, thus enlarging the measured information. The zeros are calculated from the eigenvalue problem $(-\omega_a^2 \mathbf{M}_{ij} + \mathbf{K}_{ij}) \mathbf{z} = \mathbf{0}$, where the indices i and j indicate that row i and column j of the system matrices \mathbf{M} and \mathbf{K} are deleted. For $i = j$ (driving point FRF) the system can physically be interpreted as being grounded at DOF $i = j$, which means that the above sensitivity expressions of eqns [14a, b] can directly be applied for the grounded system matrices. It can be shown that in this case the antiresonances are located between the resonances (interlacing property).

Normal-mode Residuals

The linearized normal-mode (eigenvector) residuals, ε_φ , are obtained from the differences of the measured and predicted modes at the reduced set of $N_M < N$ measured DOFs denoted by the index c :

$$\varepsilon_\varphi = \boldsymbol{\varphi}_M - \boldsymbol{\varphi}_c = \mathbf{r}_{\varphi a} - \mathbf{G}_\varphi \Delta \mathbf{p} \quad [15a]$$

where:

$$\mathbf{r}_{\varphi a} = \boldsymbol{\varphi}_M - \boldsymbol{\varphi}_{ca} \quad [15b]$$

is the residual vector containing the test/analysis differences of the analytical modes $\boldsymbol{\varphi}_{ca} = [\boldsymbol{\varphi}_{cl} \dots \boldsymbol{\varphi}_{cr} \dots \boldsymbol{\varphi}_{cR}]_a$ and the corresponding measured modes, $\boldsymbol{\varphi}_M$.

$$\begin{aligned} \mathbf{G}_\varphi &= [\dots \partial \boldsymbol{\varphi}_c / \partial p_s \dots] \\ &= [\dots \partial \boldsymbol{\varphi}_c / \partial \alpha_i \dots \partial \boldsymbol{\varphi}_c / \partial \beta_j \dots] \Big|_{\alpha=\alpha_a, \beta=\beta_a} \end{aligned} \quad [15c]$$

denotes the sensitivity matrix at linearization point and $\Delta \mathbf{p} = [\dots \Delta \alpha_i \dots \Delta \beta_j \dots]^T$ is the vector of parameter changes.

The calculation of the mode shape sensitivity matrix involves a major numerical effort. Since the sensitivity matrices are derived from the (updated) analytical model, they do not contain measurement errors, and this is an essential prerequisite for an unbiased estimate. However, it should be kept in mind that, due to the iterative process, the sensitivity matrices depend on the parameters from the previous iteration step calculated from the noise-polluted residuals in eqns [13b] and [15b]. Another advantage stems from the fact that the mode shape residuals and the sensitivities need only to be calculated for the measured DOFs, i.e., neither the analytical model needs to be condensed nor the measured mode shapes expanded to the unmeasured DOFs. It must be noted that the modal residuals have to be formed between paired mode shapes. Most often the correct mode shape correlation is checked using the modal assurance criterion $\text{MAC} = (\varphi_M^T \varphi_A)^2 / (\varphi_M^T \varphi_M \varphi_A^T \varphi_A)$ (see **Comparison of vibration properties: Comparison of modal properties**) which approaches unity if the measured mode, φ_M , and the analytical mode, φ_A , are fully correlated. Mode pairs with MAC values smaller than a certain threshold (for example, $\text{MAC} < 0.7$) should not be included in the residuals.

Input Residual

The input (or force) residual, $\boldsymbol{\varepsilon}_F$, is given by substituting the measured frequency response into the equation of motion [1b]. Since the number of measured DOFs is generally much smaller than the number of analytical DOFs, it is necessary to expand the measured vector to full model size or to condense the model order down to the number of measured DOFs by appropriate order reduction techniques (see **Finite element methods**):

$$\boldsymbol{\varepsilon}_F = \mathbf{f}_M - \hat{\mathbf{K}}_c(j\omega_M, \mathbf{p})\mathbf{y}_M \quad [16a]$$

where:

$$\hat{\mathbf{K}}_c(j\omega_M) = \hat{\mathbf{K}}_{ca}(j\omega_M) + \sum_s p_s \mathbf{S}_{cs} \quad [16b]$$

represents the updated dynamic stiffness matrix condensed to $N_M < N$ measured DOFs.

$$\hat{\mathbf{K}}_{ca}(j\omega_M) = -\omega_M^2 \mathbf{M}_{ca} + \mathbf{K}_{ca} + j\omega_M \mathbf{C}_{ca} \quad [16c]$$

is the condensed dynamic stiffness matrix at linearization point (index a), $p_s = \alpha_i$, β_j , or γ_k are the correction parameters and $\mathbf{S}_{cs} = \mathbf{K}_{ci}$, \mathbf{M}_{cj} , or \mathbf{C}_{ck} are the condensed correction submatrices, $\mathbf{y}_M(j\omega_M)$ denotes the complex frequency response vector

measured at c measurement DOFs and is \mathbf{f}_M is the vector of measured harmonic exciter forces. If $f_{Mi} = 1$ at exciter DOF i , \mathbf{y}_M represents the i th column of the measured frequency response matrix.

With eqns [16b,c] introduced, the force residual at the measured DOFs can be expressed by:

$$\boldsymbol{\varepsilon}_F = \mathbf{r}_F - \mathbf{G}_F \Delta \mathbf{p} \quad [17a]$$

where:

$$\mathbf{r}_F = \mathbf{f}_M - \hat{\mathbf{K}}_{ca}(j\omega_M, \mathbf{p}_a)\mathbf{y}_M \quad [17b]$$

$$\mathbf{G}_F = [\dots -\omega_M^2 \mathbf{M}_{cj} \mathbf{y}_m \dots \mathbf{K}_{ci} \mathbf{y}_m \dots j\omega_M \mathbf{C}_{ck} \mathbf{y}_M \dots]_a$$

and:

$$\Delta \mathbf{p} = [\dots \Delta \alpha_i \dots \Delta \beta_j \dots \Delta \gamma_k \dots]^T \quad [17c]$$

denote the residual vector, the sensitivity matrix, and the vector of parameter changes, respectively. Due to the approximation errors associated with order reduction techniques and due to the pollution of the sensitivity matrix with measurement errors, the application of the input error residuals for updating large-order models is often restricted in practice.

Pseudoresponse Residual

The pseudoresponse residual, $\boldsymbol{\varepsilon}_{PR}$, is obtained from transforming the input force residual to an output residual by multiplying the force residual of eqn [16a] with the FRF matrix, \mathbf{H}_{Ac} , of the initial model (index A). This is equivalent to exciting the initial model by the force vector, $\boldsymbol{\varepsilon}_F$, at an arbitrary frequency ω_F .

$$\boldsymbol{\varepsilon}_{PR} = \mathbf{H}_{Ac}(\omega_F) \boldsymbol{\varepsilon}_F \quad [18]$$

where:

$$\mathbf{H}_{Ac}(\omega_F) = (-\omega_F^2 \mathbf{M}_{Ac} + j\omega_F \mathbf{C}_{Ac} + \mathbf{K}_{Ac})^{-1} \quad [19]$$

is the condensed FRF matrix of the initial model. $\mathbf{H}_{Ac}(\omega_F)$ can also be interpreted as a dynamic filter. The magnification of the pseudoresponse error, $\boldsymbol{\varepsilon}_{PR}$, can be controlled by exciting the initial system with the force residual vector, $\boldsymbol{\varepsilon}_F$, at a filter frequency, ω_F . The idea behind this filtering is to reduce the unfavorable influence of the measurement errors in the sensitivity matrix.

A special case is obtained by exciting the analytical system linearized at point a by the residual force

vector, $\boldsymbol{\varepsilon}_F$, at the measured excitation frequencies. In this case, the equalities $\mathbf{H}_{Ac} = \mathbf{H}_{ca}$ and $\omega_F = \omega_M$ hold which, after their introduction into eqns [18] and [17a–c], yield the pseudoresponse residuals by:

$$\boldsymbol{\varepsilon}_{PR} = \hat{\mathbf{K}}_{ca}^{-1}(\omega_F) \boldsymbol{\varepsilon}_F = \mathbf{r}_{PR} - \mathbf{G}_{PR} \Delta \mathbf{p} \quad [20a]$$

where:

$$\mathbf{r}_{PR} = \mathbf{y}_{ca}(j\omega_M) - \mathbf{y}_M(j\omega_M) \quad [20b]$$

is the residual response at linearization point a and:

$$\begin{aligned} \mathbf{G}_{PR} \\ = \mathbf{H}_{ca} [\dots - \omega_M^2 \mathbf{M}_{cj} \mathbf{y}_M \dots \mathbf{K}_{ci} \mathbf{y}_M \dots j\omega_M \mathbf{C}_{ck} \mathbf{y}_M \dots]_a \end{aligned} \quad [20c]$$

denotes the sensitivity matrix which, as the comparison with eqn [17c] shows, represents the input sensitivity matrix weighted by \mathbf{H}_{ca} . $\Delta \mathbf{p} = [\dots \Delta \alpha_i \dots \Delta \beta_j \dots \Delta \gamma_k \dots]^T$ denotes the vector of parameter changes. Using the force residual and the pseudoresponse technique, bias and ill-conditioning problems must be considered.

Frequency Response Residuals

The linearized frequency response residuals are obtained from the differences of the measured and the analytical frequency response at the reduced set of $N_M < N$ measured DOFs, denoted by the index c .

$$\boldsymbol{\varepsilon}_R = \mathbf{y}_M - \mathbf{y}_c = \mathbf{r}_{Ra} - \mathbf{G}_R \Delta \mathbf{p} \quad [21a]$$

where:

$$\mathbf{r}_{Ra} = \mathbf{y}_M(j\omega_M) - \mathbf{y}_{ca}(j\omega_A) \quad [21b]$$

represents the residual vector containing the test/analysis differences of the frequency response at the linearization point at excitation frequency $\omega_A = \omega_M$.

$$\mathbf{G}_R = -\mathbf{H} [\dots - \omega_A^2 \mathbf{M}_j \mathbf{y} \dots \mathbf{K}_i \mathbf{y} \dots j\omega_A \mathbf{C}_k \mathbf{y} \dots] \Big|_{p=p_a} \quad [21c]$$

is the sensitivity matrix where:

$$\mathbf{H} = (-\omega_A^2 \mathbf{M} + j\omega_A \mathbf{C} + \mathbf{K})^{-1} \Big|_{p=p_a} \quad [21d]$$

denotes the FRF matrix of the analytical model calculated at the measured DOFs at the linearization point and $\Delta \mathbf{p} = [\dots \Delta \alpha_i \dots \Delta \beta_j \dots \Delta \gamma_k \dots]^T$ is the vector of parameter changes.

As in the case of the sensitivity matrix for the modal sensitivities, the frequency response sensitivity matrix [21c] is not directly corrupted by measurement errors allowing (approximately) unbiased parameter estimates, in contrast to the force and pseudoresponse residuals shown in eqns [17c] and [20c]. In addition, there is no need to expand the test vectors to the unmeasured DOFs. However, there is a crucial drawback in this formulation. Comparing measured and analytical frequency response functions, like that in Figure 6 of the application example presented at the end of this article, it may be noticed that, due to the shifts of the resonance peaks caused by the mismatch of the eigenfrequencies, the test/analysis differences at a given excitation frequency become extremely large, in particular in such cases where the ordering of the test and analysis eigenfrequencies is not the same (also called mode crossing). The consequence is that the first-order theory either fails to predict the updated model response or the rate of convergence is very low unless the test/analysis deviations are very small. The problem can be avoided if the shift of the resonance peaks is considered or by updating the FRFs only at the resonance peaks taken at the analytical and experimental eigenfrequencies which are not identical due to mass and stiffness errors. The residuals in this case are the same as in eqn [21b], except that the analytical excitation frequencies, ω_A , are replaced by the analytical eigenfrequencies, ω_n , and the experimental excitation frequencies, ω_M , by the experimental eigenfrequencies, ω_{Mn} , i.e.:

$$\omega_A \Rightarrow \omega_n \text{ and } \omega_M \Rightarrow \omega_{Mn} \quad [22]$$

One advantage of FRF updating is that it includes the possibility to identify damping parameters. The FRF residuals of eqns [21] under consideration of eqn [22] could be applied directly with the damping correction parameters, $\Delta \gamma_k$, being included. However, this possibility is very restricted because the local physical damping parameterization of eqn [11c] is not available for most structural applications. This is why the modal representation of damping is widely used in practice.

Updating Modal-damping Parameters

The approach to update initial estimates of modal-damping parameters is based on the residual in eqns [21] and [22], i.e., the analytical excitation frequencies are taken at the analytical eigenfrequencies and the experimental excitation frequencies are taken at the experimental eigenfrequencies:

$$\mathbf{e}_\zeta = \mathbf{y}_M(\omega_{Mn}) - \mathbf{y}_c(\omega_n) = \mathbf{r}_{\zeta a} - \mathbf{G}_\zeta \Delta \zeta \quad [23]$$

where:

$$\mathbf{r}_{\zeta a} = \mathbf{y}_M(j\omega_{Mn}) - \mathbf{y}_{ca}(j\omega_n)$$

is the residual vector with test/analysis differences of frequency response at linearization point, $\mathbf{y}_{ca}(j\omega_n)$ is the complex frequency response vector at excitation frequency ω_n (= analytical eigenfrequency), $\mathbf{y}_M(j\omega_{Mn})$ is the frequency response vector measured at the same DOFs at experimental excitation frequency ω_{Mn} (= experimental eigenfrequency).

To calculate the sensitivity matrix of the modal damping, the response eqn [2a] is derived with respect to the viscous modal damping parameter, ζ :

$$\mathbf{G}_\zeta = [\dots \partial \mathbf{y}(\omega_{ns}) / \partial \zeta_r \dots]_a \quad [24]$$

($r, s = 1 \dots R$ number of active modes $<= N$ = model order.)

Model Validation

The first step in assessing the model quality before or after computational model updating (CMU) is based on comparing analytical model predictions and test results (see **Comparison of vibration properties**, **Comparison of spatial properties**). Differences of test and analysis results related to eigenfrequencies, mode shapes, and FRFs most often form the basis of the initial correlation study. Of course, test data accuracy must also be checked, for example: nonlinearity, reciprocity, synthesis accuracy, weak modal excitation, mode shape spatial resolution (see **Modal analysis, experimental**, **Parameter extraction methods**). It should be noted that a minimum correlation quality is required for subsequent CMU to be successful. If the correlation is too poor then the test/analysis deviations cannot be assigned to the model parameters alone; model structure errors might also exist. The initial model is then said not to be consistent with the real physics. Of course, the test data might also be not accurate enough. In many practical cases of complicated industrial structures, the initial correlation requirement cannot be met. Very often such models are not yet suited for CMU and remodeling and/or retesting is required. It should be noted that CMU offers some kind of fine-tuning of the initial model which must be not too far away from the true model.

When the initial correlation requirements are met, computational updating of the model parameters may be applied. Requirements to be posed on CMU results are:

1. The updated model shall reproduce the test data used for CMU. This correlation requirement must be considered a compulsory minimum requirement which does not automatically guarantee an improvement of the prediction capabilities of the model. Therefore, the following additional checks for validating the updated model are necessary:
2. The computational iteration process should converge.
3. Parameter uniqueness and robustness checks should be satisfied with respect to the correct assignment of the location and the type of correction parameters. For example, if parameters without uncertainty are included in the parameter set then they should keep unchanged during CMU. If the assignment was not correct the correction parameter set was not consistent with the real physics.

Further validation steps include an assessment of the physical behavior of the updated model. Since a unique solution cannot be expected, the requirements must be related to the intended purpose for which the model is used, for example:

1. to predict the system behavior to types of load (input) or response (output) other than those used in the test
2. to predict the system behavior beyond the frequency range and/or at DOFs other than those used for CMU
3. to predict the effects of structural modifications and
4. to check if the model when used as a substructure within an assembled whole structure will improve the response of the whole structure model

Sometimes the consistency requirement, as defined above for the initial model idealization and the selected correction parameter set, may be relaxed if the quantity of experimental modal data is sufficient to fulfill one or more of the above requirements, for example, when the validity of the updated model is intentionally restricted to a specified frequency range. In this case, the updated model plays the role of an acceptable special-purpose model. In any case, a primary goal for the final model is to preserve the physical meaning of the parameters. In practical applications the restriction to inconsistent special-purpose models might be unavoidable and acceptable if the application requirements are met.

Illustrative Example

Figure 1 shows a sketch of a frame structure which was built and tested in the laboratory. The structure

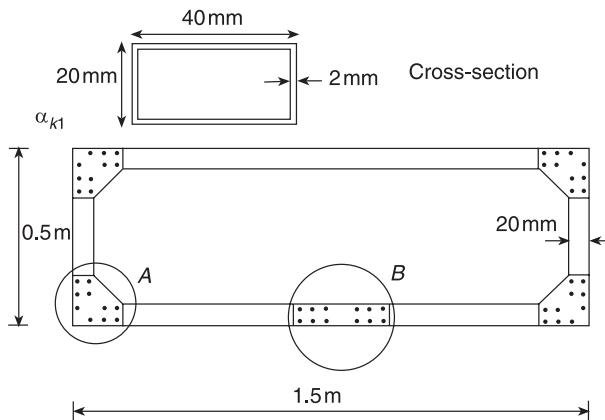

Figure 1 Frame structure, including cross-section (top).

consists of aluminum beams with hollow rectangular cross-section which were connected by bolted joints at the four corners and at the center of the lower member. The joint designs are shown in Figure 2. At the center joint the beams were connected at the webs only. The flanges were not connected, thus leading to a reduced bending stiffness intended to be identified by computational parameter updating.

The initial in-plane model of the frame consists of 40 beam elements as shown in Figure 3. The following properties have been used: Young's modulus, $E = 7 \times 10^{10}$ N m $^{-2}$; moment of inertia,

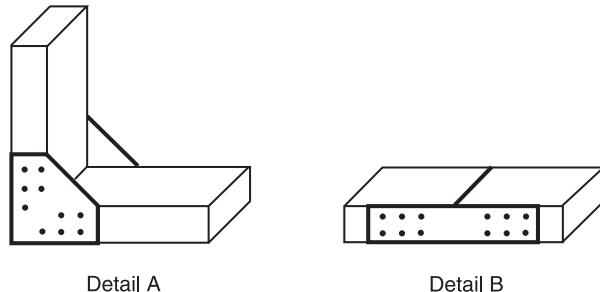

Figure 2 Joint designs.

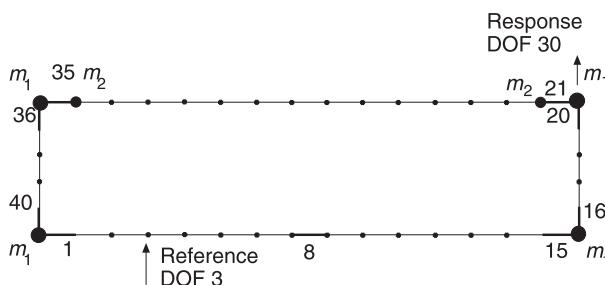

Figure 3 Frame structure, finite element model.

$I = 1.4310 \text{ cm}^4$; cross-section, $A = 2.2410 \text{ cm}^2$; density, $\rho = 2700 \text{ kg m}^{-3}$; corner joint masses, $m_1 = 0.0520 \text{ kg}$ and the masses of the bolts used to fix the soft springs for the modal test under free/free boundary condition, $m_2 = 0.0318 \text{ kg}$.

Experimental modal data were extracted from FRFs obtained from exciting the structure by an impulse hammer applied perpendicular to the beam axes at all the 40 FE nodes. The structure was suspended in soft springs to simulate free/free boundary conditions. Table 1 shows a comparison of the experimental and of the initial analytical eigenfrequencies. The MAC values indicating the degree of mode shape correlation are also shown. The frequency errors are between 0.1% for the second and -6.5% for the sixth eigenfrequency. The mode shape errors are quite small, with MAC values between 99.9% for the fourth mode and 85% for the third mode. Figure 5 shows an exploded view of the experimental mode shapes together with the modes after computational parameter updating.

During the test some slight nonlinear behavior was observed in the vicinity of the first, third, and sixth resonance belonging to the symmetrical modes, but not in the vicinity of the antisymmetric mode resonances. This was obviously caused by the nonlinear behavior of the center joint which gets high bending stress in the symmetric mode vibrations and low bending stress in the antisymmetric mode vibrations. By using the standard linear model-based modal extraction techniques, some unknown systematic errors on the experimental modal data were thus introduced.

The CMU technique was directed to identify the stiffness and mass parameters of the joints. The test/analysis differences of the first four eigenfrequencies and modes measured at 40 DOFs were minimized in the computational updating process. Three model parameters were used for updating. Parameter $p_1 \equiv \alpha_1$ refers to the correction stiffness matrix, \mathbf{K}_1 , for the bending stiffness of element 8 (center joint), parameter $p_2 \equiv \alpha_2$ to the correction stiffness matrix, \mathbf{K}_2 , for the bending stiffness of elements 40, 1, 15, 16, 20, 21, 35 and 36 (corner joints) and parameter $p_3 \equiv \beta_1$ refers to the correction mass matrix, \mathbf{M}_1 , for the mass density of element 8 (center joint).

The evolution of the computational updating over the iteration steps is presented in Figure 4 and the final results in Table 1. After eight iteration steps, the eigenfrequency deviations, Figure 4A, converged to between 0% and -1.1% . Except for mode number 3, the MAC values were better than 99% and remained nearly unchanged, whereas the MAC could be improved for mode no. 3 from 85% to 92.9%, Figure 4C. As mentioned before, this experimental

Table 1 Comparison of experimental, initial analytical, and updated modal data

No.	f_{exp} (Hz)	f_{ini} (Hz)	Error (%)	MAC (%)	f_{upd} (Hz)	Error (%)	MAC (%)
1	42.56	44.98	-5.4	99.1	42.67	-0.2	99.1
2	45.20	45.16	0.1	99.5	45.18	0.0	99.5
3	73.69	76.33	-3.5	85.0	73.35	0.5	92.9
4	130.45	131.8	-1.0	99.9	131.89	-1.1	99.9
5	186.2	183.8	1.3	99.4	184.61	0.9	99.4
6	234.2	250.3	-6.5	96.6	238.52	-1.8	97.3

mode was affected by the nonlinear structural behavior. Care should be taken here to interpret a high MAC value for this mode as a model improvement. The correction parameter changes in Figure 4B show a decrease of 57% for the stiffness parameter, p_1 , of the center joint, a small increase of about 5% for the corner joint parameter, p_2 , and an increase of 72% of the mass parameter, p_3 , of the center joint. These

results agree well with expectations based on engineering judgment since the corner joints were stiffened by the connection plates, whereas the center joint was weakened due to the missing connection of the flanges and since the masses of the bolts and the plates were not included in the initial model.

Some of the model validation criteria described in **Motion sickness** were checked. The first two criteria

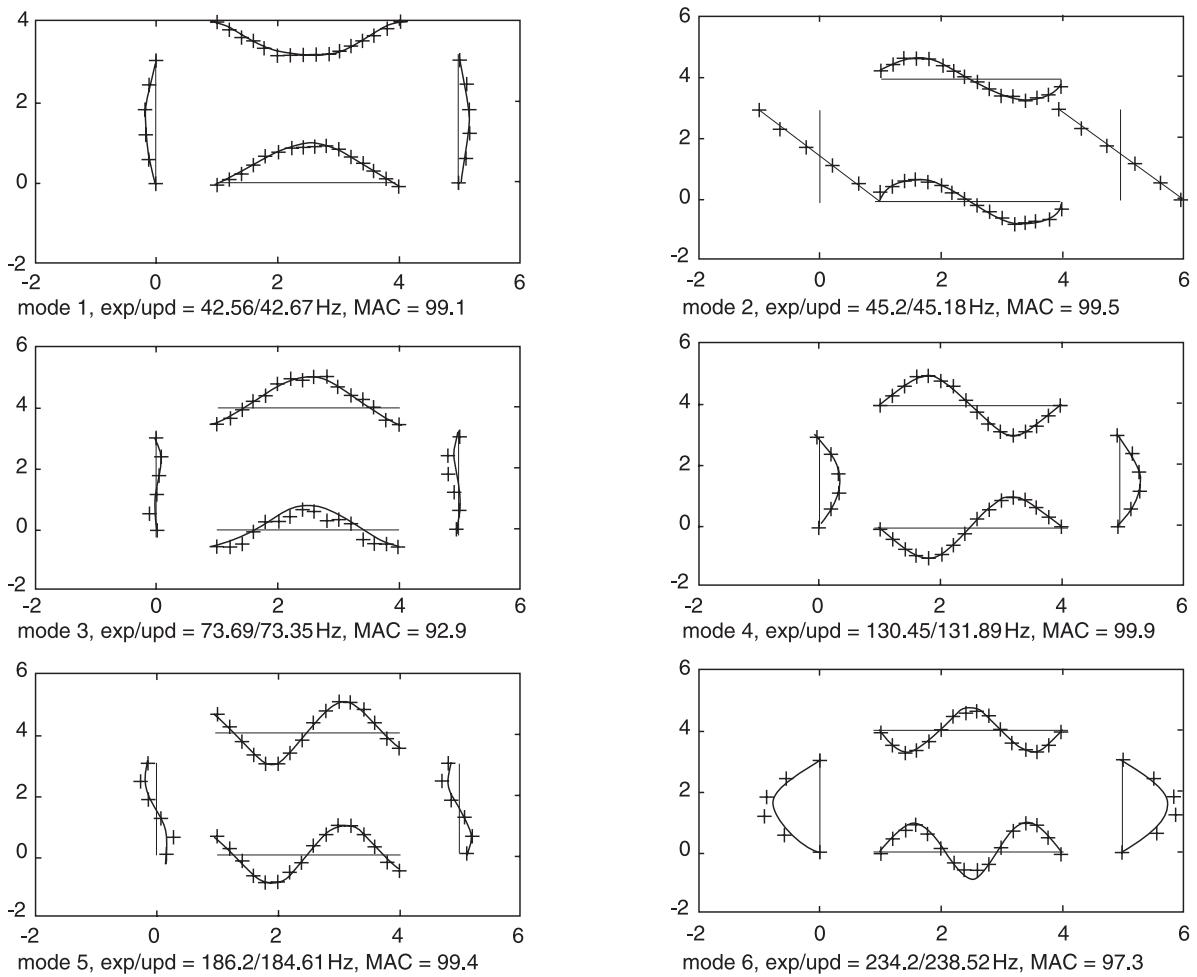

Figure 5 Comparison of experimental (+) and updated modes (—).

related to test/analysis correlation and the convergence requirement can be assessed by the results in Figure 4, which show a good test/analysis correlation for the modal data used for CMU. The mean frequency and MAC error converged to 0.21% and 2.1%. Since only the first four experimental frequencies and modes were used to update the capability of the updated model to predict the unused fifth and sixth experimental frequencies and modes could be used to assess the physical significance of the updated parameters (criterion number 5). The results listed in Table 1 show that the unused fifth and sixth eigenfrequency errors were improved from 1.3% and –6.5% before updating to 0.9% and –1.8% after updating. The corresponding MAC values were also slightly improved.

Validation criterion number 4 requires to check the system behavior to other output types than those used in test. Figure 6 shows an example for that by comparing the experimental FRF at measured

response DOF number 30 with the initial and the updated model response. The improvement of the updated model response is clearly visible, even in the frequency range of the fifth and sixth unused eigenfrequencies (Figure 6B). The magnitude of the resonance peaks could be further improved by updating the modal damping values, which is not shown for this example, where the experimental modal damping values were used to calculate the updated model response. The uniqueness and robustness checks concerning different selections of the location and the type of correction parameters (criterion number 3) revealed only moderate differences for the three correction parameters presented here, which again supports the physical significance of the updated model.

Summary

This article summarizes current procedures for model updating and validating. At first the mathematical

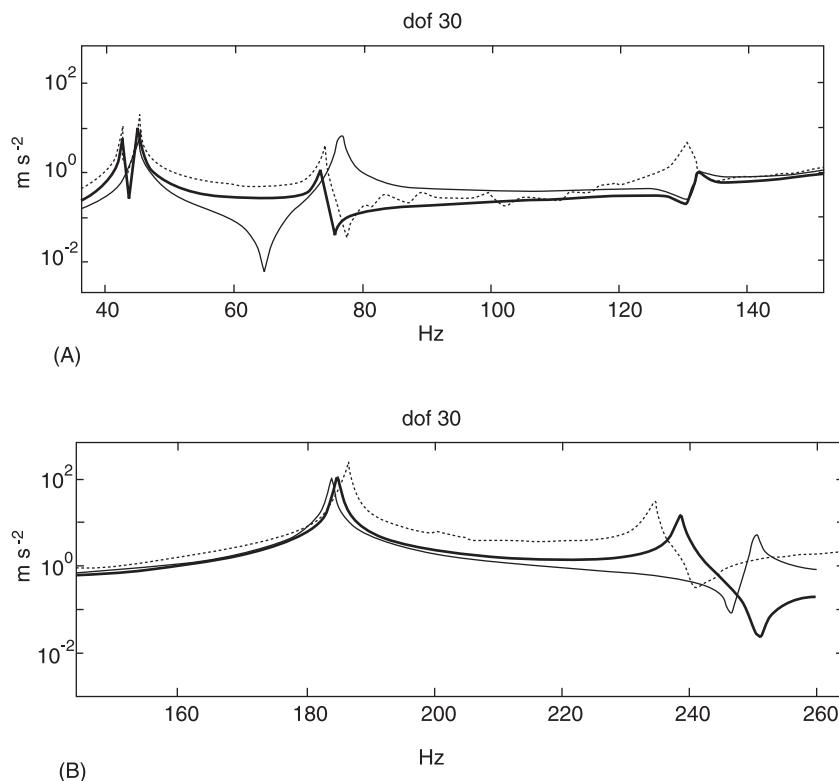

Figure 6 Comparison of experimental (...), initial (—) and updated frequency response functions (—). (A) Frequency range used for computational updating; (B) frequency range not used for computational updating.

background of the parameter identification is given with respect to the numerical techniques for solving the updating equations based on the iterative extended LS technique. The model parameterizations defining the type and location of the erroneous parameters are then used to construct the residuals formed by the test/analysis differences to be minimized. The residuals presented are formed by force and pseudoresponse equation errors, by eigenfrequency, antiresonance, mode shape, and by frequency response errors. The procedures permit the handling of incomplete test vectors, where the number of measured DOFs is much smaller than the number of DOFs of the analytical model. The basic steps of final model validation are discussed. Finally, an illustrative application of updating the model of a laboratory test structure is used to demonstrate some important updating and validating steps.

Nomenclature

E	Young's modulus
f	excitation force vector
G	sensitivity matrix
H	FRF matrix
I	moment of inertia

p	parameter vector
r	residual vector
t	time
v	model vector
W	weighting matrix
y	response vector
ϵ	residual vector
ρ	density

doi:10.1006/rwvb.2001.0084

Introduction

Motion sickness may occur when real or illusory movements of the body or the environment lead to ambiguous inferences as to movement or orientation. Oscillations associated with motion sickness are always of very low frequency, usually below 1 Hz.

With low-frequency translational oscillation, motion on the floor and at various positions on a seat are almost identical. However, if there is low-frequency rotational motion, the translational motions will differ with position around a vehicle

or vessel: they increase as the distance from the center of rotation increases. Hence, for example, there is usually more vertical oscillation at the bow and the stern of a ship than amidships. **Figure 1** illustrates the translational and rotational axes of a seated person.

The symptoms of sickness (e.g., vomiting, nausea, sweating, color changes, dizziness, headaches, and drowsiness) are normal responses to motion that are experienced by many fit and healthy people. A variety of different motions can cause motion sickness and thereby reduce the comfort and impede the activities of those afflicted, and those associated with the afflicted.

Causes of Motion Sickness

Translational and rotational oscillation, constant speed rotation about an off-vertical axis, Coriolis

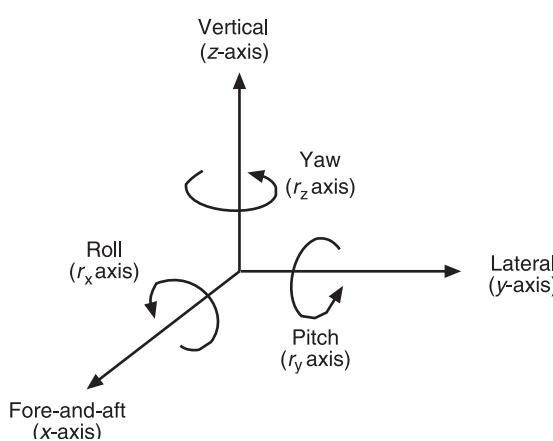

Figure 1 Axes used to report exposures of the human body to oscillation.

stimulation, movements of the visual scene, and various other stimuli producing sensations associated with movement of the body can cause sickness. Although some motions can be predicted as being more nauseogenic than others, motion sickness is neither explained nor predicted solely by the physical characteristics of motion.

Motions of the body are detected by three sensory systems: the vestibular system, the visual system, and the somatosensory system. The vestibular system is located in the inner ear and comprises the semicircular canals (sensing the rotation of the head), and the otoliths (sensing translational forces: either translational acceleration or rotation of the head relative to an acceleration field, such as the force of gravity). The eyes detect relative motion between the head and the environment, caused by either head movements (in translation or rotation) or movements of the environment, or a combination of the movements of the head and the environment. The somatosensory systems respond to force and displacement of parts of the body and give rise to sensations of body movement, or force.

In normal environments the movements of the body are detected by all three sensory systems and this leads to a sufficiently unambiguous indication of the movements of the body in space. In some other environments it is assumed that the three sensory systems give signals corresponding to different motions (or motions which are not realistic) and lead to some form of conflict. This leads to the idea of a sensory conflict theory of motion sickness in which sickness occurs when the sensory systems disagree on the motions which are occurring. However, this implies some absolute significance to sensory information, whereas the ‘meaning’ of the

information is probably learned. This led to the sensory rearrangement theory of motion sickness which states that: all situations which provoke motion sickness are characterized by a condition of sensory rearrangement in which the motion signals transmitted by the eyes, the vestibular system and the nonvestibular proprioceptors are at variance either with one another or with what is expected from previous experience. The conflict is often considered in two categories: intermodality (between vision and the vestibular receptors) and intramodality (between the semicircular canals and the otoliths within the vestibular system). For both categories it is possible to identify several types of situation in which conflict can occur.

There is evidence that the average susceptibility to sickness among males is less than that among females, and susceptibility decreases with increased age among both males and females. However, there are larger individual differences within any group of either gender at any age: some people are easily made ill by motions that can be endured indefinitely by others. The reasons for these differences are not properly understood.

Sickness Caused by Vertical Oscillatory Motion

Motion sickness is not caused by oscillation, however violent, at frequencies much above about 1 Hz: the phenomenon arises from motions at the low frequencies associated with normal postural control of the body.

Experimental Studies

The first systematic laboratory studies of motion sickness, conducted in the 1940s with naval cadets and an elevator, investigated four different frequencies from 0.22 to 0.53 Hz and found greatest sickness at the lowest frequencies. However, moderate magnitudes of motion appeared to produce the most motion sickness and the highest magnitudes the least sickness. Other studies in the series reported an absence of a reliable effect of either temperature or time of day on sickness but a correlation between sickness and responses to a questionnaire history of motion sickness.

Studies undertaken in the 1970s exposed subjects to various magnitudes of vertical oscillation at frequencies from 0.083 to 0.7 Hz for up to 2 h with no external view. Vomiting incidence ranged from 0% to 60% with higher magnitudes of acceleration being required to generate sickness at the higher frequencies; at each frequency the vomiting incidence

increased with increasing acceleration magnitude (Figure 2). The frequency of maximum sensitivity to motion sickness caused by vertical acceleration was found to be 0.167 Hz. Studies of habituation with exposures on different occasions to 0.25 Hz vertical motion at 2.2 ms^{-2} r.m.s. found that motion sickness fell during five successive experimental sessions from 75% to 30%. There was evidence that after a period of 7 days without motion, susceptibility increased.

From each of the data points shown in Figure 2 it is possible to determine the percentage of subjects vomiting per unit of acceleration; this is called normalized vomiting, expressed in percent of persons vomiting per ms^{-2} r.m.s. (Figure 3). This has been used to define a frequency weighting, called W_f , in various standards.

Field Studies of Vertical Oscillation

Vertical oscillation is believed to be a prime cause of motion sickness in some ships. The vertical motion of a vessel is often about 0.2 Hz and is greatly influenced by the pitch motion, so that these two motions have similar waveforms and spectra. For the same reason the lateral (y-axis) motion of a vessel is related to the roll motion (often at a slightly lower

frequency than the pitch motion). The large influence of these two rotational motions results in the magnitudes of translational motions varying with position around a vessel. For a rigid vessel the rotational motions are the same at all positions. A principal effect of worsening sea conditions is an increase in the magnitudes of the motions rather than a change in their frequency. The dominant frequency of motion tends to be lower in larger vessels but the variation is not usually great (Figure 4). The principal vertical acceleration of most ships is close to the frequency where motion sickness sensitivity is believed to be at a maximum. Studies of the incidence of sickness aboard ships have determined dose-effect relationships between vertical oscillation and the illness and vomiting of passengers.

The incidence of sickness is not the only problem associated with low-frequency ship motion: there may be interference with activities, impairment of the performance of ship equipment, difficulty with helicopter landing operations, undesirable deck wetness and structural damage due to 'slamming'. Each of these effects requires a different method of assessing vessel motion. Additionally, the subjective response to the sense of motion, irrespective of motion sickness, can be of interest.

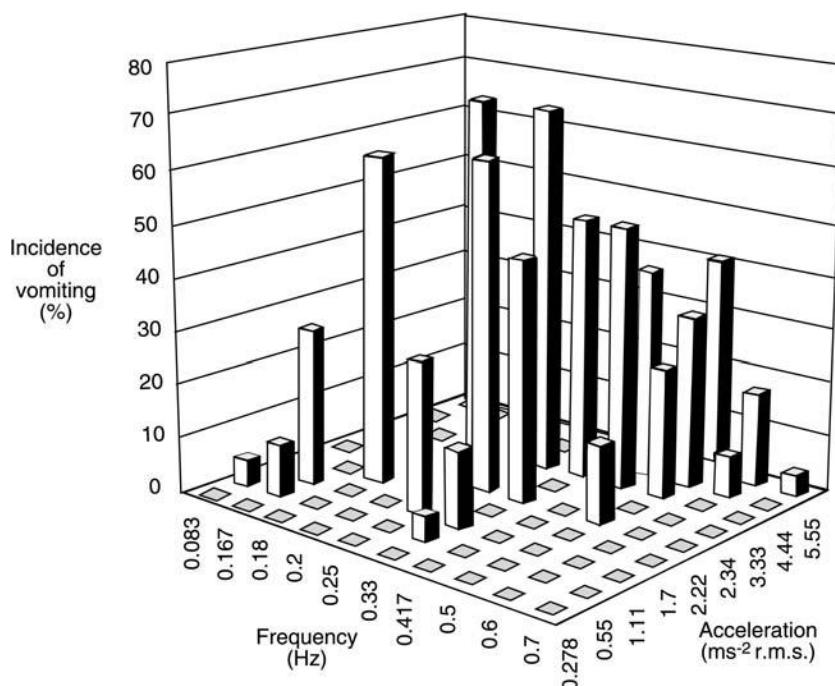

Figure 2 Incidence of vomiting associated with exposure to various magnitudes and frequencies of vertical oscillation according to McCauley *et al.* (1976). (The frequency and the magnitude axes of the figure have ordinal properties only. The percentage vomiting was 0 with 0.278 ms^{-2} r.m.s. at 0.083 Hz and at 0.167 Hz and with 1.11 ms^{-2} r.m.s. at 0.500 Hz.) (Reproduced with permission from Griffin, 1990.)

Methods of Predicting Motion Sickness from Vertical Oscillation

The various investigations of response to vertical oscillation have allowed the formulation of a frequency weighting, W_f (Figure 3), and the definition of a motion sickness dose value. The frequency weighting W_f reflects greatest sensitivity to acceleration in the range 0.125–0.25 Hz, with a rapid reduction in sensitivity to acceleration at higher frequencies. The dose measure based on data from laboratory studies and the development of sickness among passengers on ships is given by a squared relation between frequency-weighted acceleration, $a_{\text{r.m.s.}}$ (in ms^{-2} r.m.s.), and duration of exposure, t (in seconds):

$$\text{Motion sickness dose value (MSDV)} = a_{\text{rms}} t^{1/2}$$

The percentage of unadapted adults who are expected to vomit is given by $\frac{1}{3} \text{MSDV}$. This relationship was derived from exposures in which up to 70% of persons vomited during exposures lasting between 20 min and 6 h.

The MSDV has been used to predict sickness on various marine craft (ships, hovercraft, and hydrofoil) in which vertical oscillation has been shown to be the prime cause of sickness. Vertical oscillation is not the principal cause of sickness in many road vehicles and some other environments: so the above expression should not be assumed to be applicable to the prediction of sickness in all environments.

Sickness Caused by Nonvertical Oscillatory Motion

Until recently, knowledge of the effects of oscillation causing sickness was primarily restricted to vertical oscillation. However, interest in the causes of sickness in road and rail transport has stimulated investigations with fore-and-aft and lateral oscillation.

Horizontal Oscillation

Studies conducted with horizontal oscillation during the 1990s have concentrated on feelings of illness rather than vomiting incidence. The results show that illness decreases with increasing frequency from about 0.2 to 0.8 Hz if the same acceleration is used at each frequency. Increases in the magnitude or the duration of horizontal oscillation appear to increase the incidence or severity of motion sickness. The direction of horizontal oscillation (fore-and-aft or lateral) has been found to have a small effect, but this may be dependent on the subject posture, especially support for the back or head.

Oscillation (or, at least, variation in acceleration) in the horizontal directions (fore-and-aft or lateral) can cause sickness in road vehicles. The effect depends on the visual field and body posture. One study, comparing three conditions (eyes open, eyes closed, and a stationary visual field achieved with a box placed over the head) found that the eyes-open condition produced the least sickness and the box-over-the-head condition produced the greatest sickness. Another study found subjects to be more sensitive when seated

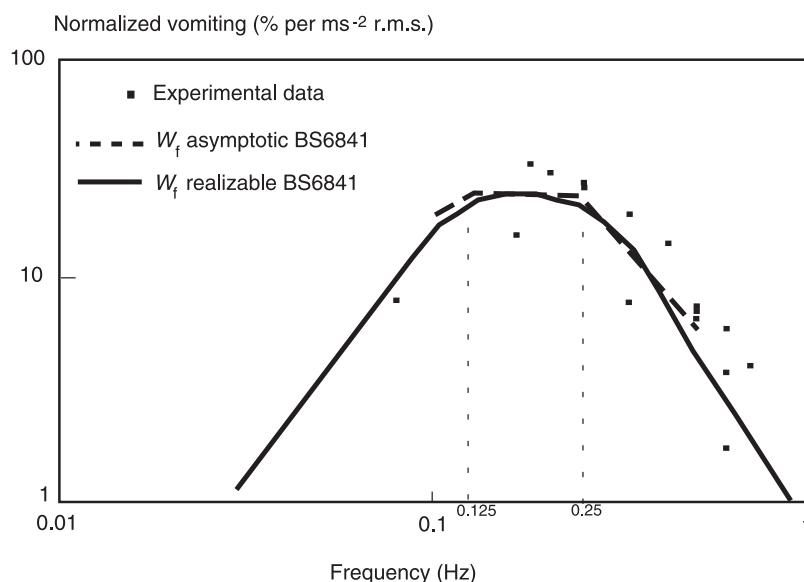

Figure 3 Effect of the frequency of vertical oscillation on the incidence of normalized vomiting during 2-h exposures compared with an asymptotic frequency weighting and the corresponding frequency weighting, W_f , defined in British Standard 6841 (1987) and ISO 2631 (1997). (Normalized vomiting is the vomiting incidence divided by the acceleration in ms^{-2} r.m.s.)

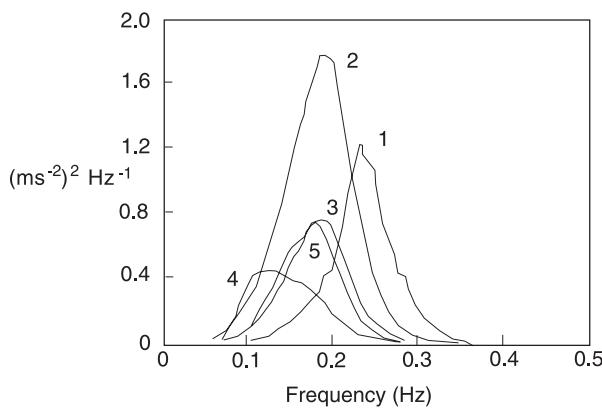

Figure 4 Average acceleration power spectral densities for vertical acceleration at central locations on five ships (resolution 0.01 Hz; based on data in Lawther and Griffin, 1988b).

facing the direction of motion than when lying along the axis of acceleration and deceleration. In road coaches, the horizontal acceleration has been shown to be correlated with the occurrence of motion sickness although, again, the effect is also influenced by the visual environment and other factors.

The concept of an MSDV (as derived from studies of sickness caused by vertical oscillation) may be satisfactory for use with horizontal oscillation, although a somewhat different frequency weighting may be required. Additionally, the frequency range for horizontal oscillation may need to be extended to frequencies below 0.1 Hz since significant acceleration can occur at such low frequencies in the horizontal direction but are less common vertically.

Rotational Oscillation

Rotational motions of the body that are sometimes associated with sickness include oscillations in roll, pitch, or yaw and constant-speed rotation when there are head movements. A consideration of the effects of rotational oscillation on sickness and on measures of translational oscillation can be complex. Rotation of the body about an earth-horizontal axis (i.e., roll or pitch for a normally seated person) alters the direction of the component of force due to gravity and will give oscillatory signals from translational accelerometers oriented along the axes of the body.

It cannot be assumed that sickness experienced in situations where there is rotational oscillation is necessarily due to the rotational acceleration: rotational oscillation causes translational oscillation at all positions other than at the center of rotation and so sickness associated with rotational oscillation could be caused by either the rotation or the translation produced by the rotation. It appears that pure roll motion at magnitudes and frequencies associated with ship motion (e.g., 0.1–0.2 Hz) is far less nauseo-

genic than the pure vertical oscillation often occurring on ships. For situations where there is simultaneous translation and rotation, it might be hypothesized that there could be a synergistic interaction such that roll (or pitch) oscillation may increase the effect of translational oscillation. However, the sickness caused by vertical oscillation in ships seems to be usefully predicted from the magnitudes of vertical oscillation without considering the extent of the roll or pitch motion.

With no visual field and no movement of the head, rotation of the restrained body at constant speed about an earth-vertical axis does not appear to cause sickness, but similar rotation about an earth-horizontal axis (about the x -, y -, or z -axis of the body) can be highly nauseogenic. Symptoms of sickness during such stimulation are reduced if there is an external view. With low-frequency rotation of a horizontal body about its z -axis, nausea appears to increase with increases in the rate of rotation. Constant-speed rotation about an axis only 4° off-vertical can induce nausea in susceptible subjects.

Constant-speed rotation about an earth-vertical axis can induce sickness rapidly if the head is moved in roll or pitch during the rotation. Only a few head movements may be required: this is a cross-coupled motion generating Coriolis forces and is a commonly used means of producing sickness in laboratory studies of antimotion-sickness drugs and in the desensitization of aircrew suffering from motion sickness. Similarly, in environments outside the laboratory, when there are two axes of rotation (e.g., yaw and roll) occurring simultaneously, sickness may be caused by Coriolis stimulation.

The motions of swings can also generate motion sickness. Two principal categories of swing have been used: (1) those secured so that the platform supporting the body swings as a simple pendulum and inclines under the action of the applied forces (i.e., two pole swings), and (2) parallel swings which are secured at either end so that they remain horizontal during swinging (i.e., four pole swings). The motions experienced by observers on the swing are different in the two cases and neither imparts a unidirectional translational acceleration.

N

NEURAL NETWORKS, DIAGNOSTIC APPLICATIONS

M Zackenhouse, Technion - Israel Institute of Technology, Haifa 32000, Israel

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0151

Neural networks are adaptive data processing systems that learn from examples in a supervised mode or discover the intrinsic structure of the data in an unsupervised mode. In recent years they have emerged as a practical technology, with successful applications in pattern recognition and function approximation. These information-processing capabilities are at the core of diagnostics as further detailed here.

Diagnostic methods are generally divided into two strategies: model-based methods and feature-based methods. Feature-based methods involve pattern recognition techniques to distinguish between differ-

ent patterns of features that are associated with different conditions. Model-based diagnostics (and feature-based fault trend assessment) are based on function approximation to relate the measured response to the underlying model. These general monitoring strategies are further divided here into the specific methods for which neural network techniques are applicable, as shown in Table 1. Each method is briefly examined in the context of neural network information processing capabilities. The appropriate neural network paradigms, the specific neural networks of choice and particular application domains are described.

Following the description of neural network applications for the different monitoring and diagnostic strategies, a critical assessment is presented, based on the relevant advantages provided by the neural network technology and the practical aspects of their successful implementation in diagnostics.

Monitoring and Diagnostic Strategies

Model Based Monitoring

Parameter updating Parameter updating involves a mapping from the space of model parameters to the space describing the response characteristics. The model might be a lumped parameter or a finite element model. The required model adjustments indicate the type and location of the fault. Model updating is also important for designing high performance control laws based on an accurate model of the system. Neural networks can learn the appropriate inverse mapping from the response characteristics to the model parameters, if the inverse mapping is unique. This is usually the case at least for small variations around the nominal model. The robustness of neural networks to noise facilitates reliable model updating even at high levels of measurement noise.

Training examples are obtained by simulating the response of the model with different sets of modified parameters. The response of the model is described in the frequency domain using frequency response functions (FRFs). However, in most cases the FRF contains a large number of points and should be further analyzed to reduce the number of inputs to the neural network. Data reduction may be based on modal analysis or on integration over frequency regions of interest.

In model updating, the neural network is used to learn the inverse mapping and to output the appropriate model changes, given the simulated response of the modified system. During operation, the network is presented with the measured response and determines the required model adjustments. In complex models, an iterative model updating may be performed on the modified model (generating new examples, re-training a new network, and re-presenting the measured vibrations) until the characteristics of the measured vibrations are close enough to those predicted by the model.

Both the multilayer neural networks (MLNN) and the radial basis function (RBF) networks provide universal function approximation and are therefore suitable for model updating applications. The RBF networks, which are linear in their weights and are therefore faster to train, have been especially popular in applications of neural networks to model updating.

Response prediction In this method the neural network is trained to model the unknown and possibly nonlinear interrelationship between vibrations at different locations under normal conditions (no fault). During monitoring, the network predicts the vibrations at one location given the vibrations at another

location. Significant deviations indicate that the system has undergone a significant change, which may reflect a faulty condition. A typical implementation of this scheme involves two accelerometers mounted at different locations, and a neural network that is trained to produce the vibration spectra in one sensor (desired output) given the vibration spectra at the other sensor (input pattern). In operation, the predicted spectra is compared to the measured spectra, and their mean square difference is computed as a measure of the deviation from normal operation. This two-sensor technique has been successfully demonstrated in the monitoring of check valves and pump-motor bearings.

Assuming the monitored system is linear, at least around the normal working range, the neural network learns the transfer function of the system between the two accelerometers. Faults, which modify the structure of the system, affect the transfer function, and consequently, the relationship between the vibrations at the different locations. Thus, the predicted vibrations based on the learned transfer function at normal conditions, deviates from the measured vibrations.

Feature Based Monitoring

Feature extraction Feature extraction is a critical initial step in any monitoring and fault identification system. The extracted features serve as the input to a classifier for further fault identification. Thus, feature extraction should preserve the critical information for decision-making while excluding irrelevant information that increases the computation burden. Reducing the dimension of the feature space facilitates the development of the subsequent classifier, both in terms of the number of training examples and the amount of time needed for its training.

Neural networks can learn to detect and extract significant features in the input patterns. The initial feature space is converted to a lower dimension feature space in such a way that the statistical properties and the critical similarity and differences in the original feature space are preserved. The initial feature space may include, for example, the spectrum of measured vibrations, and is usually of high dimension. Neural networks learn to generate potentially new features, which are linear or nonlinear functions of the initial features, under unsupervised learning. Two distinguished neural network approaches to feature extraction include data compression using auto-associative networks and self-organizing feature maps.

Data compression Data compression is achieved by training the neural network to learn the identity map:

Two types of neural networks, the auto-associative neural network (ANN) and the re-circulating neural network (ReNN), are commonly used for data compression.

ANNs are multilayer feedforward networks that learn the identity map. They include an input layer, one or three hidden layers and an output layer. The network is trained using supervised learning, where the target output is identical to the input pattern. By restricting the number of hidden neurons in the middle layer, the network learns to compress the input pattern in such a way that the original pattern can be reconstructed at the output layer. Thus, the middle layer provides a compressed representation of the input pattern, which preserves, as well as possible, the critical features of the input pattern. Feature extraction is achieved by presenting the input pattern to the network and reading the representation at the middle layer. The mapping from the input layer to the middle layer is linear, when there is a single hidden layer, and nonlinear, if there are more (odd number) hidden layers.

The re-circulating neural network is a four-layer auto-associative type network, which repeats the data compression process twice and compares the two results. Its basic structure is equivalent to two identical ANNs, where the output of one is the input to the next. Error signals are received from two sources: reconstruction error in the first ANN and compression-error between the two compressed representations.

Feature extraction using data compression has been applied to diagnose rolling element bearing based on the spectrum of the vibrations. The vector of activity across the hidden layer was used as the input to a subsequent neural network-based classification stage for fault identification.

Self-organizing feature maps (SOFM) Self-organizing feature maps transform the input vector of arbitrary dimension into a one- or two-dimensional discrete map, referred to as the feature map. The neurons in a one- or two-dimensional feature map are arranged in a vector or an array, respectively. A unique aspect of SOFM is the significance of the order of the neurons, which forces neighboring neurons to be mapped to similar input patterns.

The neurons in the feature map describe prototypes of the input patterns in the form of their weights. The distribution of these prototypes reflects variations in the density of the input patterns across the input space, such that a large number of neurons are assigned to dense regions of the input space. These clusters, or dense regions in the input space, are usually associated with distinguished fault-classes,

so subsequent classification based on the prototypical neurons is simplified. The dimension of the feature map is determined by the dimension of the map, and is usually restricted to one or two. The number of neurons reflects the number of grid points used to cover the map. Thus, a two-dimensional feature map may be viewed as a, potentially folded, plane in the high-dimensional space determined by the inputs.

During learning, the SOFM is presented with the input patterns and learns a set of prototypical patterns in a topological order. During operation the input pattern is presented to the SOFM to determine the activity across the feature map, which identifies the close-by prototypes. This activity may then be used as input to a subsequent classifier. SOFM have been used, for example, to extract features from time-frequency representation of vibrations in order to determine the classes of transient events in machining.

Fault detection Fault detection is usually treated as a classification task involving two classes, corresponding to normal and faulty conditions. As such, fault detection is a simple case of fault identification, having only two conditions: normal and abnormal or usable and worn tool. Fault identification is described in detail in the next subsection. However, fault detection may also be achieved using a novelty measure, which signifies when the newly measured pattern is significantly different from those measured under normal operating conditions.

Novelty measure The key point in developing a novelty measure is to differentiate between significant changes and those attributed to normal fluctuations. To learn the normal range of patterns, an ANN is trained to duplicate (auto-associate) a wide range of patterns corresponding to normal operation. Discrimination power is obtained by limiting the number of neurons in the middle layer, so the network is forced to extract the significant features in the normal patterns. Once trained, the ANN is used to compute a novelty index by presenting it with a new pattern and computing the duplication error, i.e., the distance between the network output and the presented pattern.

Since the network was trained to auto-associate patterns that correspond to normal conditions, the novelty of such patterns should be small. In contrast, patterns corresponding to faulty conditions would not be duplicated well, and their novelty index would be significant. Structural fault detection with the novelty index was demonstrated using a simulated lumped-parameter structure. The input patterns, which the network learned to duplicate, were the transmissibility functions between two masses.

Fault identification Fault identification can be posed as a classification problem where the classes are the fault types. In simple gearbox transmission, for example, the faults may include specific bearing-related faults and specific gear-related faults. In a more complex gearbox, fault identification involves the localization of the fault to the particular faulty gear, bearing or shaft.

Neural networks can generate arbitrary decision regions, which may be nonconvex and disjoint. However, their ability to learn the appropriate decision regions critically depends on their size and on the number of representative training examples. The size of the neural network depends on the number of input features and on the number of output classes. Thus, only those input features that enhance separation of the fault classes should be included.

Assuming that adequate input features have been properly selected, and that there are sufficient, well-representative, examples, neural network can be trained to perform the classification task. In most cases, the training examples consist of measurements taken while a specific fault has been introduced in the system, so the fault class of the measured input feature-vector is known. Thus, it is natural to train the network in supervised mode.

Feedforward networks The networks of choice are variants of the single- (no hidden layer) or multilayer feed forward (SLFF or MLFF) neural networks (where only layers with adaptive neurons are counted). Each output neuron in a single-layer network generates a decision boundary in the form of a hyperplane. Thus, single-layer networks are appropriate only when the fault types are linearly separable. Proper feature selection may be critical in formulating the classification task in a space where the fault-classes are linearly separable. Functional link networks may be used where, based on initial analysis of the problem, specific nonlinear functions of the initial set of inputs are computed as features for the network. If the feature selection is appropriate, the classification problem may be reduced to a linearly separable problem, which can be performed by a SLFF network.

MLFF networks, even when restricted to two layers, can generate arbitrary complex decision regions by combining the decision regions generated by the neurons in the hidden layer. However, the additional hidden neurons increase the number of free parameters of the network and thus require a large number of examples for proper training.

A hybrid approach involves a multi- (specifically, two-) layer network, with additional direct connections from the input layer to the output layer. This architecture is different from standard MLFF archi-

ture, where neurons in one layer are connected to neurons in the adjacent layer only. The direct input-output connections support gross linear separation of the input space and free the hidden neurons to form discriminating features to handle the nonlinearly separable regions.

Training may be performed with the back-propagation algorithm. However, this algorithm is known for its slow convergence. Other learning algorithms with better convergence properties, like the Levenberg–Marquart (LM) algorithm, are available.

Competitive networks Competitive networks learn in an unsupervised mode and detect clusters in the data. Their use for classification depends on associating each detected cluster with the appropriate condition class, and thus requires that the condition of each example be known (as in supervised learning). The success of the classifier depends on the extent to which the examples in each cluster are associated with the same condition. This usually requires that the number of class-dependent clusters be known ahead of time.

A family of networks that are based on the adaptive resonance theory (ART) can provide stable adaptive clustering, so that a new category (represented by a new output neuron) is generated when a new pattern does not fit any of the existing clusters. The degree of similarity that is required for inner category clustering is adjustable, using a parameter known as the vigilance parameter. The vigilance parameter can be selected to assure that clustered patterns are associated with the same condition. Thus, ART networks facilitate real-time learning during regular operation by automatically generating a new category whenever a novel input pattern is detected.

Fault assessment Fault assessment refers to the prediction of the future condition or the lifetime of a system with a deteriorating fault, so early warnings can be issued. It involves trend analysis or time series prediction, to predict the future level of the vibration indicators or the lifetime of the faulty element. Neural networks have the potential for learning nonlinear prediction, and thus for successfully forecasting machine deterioration.

Fault trend analysis Fault trend analysis is performed to detect signs of deterioration and trigger early warnings based on the predicted level of important vibration indicators. The next level of the vibration indicator is predicted, based on its current and previous levels. Trend analysis can be formulated as a mapping from a set of time-lagged indicator levels to the next indicator level. This mapping can be learned

using standard MLFF networks, where the inputs are the current and the time-lagged indicator levels and the output is the next level. However, recurrent neural networks (RNN) have better performance in time series prediction. RNN is a MLFF network with an additional feedback path from the output neuron to the input neurons. Thus, the input vector includes both the current and time-lagged indicator levels and the current and time-lagged network predictions. The feedback path provides short-term memory and makes RNN suitable for learning temporal behavior.

Lifetime trend analysis Lifetime trend analysis is targeted at estimating the lifetime of a faulty component based on several diagnostics indices. It can be formulated as a mapping from a set of features, the diagnostic indices, to the lifetime of the faulty component. Reliable lifetime estimation requires multiple indices, which usually vary nonlinearly with the state of the component. Since the functional form of the mapping is not known, its estimation involves nonparametric regression analysis, which can be performed using neural networks.

The nonparametric regression underlying lifetime trend analysis may be learned by different neural network paradigms, including the MLFF network. However, to the extent that each diagnostic index depends primarily on the lifetime of the faulty element, the lifetime is actually represented by a curve in the space defined by the indices and the lifetime. Curve-fitting involves a one-dimensional feature map where the relevant feature is the lifetime. A piecewise linear curve-fitting can be constructed using self-organizing feature maps. The location of each neuron in the one-dimensional map is determined by the weights of its connections to the underlying space. During learning, the weights are adjusted so the neurons are re-distributed along the data samples in a topological order. Their final weight-vectors determine the location and distribution of the knots of the piecewise linear fit to the curve. The direct use of SOFM for nonparametric regression analysis may result in disordered knots and a slightly modified algorithm, known as constrained topological mapping (CTM), is recommended.

Critical Assessment

Neural networks can approximate any continuous multivariate function or any high-dimension decision boundary. Moreover, they learn to perform the desired processing task from examples, without relying on any probabilistic distribution model. However, their performance depends on the structure of the network (e.g., the number of hidden neurons) and

the training set. Thus, while neural networks can be powerful diagnostic tools, their development should account for their specific characteristics.

Advantages for Diagnostic Applications

Approximation power The power of neural networks to approximate general continuous functions is established by a universal approximation theorem, which guarantees the existence of a neural network, with a single hidden layer, which is capable of approximating any continuous function. Furthermore, in spaces of large dimension, neural networks offer a great advantage for function approximation over series expansion on a fixed set of functions. For neural networks, the error falls as the order of $1/M$ where M is the number of hidden units, irrespective of the dimension of the input space d . In contrast, when a fixed set of basis function is used, the error decreases as the order of $1/M^{2/d}$.

Robustness to noise Both training and testing can be successfully performed even when the examples are noisy.

High dimension feature space There is no inherent limitation on the number of features in the input to the neural network. Thus, neural network can be used in diagnostic problems that cannot be resolved, based on a single feature, but require multiple features. However, the training requirements – the burden of preparing a large set of adequate examples and the time required for training – increase with the number of input neurons. Thus, this advantage should be used wisely by including only significant features.

Generalization The trained network can interpolate and extrapolate to operate on novel inputs, which have not been included in the training examples. However, this can be done reliably only when the training examples are adequate, both in terms of their number and distribution. This important issue, known as the generalization power, has significant consequence in terms of the size of the network and the size of the training set.

In the context of classification, for example, the utility of a classifier is determined by the *probability* that a randomly selected new example is correctly classified. This unknown probability defines the generalization performance of the classifier. Given a set of training examples, the probability of correct classification can be estimated by the *frequency* of self-classification, i.e., the rate of correct classification of the training examples. The bias of this estimator is of critical importance in assuring the generalization of the network to unknown examples. In particular, if

the number of training examples is not sufficient, the network may be overtrained and achieve a high frequency of self-classification, but the generalization performance may be poor. General rules have been developed, which determine the minimum number of examples needed to train a classifier with a given number of free parameters. The number of free parameters in a neural network is the number of weights and so these rules relate the number of required examples to the size of the network.

Sensor fusion As mentioned above, neural networks can operate in a high-dimensional feature space. In particular, these features may be extracted from measurements taken by different sensors, so the network performs sensor fusion. Sensor fusion is important in a number of diagnostics applications, and in particular in tool condition monitoring, where both acoustic emission and cutting force measurements are important for determining the degree of tool wear.

Implementation Issues

Data sources Neural networks are trained and tested using a set of examples, which should be representative of the expected cases. Training examples can be collected over time as actual faults are developed, but this is usually impractical. Instead, it is customary to conduct a test program where measurements are taken under different conditions, with a healthy system and with faulty components installed. However, experiments usually produce a very limited set of examples. Even in very exhaustive test programs, only one or two examples of the same type of fault are included. Given the quasistatic nature of most faults, a test program conducted with a specific faulty element provides essentially a single example to a neural network classifier. Multiple examples would require collecting data with different faulty elements in place.

An alternative approach is to generate the training examples analytically, by running a model of the system. Acknowledging the limitations of most models, the preferred strategy is to consider only the changes in the dynamic characteristics rather than their absolute value. This approach is especially attractive in structural damage analysis, where appropriate models of the structure and the damage can be constructed.

Number of examples There are several bounds on the number of examples needed for a good generalization. A general rule for good generalization in classification tasks is that $N > (W / \epsilon)$, where N is the number of examples, W the number of weights and ϵ the permitted fraction of errors on test. This implies that the number of examples should be 10

times the number of weights to guarantee a less than 10 percent probability of error, even when the training examples were correctly classified.

The distribution of examples should reflect the actual distribution of the cases. Thus, special care should be taken when generating experimental examples. Experimental programs are usually based on running the system with known faults and measuring the vibration for an extended period of time. However, in most cases the state of the fault does not change during this period and so the relevant statistical features are not expected to change. In this case the whole test provided a single example. To produce multiple examples, multiple tests with different instances of the same type of fault, should be included.

Other considerations Practical issues for successful implementation of neural networks, which are not specific to diagnostic applications, include (i) network structure, and in particular the number of hidden neurons, (ii) normalization, and (iii) cross-validation. The reader is referred to texts on neural networks for these general issues.

doi:10.1006/rwvb.2001.0150

Neural structures are often used in order to solve difficult nonlinear problems for which a classical solution does not give good results. No mathematical model of the world is needed. In fact, the world and the problem are represented by examples of situations.

Let us consider diagnostic problems. Given an observation on the system, one has to decide about the state of the system (normal, abnormal, etc.). Let us suppose one chooses a neural network as a solution for this decision system.

The task of the neural network is to learn a model of the world in which it is embedded and to maintain this model as sufficiently consistent with the real world in order to solve the diagnostic problem for which it has been built. For example:

1. the known world state is represented by facts;
2. observations on the system are obtained with sensors: they are noisy, with errors due to sensor noise and system imperfections. One extracts examples from these observations and these examples are used for training the network. An example is composed of an input signal and the corresponding desired output (normal state, abnormal state, ...). This set of examples represents the knowledge one has about the problem to be solved. Its quality is very important because it is the only knowledge about the diagnostic problem.

Given this set of examples the design of the neural network may proceed according to the following two phases:

1. A learning phase: an appropriate architecture is chosen for the neural network and a transfer function for each neuron. A subset of examples is used to train the network by means of a suitable algorithm.
2. A generalization phase: other examples (not used before) are tested with the preceding structure and a recognition index is computed. This index characterizes the quality of the decision system; for example, it can be an estimation of the error probability.

Neuron

A neuron is an information processing unit. A general model of a neuron is given in Figure 1. It can be decomposed into three parts:

1. a set of weighted inputs. To the input i is associated the weight w_i . The weight can be positive, when the associated link is said to be excitatory; if it is negative, the link is said to be inhibitory. There is a specific link associated to a threshold t ; it is not an input, it has the effect of lowering the input of the activation function;
2. an adder, making a linear combination of the weighted inputs;
3. an activation function which limits the amplitude of the output either in $[-1,1]$ or $[0,1]$.

The neuron can be described with the equation:

$$y = f(u) = f\left(\sum_{j=1}^d w_j x_j - t\right) \quad [1]$$

The threshold t applies an affine transformation to the output u of the linear combination. The equation can be formalized in order not to distinguish the inputs from the threshold:

$$\begin{aligned} u &= \sum_{j=0}^d w_j x_j \\ y &= f(u) \end{aligned} \quad [2]$$

with:

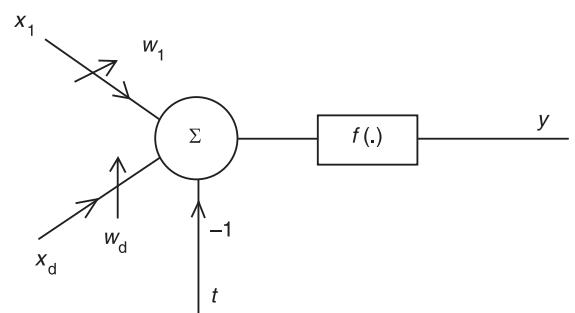

Figure 1 General model of a neuron.

$$\begin{aligned} x_0 &= -1 \\ w_0 &= t \end{aligned} \quad [3]$$

Three types of activation functions may be distinguished:

1. A threshold function:

$$f(u) = \begin{cases} 1 & u \geq 0 \\ 0 & u < 0 \end{cases} \quad [4]$$

Such a neuron is called a McCulloch–Pitts neuron: its output is a binary one.

2. A piecewise linear function:

$$f(u) = \begin{cases} 1 & u \geq 1/2 \\ u & -1/2 < u < 1/2 \\ 0 & u < -1/2 \end{cases} \quad [5]$$

In this case, the neuron is either a linear combiner or a threshold function.

3. A sigmoid function: this function is a strictly increasing one with derivative properties. An example is the logistic function:

$$f(u) = \frac{1}{1 + \exp(-au)} \quad [6]$$

The value a is called the slope parameter. By modifying its value, one gets different slopes. The value of the slope at the origin is $a/4$. If a approaches infinity, the sigmoid function becomes a threshold one. It is easy to introduce modifications in order that the values of the activation function be between $[-1, 1]$:

for the threshold function:

$$f(u) = \begin{cases} 1 & u > 0 \\ 0 & u = 0 \\ -1 & u < 0 \end{cases} \quad [7]$$

For the sigmoid function, the hyperbolic tangent function is used:

$$f(u) = \tanh\left(\frac{au}{2}\right) = \frac{1 - \exp(-au)}{1 + \exp(-au)} \quad [8]$$

Network Architecture

Each architecture is associated with a learning algorithm in order to train the weights. Four architectures can be considered:

1. The single layer feedforward network: such a network is composed only of a layer: inputs are applied to all the neurons of this layer which computes the output. It is a feedforward neural network. An associative memory is an example of such a structure.
2. The multilayers network: Such a network is composed of an input layer, one or more hidden layers and a layer of output neurons. The user chooses the number of hidden layers. By adding different hidden layers, the network acquires a more extensive knowledge on the problem. Each neuron in each layer is connected to the outputs of neurons of the preceding layer. If the network has d source nodes, n_1 neurons in the first hidden layer, n_2 in the second one, q in the output layer, it is said to be a $(d; n_1; n_2; q)$ network. The network can be fully connected (each neuron in each layer is connected to every node in the adjacent forward layer) or partially connected.
3. Recurrent networks: in a recurrent network, there is at least one feedback loop. Such a structure can be complex when there are hidden neurons.
4. Lattice structures: a lattice consists of a one-dimensional or higher-dimensional array of neurons with a corresponding set of source nodes that supply the input signal to the source array. The dimension of the lattice refers to the number of the dimension of the space in which the graph lies.

Error-correction Learning

In order to train the network, one needs a set of patterns. For each pattern $x_i(k)$ presented at time k to the network, one knows the desired response or target denoted $d_i(k)$. The pair composed of the input pattern $x_i(k)$ and the desired response $d_i(k)$ is the example presented at time k . The set of examples is called the training set. Let $y_i(k)$ be the output of neuron i for the example k . This output is generally different from the desired response and an error signal $e_i(k)$ can be computed:

$$e_i(k) = d_i(k) - y_i(k) \quad [9]$$

In the error-correction learning, a cost function is minimized, and is defined as the mean-squared value of the sum of squared errors:

$$J = \frac{1}{2} E \left[\sum_i e_i^2(k) \right] \quad [10]$$

The sum is taken over all the neurons in the output layer of the network. A method of gradient descent

will be used to minimize the cost function. Because the corresponding probability laws are not known, an estimate of J is used, which is an instantaneous value $E(k)$:

$$E(k) = \frac{1}{2} \sum_i e_i^2(k) \quad [11]$$

The network can then be optimized by minimization of $E(k)$, the variables being the weights of the network. The adjustment $\Delta w_{ij}(k)$ at iteration k is given by:

$$\Delta w_{ij}(k) = \alpha e_i(k) x_j(k) \quad [12]$$

This rule is called the error-correction rule, with α determining the rate of learning.

Perceptron

The perceptron is the simplest architecture for a neural network (Figure 2). It can be used only when patterns are linearly separable. Its architecture is based on a single neuron with weighted inputs. Let x_1, x_2, \dots, x_d be the inputs of the neuron, w_1, w_2, \dots, w_d , the corresponding weights. A specific ‘input’ consists in the threshold θ . A linear combination is computed:

$$u = \sum_{i=1}^d w_i x_i - \theta \quad [13]$$

The $f(\cdot)$ function is a threshold one:

$$y = \begin{cases} 1 & u \geq 0 \\ -1 & u < 0 \end{cases} \quad [14]$$

Consider the problem of two sets ω_1 and ω_2 of data in a d -dimensional space. Such a structure can separate

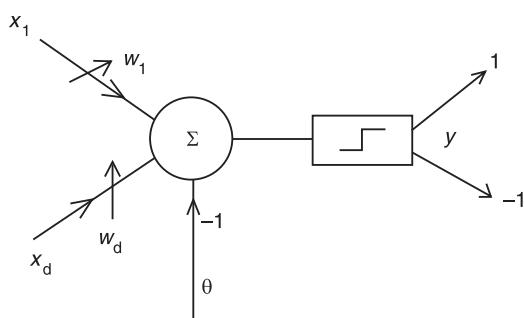

Figure 2 Perception architecture for a neural network.

them, if they are linearly separable by a plane, the equation being:

$$\sum_{i=1}^d w_i x_i - \theta = 0 \quad [15]$$

The output will be (1) for data from ω_1 and (-1) for data from ω_2 . Equation [15] corresponds to a perceptron architecture.

Learning Algorithm

In order to explain the learning algorithm, some modifications have to be introduced in the definition of different data. In fact, the problem will be easier to understand if a $(d+1)$ component is introduced.

To define vectors \mathbf{x} and \mathbf{w} :

$$\mathbf{x} = \begin{pmatrix} -1 \\ x_1 \\ \vdots \\ x_d \end{pmatrix} \quad \mathbf{w} = \begin{pmatrix} \theta \\ w_1 \\ \vdots \\ w_d \end{pmatrix} \quad [16]$$

Then u is simply the inner product of \mathbf{x} by \mathbf{w} :

$$u = \mathbf{w}^T \mathbf{x} \quad [17]$$

Then if two sets are linearly separable:

$$\begin{aligned} \mathbf{w}^T \mathbf{x} \geq 0 &\Rightarrow \mathbf{x} \in \omega_1 \\ \mathbf{w}^T \mathbf{x} < 0 &\Rightarrow \mathbf{x} \in \omega_2 \end{aligned} \quad [18]$$

If the two sets of examples (training sets of respective size n_1 and n_2) are finite sets, they have to be modified in order to get infinite sets. The training set T is constituted by:

$$\begin{aligned} \mathbf{x}_{11}, \mathbf{x}_{12}, \dots, \mathbf{x}_{1n_1}, \mathbf{x}_{21}, \mathbf{x}_{22}, \dots, \dots, \mathbf{x}_{2n_2}, \mathbf{x}_{11}, \\ \mathbf{x}_{12}, \dots, \mathbf{x}_{1n_1}, \mathbf{x}_{21}, \mathbf{x}_{22}, \dots, \mathbf{x}_{2n_2}, \dots \end{aligned} \quad [19]$$

which will be written:

$$\mathbf{x}(1), \mathbf{x}(2), \dots, \mathbf{x}(n_1), \mathbf{x}(n_1 + 1), \mathbf{x}(n_1 + 2), \dots \quad [20]$$

(n) means that it is the n th pattern which is presented to the perceptron.

Beginning with an initial choice $\mathbf{w}(0)$, the training algorithm is a well-known one:

1. $\mathbf{w}(n+1) = \mathbf{w}(n)$ if $\mathbf{w}^T(n)\mathbf{x}(n) > 0$ and $\mathbf{x}(n) \in \omega_1$
2. $\mathbf{w}(n+1) = \mathbf{w}(n)$ if $\mathbf{w}^T(n)\mathbf{x}(n) < 0$ and $\mathbf{x}(n) \in \omega_2$
3. $\mathbf{w}(n+1) = \mathbf{w}(n) - \alpha(n)\mathbf{x}(n)$ if $\mathbf{w}^T(n)\mathbf{x}(n) > 0$ and $\mathbf{x}(n) \in \omega_2$

$$4. \mathbf{w}(n+1) = \mathbf{w}(n) + \alpha(n)\mathbf{x}(n) \quad \text{if } \mathbf{w}^T(n)\mathbf{x}(n) < 0 \\ \text{and } \mathbf{x}(n) \in \omega_1$$

$\alpha(n)$ is the learning parameter: it controls the adjustment applied to each weight. Usually, this parameter is a constant one and the algorithm is called a fixed increment one. The only constraint is that this parameter must be positive.

It can be easily proved that this algorithm (the weights become constant) converges in a finite number of iterations if the sets are linearly separable.

The problem with this algorithm is as follows: at some iteration, if the weights continue to be modified, one does not know if it is due to the fact that the training is not terminated or to the fact that the sets are not linearly separable.

The previous algorithm can be written in another form, which is a more general one. Using the $f(\cdot)$ definition and the $d[\mathbf{x}(n)]$:

$$d[\mathbf{x}(n)] = \begin{cases} 1 & \text{if } \mathbf{x}(n) \in \omega_1 \\ -1 & \text{if } \mathbf{x}(n) \in \omega_2 \end{cases} \quad [21]$$

$d[\mathbf{x}(n)]$ is called the desired output for input $\mathbf{x}(n)$. The algorithm is simply written:

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \alpha(n)\{d[\mathbf{x}(n)] - y(n)\}\mathbf{x}(n) \quad [22]$$

It is the difference between the desired output and the observed input which is used for weight modification. It is an error-correction training algorithm.

Link with a Gaussian Classifier

The perceptron can be considered as a special case of a usual decision problem of classification between two classes in pattern recognition. Suppose there are two classes, each following a normal distribution:

$$\begin{aligned} \omega_1 : N(\mathbf{m}_1, \Sigma_1) \\ \omega_2 : N(\mathbf{m}_2, \Sigma_2) \end{aligned} \quad [23]$$

The equation of a normal distribution is:

$$f(\mathbf{x}/\omega_i) = (2\pi)^{-d/2} \det(\Sigma_i)^{-1/2} \\ \times \exp \left[-(\mathbf{x} - \mathbf{m}_i)^T \Sigma_i^{-1} (\mathbf{x} - \mathbf{m}_i) \right] \quad [24]$$

where: Σ_i is the covariance matrix and \mathbf{m}_i is the mean vector. Consider the case where the two classes are equiprobable and have the same covariance matrix Σ .

The decision between the two classes is based on the log-likelihood function which is the difference between the log-likelihood for class 1 and the log-

likelihood for class 2. The log-likelihood for class ω_i , $l_i(\mathbf{x})$, is:

$$l_i(\mathbf{x}) = \mathbf{m}_i^T \Sigma^{-1} \mathbf{x} \quad [25]$$

Therefore, the log-likelihood function $l(\mathbf{x})$ is written:

$$l(\mathbf{x}) = \\ (\mathbf{m}_1 - \mathbf{m}_2)^T \Sigma^{-1} \mathbf{x} - \frac{1}{2} \left(\mathbf{m}_1^T \Sigma^{-1} \mathbf{m}_1 - \mathbf{m}_2^T \Sigma^{-1} \mathbf{m}_2 \right) \quad [26]$$

This expression is a linear function of vector \mathbf{x} which can be written:

$$l(\mathbf{x}) = \mathbf{w}^T \mathbf{x} - t \quad [27]$$

with:

$$\mathbf{w} = \Sigma^{-1}(\mathbf{m}_1 - \mathbf{m}_2) \quad [28]$$

$$t = \frac{1}{2} \left(\mathbf{m}_1^T \Sigma^{-1} \mathbf{m}_1 - \mathbf{m}_2^T \Sigma^{-1} \mathbf{m}_2 \right) \quad [29]$$

One recognizes the classic perceptron equation. The classification rule is the following:

$l > 0$: assign \mathbf{x} to class ω_1

$l < 0$: assign \mathbf{x} to class ω_2

Gaussian classifier between two classes having the same covariance matrix is analogous to a single layer perceptron.

Conclusion

Notice that the single-layer perceptron is a good solution if the sets are linearly separable. In the case it being not true, no one has any information about the solution of the algorithm. If the convergence is not reached after a finite number of iterations, it can be either because the algorithm needs more iterations or because the sets are not linearly separable.

Multilayer Network

In Figure 3, the structure of a fully connected multi-layer network with hidden layers is indicated. Each neuron is connected with all neurons in the previous layer and with neurons in successive layers.

According to the previously described two phases, this network runs two ways:

1. usual running. An input signal is applied at the input of the network, propagates neuron by

neuron and an output signal is produced. The propagation is a forward one.

2. training running. When an input signal from the set of examples is applied to the network, an error signal is generated from the difference between the observed output and the desired one. This error is propagated backwards, layer by layer through the network. This propagation permits the learning of the weights of the network. This kind of training algorithm is called back propagation algorithm.

Back Propagation Algorithm

An error signal e_k is computed for each neuron k of the output layer at iteration n after the example n (or pattern n) has been presented. It is defined by:

$$e_k(n) = d_k(n) - y_k(n) \quad [30]$$

$d_k(n)$ is the desired output of neuron k at iteration n
 $y_k(n)$ is the observed output of neuron k at iteration n

The instantaneous sum of square error is written from eqn [11]:

$$E(n) = \frac{1}{2} \sum_{k \in O} e_k^2(n) \quad [31]$$

O indicates the output layer of the network. To describe a training method, working pattern by pattern: the adjustments of the weights will be done in accordance with each observed error mean observed for each pattern. Two cases have to be considered: the first is dedicated to weight modification of neurons from the output layer, the second to weight modification of a neuron in a hidden layer.

In the first case, neuron j belongs to the output layer. The internal activity of the neuron is written:

$$u_j(n) = \sum_{i=0}^p w_{ji}(n) y_i(n) \quad [32]$$

where p is the total number of inputs of neuron j . Its output is:

$$y_j(n) = f[u_j(n)] \quad [33]$$

To train the weights, a gradient optimization algorithm is applied. Starting with an initial value $w_{ji}(0)$, the weight $w_{ji}(n)$ is modified at each iteration by a quantity $\Delta w_{ji}(n)$, which is deduced from the instantaneous gradient $\partial E(n)/\partial w_{ji}(n)$:

$$\frac{\partial E(n)}{\partial w_{ji}(n)} = \frac{\partial E(n)}{\partial e_j(n)} \frac{\partial e_j(n)}{\partial y_j(n)} \frac{\partial y_j(n)}{\partial u_j(n)} \frac{\partial u_j(n)}{\partial w_{ji}(n)} \quad [34]$$

It is easy to show the following results:

$$\frac{\partial E(n)}{\partial w_{ji}(n)} = -e_j(n) f'[u_j(n)] y_i(n) \quad [35]$$

The correction factor for weight $w_{ji}(n)$ is written:

$$\Delta w_{ji}(n) = \alpha e_j(n) f'[u_j(n)] y_i(n) \quad [36]$$

with α as the learning parameter. Equation [36] can be written:

$$\Delta w_{ji}(n) = \alpha \eta_j(n) y_i(n) \quad [37]$$

with

$$\eta_j(n) = e_j(n) f'[u_j(n)] \quad [38]$$

where $\eta_j(n)$ is equivalent to a local gradient.

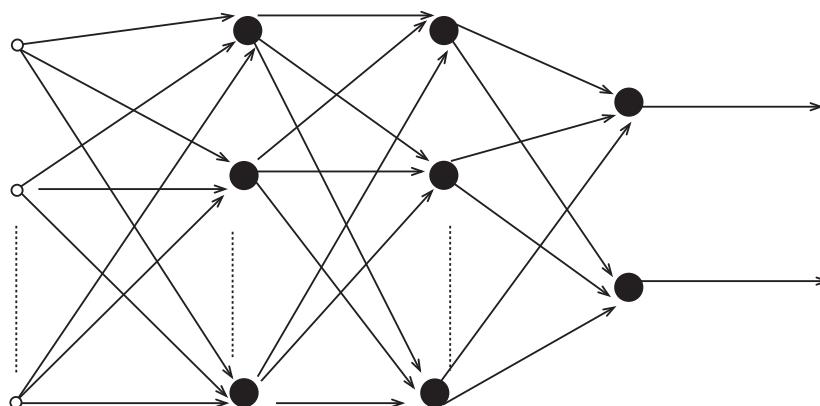

Figure 3 Structure of a fully connected multilayer network with hidden layers.

In the second case, neuron j belongs to a hidden layer if neuron j belongs to a hidden layer, it is not directly accessible. It is impossible to evaluate the $e_j(n)$, difference between the observed and the desired output because it is not known which output is desired. It is necessary to restart the computing, and the error signal for a hidden neuron has to be determined recursively from the error signals of all the neurons to which this neuron is directly connected:

$$\frac{\partial E(n)}{\partial w_{ji}(n)} = \frac{\partial E(n)}{\partial y_j(n)} \frac{\partial y_j(n)}{\partial u_j(n)} \frac{\partial u_j(n)}{\partial w_{ji}(n)} \quad [39]$$

$$\begin{aligned} \frac{\partial E(n)}{\partial w_{ji}(n)} &= \left\{ f'[u_j(n)] \sum \eta_k(n) w_{kj}(n) \right\} y_i(n) \frac{\partial E(n)}{\partial w_{ji}(n)} \\ &= \frac{\partial E(n)}{\partial y_j(n)} f'[u_j(n)] y_i(n) \end{aligned} \quad [40]$$

By a simple computation:

$$\frac{\partial E(n)}{\partial y_j(n)} = - \sum e_k(n) f'[u_k(n)] w_{kj}(n) \quad [41]$$

$$\frac{\partial E(n)}{\partial y_j(n)} = - \sum \eta_k(n) w_{kj}(n) \quad [42]$$

where $\eta_k(n)$ is based on the knowledge of the error signals, $e_k(n)$, for all the neurons belonging to the layer to the immediate right of hidden neuron, j , and are connected to this neuron.

If one uses a sigmoid activation function:

$$y_j(n) = \frac{1}{1 + \exp[-u_j(n)]} \quad [43]$$

So:

$$y'_j(n) = \frac{\exp[-u_j(n)]}{\{1 + \exp[-u_j(n)]\}^2} = y'_j(n)[1 - y'_j(n)] \quad [44]$$

There are two training formula according to the position of the neuron:

1. for a neuron in the output layer:

$$\eta_j(n) = [d_j(n) - y_j(n)] y_j(n)[1 - y_j(n)] \quad [45]$$

2. for a hidden neuron:

$$\eta_j(n) = y_j(n)[1 - y_j(n)] \sum_l \eta_l(n) w_{lj}(n) \quad [46]$$

Rate of Learning

This algorithm is an approximation to the trajectory in the weight space. The role of the training rate parameter is important: the smaller it is, the smaller will be the modifications of the weights from iteration to another one and the smoother will be the trajectory. By choosing a larger value for the training rate parameter, the network may become oscillatory.

A simple method for increasing the rate of learning and for diminishing the risk of instability is to modify the rule by including a momentum term:

$$\Delta w_{jk}(n) = \gamma w_{jk}(n-1) + \alpha \eta_j(n) y_k(n) \quad [47]$$

where γ is positive and controls the loop introduced by using the previous modification.

Adding momentum in the algorithm may have interesting effects on the behavior of the algorithm. It can also prevent the process from finishing in a shallow local minimum of the error function.

Presentation of Patterns

An epoch is a complete presentation of the entire training set. Two ways can be used for presenting patterns:

1. each training pattern is presented singly and the parameter updating is done afterwards. This is how the algorithm has been described each time a pair (x_i, d_i) is presented to the network and the weights are computed according to the error detected at the output. This mode is often called the pattern mode.
2. weights updating is done after the presentation of all the training examples, that is, after an epoch. This mode is called batch mode. The estimation of the mean error is better than in the pattern mode, but the value of updating Δw_{ji} in the pattern mode is an estimate of the same quantity in the batch mode.

Stopping Criteria

In order to finish the weight adjustments, several different criteria may be used. If w^* is the solution corresponding to a minimum of the error function (this minimum can be local or global); for this value, the gradient vector of the error function is zero, so a criterion can be based on the computation of this vector:

1. first criterion: the norm of the gradient vector is smaller than a chosen threshold.

Another possibility is based on the stationary property of the error function for a global or local minimum:

2. second criterion: the absolute rate of change in the average squared error per epoch is smaller than a chosen threshold.

At last, one can use the value of the error function:
 3. third criterion: the value of the error function is smaller than a chosen threshold.

Using a Multilayer Network

If we want to classify patterns coming from M classes, the output of the network may be composed of M cells. If $\mathbf{x}(n)$ is the pattern at the input at time n and $y_m(n)$ is the value of the output of the cell m , the $y_m(n)$ is one of the results of a nonlinear transformation $\Phi(\cdot)$ of the input $\mathbf{x}(n)$:

$$y(n) = \Phi[\mathbf{x}(n)] \quad [48]$$

Suppose now that the desired output is a binary one, that is:

- $d_m(n)$, desired output of cell m is equal to one when the pattern $\mathbf{x}(n)$ belongs to class m
- $d_m(n)$ is equal to zero when the pattern $\mathbf{x}(n)$ belongs to another class.

The mean-squared error J is defined by:

$$J = \frac{1}{2N} \sum_{n=1}^N \|d(n) - \Phi[\mathbf{x}(n)]\|^2 \quad [49]$$

If \mathbf{w}^* is the optimum vector minimizing J , $\Phi(\mathbf{w}^*, \mathbf{x})$ is a mean-squared approximation of $E[\mathbf{d}/\mathbf{x}]$. Under the choice of values of $d_m(n)$, $E[\mathbf{d}/\mathbf{x}]$ equals the *a posteriori* class probability. Therefore if \mathbf{d}_m has a 1 in m th position indicating the pattern belongs to class m , $E[\mathbf{d}_m/\mathbf{x}]$ equals $Pr(\text{class } m/\mathbf{x})$.

So using classical Bayes decision theory, the rule classification is simply:

- $\mathbf{x}(n)$ is associated with class m if $\Phi_m[\mathbf{x}(n)] > \Phi_j[\mathbf{x}(n)] \quad \forall j \neq m$ where $\Phi_m[\mathbf{x}(n)]$ are the components of vector Φ .

So, if the network has been trained using the previous desired outputs, a new vector is classified in the class corresponding to the cell with maximum output. Notice also that the outputs may be used as a value for membership functions in fuzzy decision. Using such a decision rule, the class membership is characterized by a M -components vector $\boldsymbol{\mu}$:

$$\boldsymbol{\mu} = \begin{Bmatrix} y_1 \\ \vdots \\ y_M \end{Bmatrix} \quad [50]$$

The only condition is the use of an activation function with values in $[0, 1]$.

Radial-basis Function Networks

Consider a multilayer network with only a hidden layer and linear outputs (Figure 4). The neuron k of the output layer has the weight w_k , the neuron j of the hidden layer, the weight p_j . The output of such a multilayer network is written:

$$y_k = \sum_j w_{kj} f(p_j, \mathbf{x}) + w_{k0} \quad [51]$$

For example, one can choose a sigmoid function:

$$g(p_j, \mathbf{x}) = \frac{1}{1 + \exp(-p_j^T \mathbf{x})} \quad [52]$$

One can see that the expression [51] is identical to the decomposition of the value y_i on to a basis of functions. The argument of each function is the inner product between the input and a weight vector. This representation is characterized by the important number of neurons implied in the computation of the output.

Definition of Radial-basis Function (RBF) Networks

Radial-basis function networks use this property but are different in the fact that the representation is local by using local basis functions. A prototype is associated with each basis function and the value of this function is dependent on the distance between the input and this prototype.

$$g(p_j, \mathbf{x}) = \phi_i(\mathbf{x}) = \phi_i(\|\mathbf{x} - p_i\|) \quad [53]$$

The functions $\phi_i()$ are maximum for $\mathbf{x} = p_i$ and tend to zero when \mathbf{x} tends to infinity. The most used function is the gaussian one:

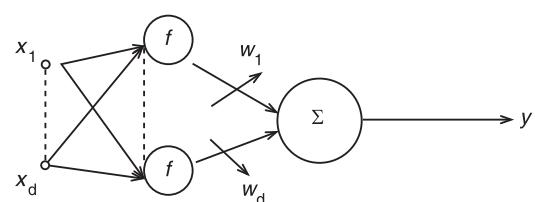

Figure 4 Multilayer network with a hidden layer and linear outputs.

$$\phi_i(\mathbf{x}) = \exp\left[-\frac{1}{2}(\mathbf{x} - \mathbf{p}_i)^T \Sigma_i^T (\mathbf{x} - \mathbf{p}_i)\right] \quad [54]$$

Σ_i is the covariance matrix associated with the corresponding neuron. Often, one uses a diagonal form for Σ_i as $\Sigma_i = \sigma_i^2 I$. In the general case, this matrix must be positive definite. Iso-activation curves are hyper ellipsoids in a $(d - 1)$ space.

Only, a small number of basis functions are implied in the computation of the output for a given input. For example, if an input is in an area far from all the prototypes, the activation of the hidden neurons will be weak. This property is very interesting for some diagnostic problems where the knowledge is incomplete.

Some problems can be solved using radial-basis architecture, which cannot be solved using classical multilayer architecture: they can detect new situations, which is impossible for multilayer networks. For example, all the outputs can be near zero for some inputs, indicating that this input does not correspond to an input used for training.

Consider a radial-basis function network with p hidden neurons, the activation function of each neuron being eqn [54]. The bias term can be put in the sum by using a specific cell with an activation function identical to one. So:

$$y_k = \sum_{j=0}^M w_{kj} \phi_j(\mathbf{x}) \quad [55]$$

$$\phi_0(\mathbf{x}) = 1 \quad \forall \mathbf{x}$$

Let:

$$\mathbf{W} = \{w_{kj}\} \quad \Phi = \{\phi_j\} \quad [56]$$

Therefore:

$$\mathbf{y} = \mathbf{W}\Phi \quad [57]$$

This network, as the previous one, can also solve approximation problems.

Training of RBF networks

In order to simplify the notations, consider a network with only an output, which is called a regularization network.

Three kinds of parameters have to be determined: the prototypes \mathbf{p}_j , the covariance matrices Σ_j and the weight matrix \mathbf{W} . We can use also the error-correction rule, which can be implemented using a gradient-descent procedure.

To define as an instantaneous cost function:

$$E = \frac{1}{2} \sum_{i=1}^n e_i^2 \quad [58]$$

where n is the number of training examples, and e_i is the error signal defined by:

$$e_i = d_i - y_i \quad [59]$$

The solution is given by the following equations:

- weights

$$\begin{aligned} \frac{\partial E(n)}{\partial w_i(n)} &= \sum_{j=1}^n e_j(n) \phi\{\|\mathbf{x}_j - \mathbf{p}_j(n)\|\} \\ w_i(n+1) &= w_i(n) - \alpha_i \frac{\partial E(n)}{\partial w_i(n)} \end{aligned} \quad [60]$$

- prototypes

$$\begin{aligned} \frac{\partial E(n)}{\partial p_i(n)} &= 2w_i(n) \sum_{j=1}^n e_j(n) \phi'\{\|\mathbf{x}_j - \mathbf{p}_i(n)\|\} \\ &\quad \times \Sigma_i^{-1}(n) [\mathbf{x}_j - \mathbf{p}_i(n)] \\ p_i(n+1) &= \mathbf{p}_i(n) - \beta \frac{\partial E(n)}{\partial \mathbf{p}_i(n)} \end{aligned} \quad [61]$$

- Covariance matrix

$$\begin{aligned} \frac{\partial E(n)}{\partial \Sigma_i^{-1}(n)} &= -w_i(n) \sum_{j=1}^n e_j(n) \\ &\quad \times \phi'\{\|\mathbf{x}_j - \mathbf{p}_i(n)\|\} A_{ji}(n) \\ Q_{ji}(n) &= [\mathbf{x}_j - \mathbf{p}_i(n)][\mathbf{x}_i - \mathbf{p}_i(n)]^T \\ \Sigma_i^{-1}(n+1) &= \Sigma_i^{-1}(n) - \gamma \frac{\partial E(n)}{\partial \Sigma_i^{-1}(n)} \end{aligned} \quad [62]$$

Comparison of RBF and Multilayer Networks

These two kind of networks are both approximators. But there are some differences between these two kinds of architecture:

1. a multilayer network may have more than one hidden layer. The RBF network has only one.
2. in a RBF, the hidden layer is nonlinear and the output layer linear. On the other hand, all the layers in the multilayer network are nonlinear.

3. the activation function of a RBF is based on the distance between the pattern and the prototype. The activation function of a multilayer network is based on the computation of an inner product.
4. the nodes of a multilayer network have all the same activation function; it is not the case for RBF networks.
5. the approximation for a RBF network is a local one. On the contrary, multilayer networks realize global approximation in the entire space.

Using RBF Networks

For solving diagnostic problems, one has two possibilities, (i) either to train as many RBF networks as there are classes: each RBF classifies to a class. Then, the input pattern is associated with the output of the network, which is maximum. Or (ii) to train a network with as many outputs as there are classes. The input vector is then associated with the class corresponding to the maximum output. In each case, it is also possible to use fuzzy decision: the value of the output is the value of the membership function for the corresponding class. But this kind of network has another possibility, not existing for multilayer networks: when all the outputs are very small, it may indicate that the pattern comes from a class which has not been represented in the training set. So, this network can classify with an incomplete training set. Further, when there are two or more maximums in the outputs, it may indicate that the pattern may belong to more than one class. RBF network can classify with an ambiguity possibility.

Nomenclature

e	error
i	input
J	mean-squared error
$l(\mathbf{x})$	log-likelihood function
\mathbf{m}	mean vector
O	output layer of the network
t	threshold
T	training set
u	output
w	weight
\mathbf{W}	weight matrix
Σ	covariance matrix

NOISE

Noise Radiated from Elementary Sources

doi:10.1006/rwvb.2001.0145

Introduction

Sound is a pressure wave that propagates through an elastic medium at some characteristic speed. It is the molecular transfer of motional energy and cannot therefore pass through a vacuum. For this wave

motion to exist, the medium has to possess inertia and elasticity. Whilst vibration relates to such wave motion in structural elements, noise relates to such wave motion in fluids (gases and liquids). Two fundamental mechanisms are responsible for sound generation in typical engineering-type applications. They are:

1. the vibration of solid bodies resulting in the generation and radiation of sound energy – these sound waves are generally referred to as structure-borne sound
2. flow-induced noise resulting from pressure fluctuations induced by turbulence and unsteady flows – these sound waves are generally referred to as aerodynamic sound.

Both of the above sound generation mechanisms are associated with changes in volume velocity density due to either structural or aerodynamic excitation mechanisms. Sound pressure can also be generated through changes in force density. For instance, external electric and magnetic fields produce forces on ionized gas or plasma and are characterized as the acoustical sources of plasma waves. This article is, however, only concerned with the sound generation by the changes in the volume velocity density, specifically for the structural excitation mechanism.

With structure-borne sound, the regions of interest are generally in a fluid (usually air) at some distance from the vibrating structure. Here, the sound waves propagate through the stationary fluid (the fluid has a finite particle velocity due to the sound wave, but a zero mean velocity) from a readily identifiable source to the receiver. The region of interest does not therefore contain any sources of sound energy, i.e., the sources which generate the acoustic disturbance are external to it and can be described as boundary conditions. Classical acoustical theory (analysis of the homogeneous wave equation) can be used for the analysis of sound waves generated by these types of sources. The solution for the acoustic pressure fluctuation describes the wave field external to the source as boundary conditions. If required, the source can be accounted for in the wave field by considering the initial, time-dependent conditions.

With aerodynamic sound, the sources of sound are not so readily identifiable and the regions of interest can be either within the fluid flow itself or external to it. When the regions of interest are within the fluid flow, they contain sources of sound energy because the sources are continuously being generated or convected with the flow (e.g., turbulence, vortices, etc.). These aerodynamic sources therefore have to be included in the wave equation for any subsequent analysis of the sound waves in order that they can be correctly identified. The wave equation is now inhomogeneous (because it includes the spatially distributed source terms) and its solution is somewhat different to that of the homogeneous wave equation in that it now describes both the source and the wave fields.

The vast majority of engineering noise and vibration control relates to sources which can be readily identified, and regions of interest which are outside the source region – in these cases the homogeneous wave equation is sufficient to describe the wave field and the subsequent noise radiation provided that the boundary conditions can be specified. There are, however, instances where the inhomogeneous wave equation has to be used in place of the more familiar

homogeneous wave equation. The advantage of the inhomogeneous wave equation is that it can be used for modeling noise radiation from sound sources in both situations. In this article, the noise radiated from elementary vibrational sources is derived directly from the inhomogeneous wave equation.

Sound Waves and Sound Sources

Most noise sources that are of concern to engineers (e.g., vehicles, construction equipment, industrial machinery, appliances, flow-duct systems, etc.) can be modeled in terms of simple sources. It is therefore instructive to analyze the characteristics of some of these idealized sound sources. Consider sound wave propagation through a compressible fluid of mass density ρ_o with finite volume elasticity. The combination of the fluid kinetic inertia and elastic recovery characteristics provides the two requisites for the generation and propagation of sound waves. Sound waves are described by sound pressure $p(\mathbf{r}, t)$ and particle velocity $\mathbf{v}(\mathbf{r}, t)$. The dynamic property of sound waves is characterized by:

$$\rho_o \frac{\partial \mathbf{v}}{\partial t} = -\nabla p \quad [1]$$

and the thermal dynamic property is characterized by:

$$\frac{\partial p}{\partial t} = -P_o \gamma \nabla \cdot \mathbf{v} \quad [2]$$

where P_o is the atmospheric pressure and γ is the ratio of specific heats. The two properties described in eqns [1] and [2] (Euler's field equations) mathematically generate the wave equation (Helmholtz equation) of sound pressure in a compressible fluid:

$$\nabla^2 p - \frac{1}{c_o^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad [3]$$

where $c_o = \sqrt{P_o \gamma / \rho_o}$ is the speed of sound.

As mentioned earlier, sound pressure may be generated through force density (force per unit volume) $\mathbf{q}_f(\mathbf{r}_o)$ and volume velocity density $q_v(\mathbf{r}_o)$ due to external excitation mechanisms, such as the out-of-plane vibration of structures. With the external inputs, the Euler's field equations become:

$$\nabla p + \rho_o \frac{\partial \mathbf{v}}{\partial t} = \mathbf{q}_f(\mathbf{r}_o) \quad [4]$$

and:

$$\frac{1}{P_o \gamma} \frac{\partial p}{\partial t} + \nabla \cdot \mathbf{v} = q_v(\mathbf{r}_o) \quad [5]$$

which results in the inhomogeneous Helmholtz equation:

$$\nabla^2 p - \frac{1}{c_o^2} \frac{\partial^2 p}{\partial t^2} = \nabla \cdot \mathbf{q}_f(\mathbf{r}_o) - \rho_o \frac{\partial q_v(\mathbf{r}_o)}{\partial t} \quad [6]$$

This article is concerned with the sound generation by the volume velocity density. As a result, only the second term in the right-hand side of eqn [6] is considered here.

Green's Functions and the Sound Pressure Field

The general solution to the inhomogeneous wave equation can be obtained by superposition of the acoustic fields due to simple point sources. In order to do this, a Green's function needs to be introduced. Green's functions satisfy the inhomogeneous wave equation, and if the medium surrounding the source is stationary and not restricted by any boundaries, they are commonly referred to as free-space Green's functions. The Green's function can be interpreted as the solution to the wave equation in free space for an applied unit, time-harmonic, point source, or as the solution to the wave equation in free space for a unit, impulsive, point source. An important property of the Green's function is that it is symmetrical, i.e., it remains the same when the source and the receiver positions are interchanged. This property, commonly known as reciprocity, has important applications in noise and vibration control.

The sound pressure in a free field is obtained using the Green's function technique. By solving the steady-state Green's equation:

$$\nabla^2 g(\mathbf{r}|\mathbf{r}_o) + k^2 g(\mathbf{r}|\mathbf{r}_o) = -\delta(\mathbf{r} - \mathbf{r}_o) \quad [7]$$

the free-space Green's function is obtained as:

$$g(\mathbf{r}|\mathbf{r}_o) = \frac{1}{4\pi|\mathbf{r} - \mathbf{r}_o|} e^{-jk|\mathbf{r} - \mathbf{r}_o|} \quad [8]$$

The Green's equation and the Green's function lead to the expression of the sound pressure in free space generated by the volume velocity density of the sound source as:

$$p(\mathbf{r}, t) = j\rho_o \omega \int \frac{q_v(\mathbf{r}_o)}{4\pi|\mathbf{r} - \mathbf{r}_o|} e^{j\omega t - jk|\mathbf{r} - \mathbf{r}_o|} dV_o \quad [9]$$

For a confined source distribution $kr_0 \ll 1$, the sound field generated can be divided into three regions in terms of the ratio between the observation location r and the wavelength λ of the sound wave. Here:

1. for the near field: $r/\lambda \ll 1$
2. for the middle field: $r/\lambda \sim 1$
3. and, for the far field: $r/\lambda \gg 1$

In the near-field region ($kr \ll 1$), the sound pressure distribution as a function of distance r is highly dependent upon the distribution of the sound source. The sound pressure is controlled not only by the $1/r$ terms, but also by higher-order terms such as $1/r^{l+1}$ ($l = 1, 2, 3, \dots$). In the far-field region ($kr \gg 1$), however, the condition of $r \gg r_0$ allows for the following approximations:

$$\frac{1}{|\mathbf{r} - \mathbf{r}_o|} \cong \frac{1}{r} \quad [10a]$$

for the amplitude in eqn [9] and:

$$|\mathbf{r} - \mathbf{r}_o| \cong r - r_o \cos \Theta \quad [10b]$$

for the exponential term in eqn [9], where:

$$\cos \Theta = \cos \theta \cos \theta_o + \sin \theta \sin \theta_o \cos (\phi - \phi_o) \quad [11]$$

As a result, the far-field sound pressure is:

$$p(\mathbf{r}, t) = j\rho_o \omega \frac{e^{j\omega t - jkr}}{4\pi r} \int q_v(\mathbf{r}_o) e^{jkr_o \cos \Theta} dV_o \quad [12]$$

which is a typical radiating field with its magnitude decaying as a function of r^{-1} .

Multipole Descriptions of a Radiating Sound Field

The far-field sound radiation from a confined source can be Taylor-expanded in terms of the nondimensional size of the sound source kr_o :

$$p(\mathbf{r}, t) = j\rho_o \omega \frac{e^{j\omega t - jkr}}{4\pi r} \times \sum_{l=0}^{\infty} \frac{1}{l!} \int q_v(\mathbf{r}_o) (jkr_o \cos \Theta)^l dV_o \quad [13]$$

The directivity-dependent terms $(\cos \Theta)^l$ represent the far-field monopole, dipole, and quadrupole sound radiation when $l = 0, 1, 2$. This can be illustrated by expressing $(\cos \Theta)^l$ in Legendre polynomials and then in spherical harmonic functions. Using the Legendre polynomials to express $(\cos \Theta)^l$, eqn [13] becomes:

$$p(\mathbf{r}, t) = j\rho_o \omega \frac{e^{j\omega t - jkr}}{4\pi r} \times \sum_{l=0}^{\infty} \int q_v(\mathbf{r}_o) a_l P_l(\cos \Theta) dV_o \quad [14]$$

where for $kr_o \ll 1$:

$$a_0 \cong 1 \quad [15a]$$

$$a_1 \cong jkr_o \quad [15b]$$

and:

$$a_2 \cong \frac{1}{3}(jkr_o)^2 \quad [15c]$$

Using the spherical harmonic functions for the Legendre polynomials, we finally obtain the multipole expansion of the radiating sound field:

$$p(\mathbf{r}, t) = j\rho_o \omega \frac{e^{j\omega t - jkr}}{r} \sum_{l=0}^{\infty} \sum_{m=-l}^l q_{lm} Y_{lm}(\theta, \phi) \quad [16]$$

where the coefficients of the (l, m) th-order radiating modes are:

$$q_{lm} = \frac{(-1)^m}{2l+1} \int q_v(\mathbf{r}_o) (jkr_o)^l a_l Y_{lm}^*(\theta_o, \phi_o) dV_o \quad [17]$$

The spherical harmonic functions are defined as:

$$Y_{lm}(\theta, \phi) = \sqrt{\frac{(2l+1)}{4\pi} \frac{(l-m)!}{(l+m)!}} P_l^m(\cos \theta) e^{im\phi} \quad [18]$$

where the $P_l^m(\cos \theta)$ are the associated Legendre polynomials and are:

$$P_l^m(x) = \frac{(-1)^m}{2^l l!} (1-x^2)^{m/2} \frac{d^{l+m}}{dx^{l+m}} (x^2 - 1)^l \quad [19]$$

with $x = \cos \theta$. When m is a negative number, the following relationship is used:

$$Y_{l-m}(\theta, \phi) = (-1)^m Y_{lm}^*(\theta, \phi) \quad [20]$$

In eqn [16], the monopole, dipole, and quadrupole sound radiations are represented by the fundamental radiation modes described by the spherical harmonic functions with $l = 0$ ($m = 0$), $l = 1$ ($m = -1, 0, 1$), and $l = 2$ ($m = -2, -1, 0, 1, 2$). Table 1 shows the corresponding radiating modes and their directivities.

Monopole Sound Radiation

A monopole is a single, spherical sound source which radiates sound waves that are only a function of the radial distance, r , from the source. Some typical examples of monopole sound sources associated with vibrating structures are small electric motors, pumps, and certain types of traffic noise (at medium distances away from a single vehicle – at larger distances the source can sometimes appear to be a dipole). Aerodynamic monopole sound sources include unsteady combustion from a furnace, sirens, pulsed jets, and cavitation.

The volume velocity density of a point source with volume velocity Q at $\mathbf{r}_o = 0$ is:

$$q_v(\mathbf{r}_o) = Q \delta(\mathbf{r}_o) \quad [21]$$

With such a source distribution, the nonzero solution of eqn [17] is:

$$q_{00} = \frac{Q}{\sqrt{4\pi}} \quad [22]$$

which gives rise to the radiated monopole sound pressure:

$$p(\mathbf{r}, t) = \frac{j\rho_o \omega Q}{4\pi r} e^{j\omega t - jkr} \quad [23]$$

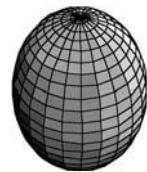

where $j\rho_o \omega Q$ is called the strength of the point source.

Dipole Sound Radiation

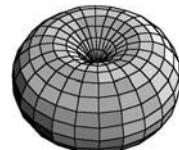

A dipole is a sound source model that is comprised of two monopoles in close proximity to each other. They are also of equal source strength and oscillate 180° out of phase with each other. A net fluctuating force is produced because of this out-of-phase oscillation. A dipole is thus produced by the fluctuating

Table 1 (See Plate 47). Spherical harmonic functions $Y_{lm}(\theta, \phi)$ and their directivities $|Y_{lm}(\theta, \phi)|$ $i = 0$

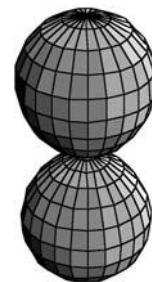

$$Y_{00}(\theta, \phi) = \frac{1}{\sqrt{4\pi}}$$

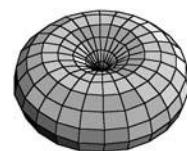

$$Y_{11}(\theta, \phi) = -\sqrt{\frac{3}{8\pi}} \sin \theta e^{j\phi}$$

 $i = 1$

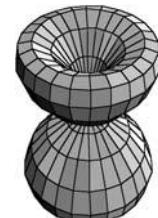

$$Y_{10}(\theta, \phi) = \sqrt{\frac{3}{4\pi}} \cos \theta$$

$$Y_{22}(\theta, \phi) = \frac{1}{4} \sqrt{\frac{15}{2\pi}} \sin^2 \theta e^{j2\phi}$$

 $i = 2$

$$Y_{21}(\theta, \phi) = -\sqrt{\frac{15}{8\pi}} \sin \theta \cos \theta e^{j\phi}$$

$$Y_{20}(\theta, \phi) = \sqrt{\frac{5}{4\pi}} \left(\frac{3}{2} \cos^2 \theta - \frac{1}{2} \right)$$

pressure forces (generated by the out-of-phase oscillations of the two monopoles in close proximity to each other) acting along the axis between the two sources.

Figure 1 shows a distribution of two point sources with equal strength but opposite phase. They are located along the Z axis, separated by a distance, d . The volume velocity density of the source is:

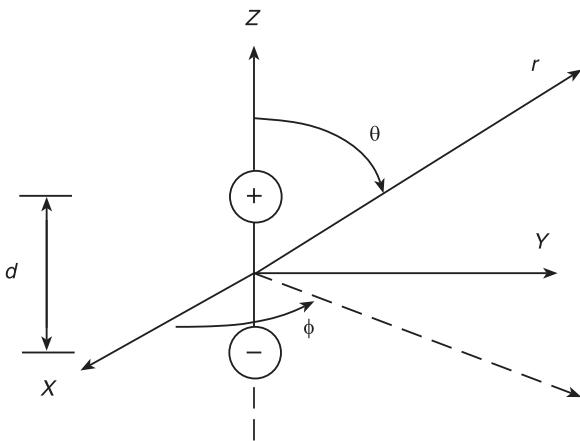

Figure 1 Spherical coordinates and a dipole sound source distribution.

$$q_v(\mathbf{r}_o) = Q\delta\left(\mathbf{r}_o - \frac{d}{2}\hat{z}\right) - Q\delta\left(\mathbf{r}_o + \frac{d}{2}\hat{z}\right) \quad [24]$$

The nonzero term of eqn [17] is:

$$q_{10} = \frac{jQkd}{3} \sqrt{\frac{3}{4\pi}} \quad [25]$$

Thus, the radiated sound pressure has the form:

$$\begin{aligned} p(\mathbf{r}, t) &= j\rho_o\omega \frac{e^{j\omega t-jkr}}{r} q_{10} Y_{10}(\theta, \phi) \\ &= -\rho_o\omega \frac{Qkd}{4\pi r} \cos \theta e^{j\omega t-jkr} \end{aligned} \quad [26]$$

which has the directivity of a dipole ($Y_{10}(\theta\phi)$).

If the source distribution is along the y -axis, as shown in **Figure 2**, the volume velocity density is:

$$q_v(\mathbf{r}_o) = Q\delta\left(\mathbf{r}_o - \frac{d}{2}\hat{y}\right) - Q\delta\left(\mathbf{r}_o + \frac{d}{2}\hat{y}\right) \quad [27]$$

The corresponding nonzero terms from eqn [17] are:

$$q_{11} = \frac{1}{3}Qkd\sqrt{\frac{3}{8\pi}} \quad [28a]$$

and:

$$q_{1-1} = q_{11} \quad [28b]$$

Thus the resultant sound field is:

$$\begin{aligned} p(\mathbf{r}, t) &= j\rho_o\omega \frac{e^{j\omega t-jkr}}{r} [q_{11} Y_{11}(\theta, \phi) + q_{1-1} Y_{1-1}(\theta, \phi)] \\ &= -j\rho_o\omega \frac{Qkd}{4\pi r} \sin \theta \cos \phi e^{j\omega t-jkr} \end{aligned} \quad [29]$$

which also shows a dipole directivity. Note that the dumbbell radiation directivity in the y -axis is due to the superposition of two donut-shaped radiating modes ($Y_{11}(\theta\phi)$ and $Y_{1-1}(\theta\phi)$).

Quadrupole Sound Radiation

Monopoles were modeled as single oscillating spheres, and dipoles were modeled as two equal spheres oscillating out of phase. A natural extension to these acoustic source models is two dipole sources in close proximity to each other and oscillating 180° out of phase with each other. Such a sound source is called a quadrupole. Whereas a dipole has one axis (i.e., the fluctuating pressure forces act along the axis between the two sources), a quadrupole has two. The two dipoles oscillating out of phase with each other result in no net addition or subtraction of mass away from the source, and no resultant force, i.e. there is no physical mechanism available for the mass or the momentum to vary. The quadrupole does, however, apply a stress to the medium and it is this fluctuating stress that generates the sound (monopoles generate sound via fluctuating surface velocities or the addition/subtraction of mass from a source region, and dipoles generate sound via fluctuating forces). In gas flows, for instance, quadrupoles are generated by the viscous stresses within the gas.

Both longitudinal (**Figure 3A**) and lateral (**Figure 3B**) quadrupoles are also special cases of source distribution according to eqn [17]. The source distribution of a longitudinal quadrupole is

$$q_v(\mathbf{r}_o) = Q\delta(\mathbf{r}_o - d\hat{x}) - 2Q\delta(\mathbf{r}_o) + Q\delta(\mathbf{r}_o + d\hat{x}) \quad [30]$$

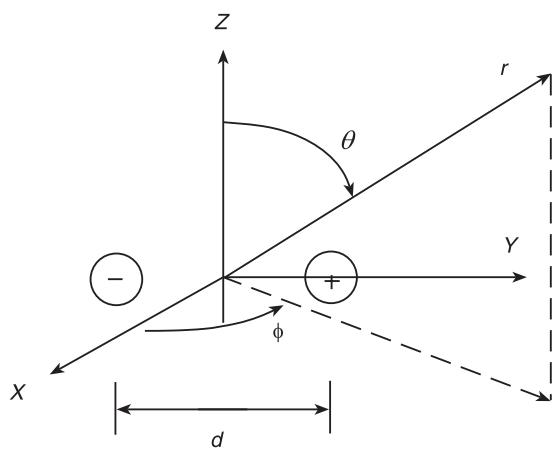

Figure 2 Dipole source distribution in the y -axis.

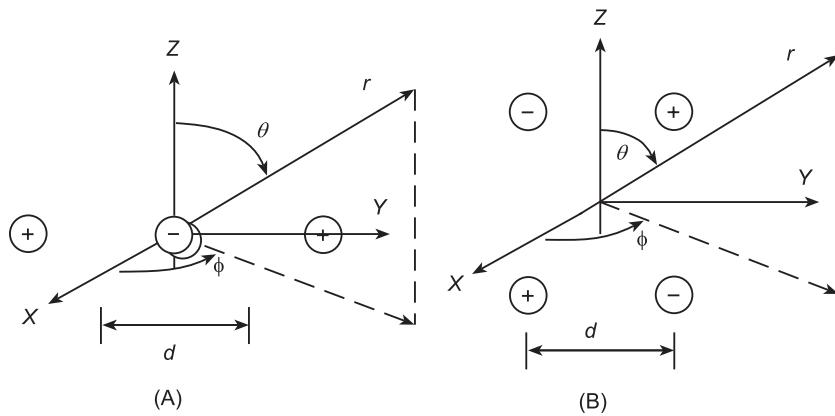

Figure 3 (A) A longitudinal quadrupole and (B) a lateral quadrupole.

whilst that of a lateral quadrupole is:

$$\begin{aligned} q_v(\mathbf{r}_o) = & Q \delta\left(\mathbf{r}_o - \frac{d}{2}\hat{\mathbf{y}} - \frac{d}{2}\hat{\mathbf{z}}\right) \\ & - \delta\left(\mathbf{r}_o + \frac{d}{2}\hat{\mathbf{y}} - \frac{d}{2}\hat{\mathbf{z}}\right) \\ & + \delta\left(\mathbf{r}_o + \frac{d}{2}\hat{\mathbf{y}} + \frac{d}{2}\hat{\mathbf{z}}\right) \\ & - \delta\left(\mathbf{r}_o - \frac{d}{2}\hat{\mathbf{y}} + \frac{d}{2}\hat{\mathbf{z}}\right) \end{aligned} \quad [31]$$

For a longitudinal quadrupole, the nonzero q_{lm} are:

$$q_{22} = -\frac{1}{30}Q(kd)^2 \sqrt{\frac{15}{2\pi}} \quad [32a]$$

$$q_{2-2} = q_{22} \quad [32b]$$

and:

$$q_{20} = -\frac{1}{15}Q(kd)^2 \sqrt{\frac{5}{4\pi}} \quad [32b]$$

Thus, the radiated sound pressure is:

$$\begin{aligned} p(\mathbf{r}, t) = & j\rho_o\omega \frac{e^{j\omega t-jkr}}{r} [q_{20}Y_{20}(\theta, \phi) \\ & + q_{2-2}Y_{2-2}(\theta, \phi) + q_{22}Y_{22}(\theta, \phi)] \\ = & -j\rho_o\omega Q(kd)^2 \frac{e^{j\omega t-jkr}}{4\pi r} [1/3 - \sin^2\theta \sin^2\phi] \end{aligned} \quad [33]$$

The lateral quadrupole has the following nonzero q_{lm} terms:

$$q_{21} = \frac{1}{15}Q(kd)^2 \sqrt{\frac{15}{8\pi}} \quad [34a]$$

and:

$$q_{2-1} = q_{21} \quad [34b]$$

which results in:

$$\begin{aligned} p(\mathbf{r}, t) = & j\rho_o\omega \frac{e^{j\omega t-jkr}}{r} [q_{2-1}Y_{2-1}(\theta, \phi) + q_{21}Y_{21}(\theta, \phi)] \\ = & \rho_o\omega Q(kd)^2 \frac{e^{j\omega t-jkr}}{4\pi r} \sin\theta \cos\theta \sin\phi \end{aligned} \quad [35]$$

The directivity patterns of the longitudinal and lateral quadrupole sound radiation are shown in Table 2.

Sound Power Radiation

The sound power radiated from a confined sound source is calculated by the far-field sound pressure and fluid particle velocity:

$$W = \frac{1}{2} \int_0^\pi \int_0^{2\pi} \text{Re}[p v_r^*] r^2 \sin\theta d\theta d\phi \quad [36]$$

where v_r is the far-field fluid particle velocity in the radial direction:

$$\begin{aligned} v_r(\mathbf{r}, t) = & -\frac{1}{j\rho_o\omega} \frac{\partial p(\mathbf{r}, t)}{\partial r} \\ \cong & \frac{j\rho_o\omega e^{j\omega t-jkr}}{\rho_o c_o r} \sum_{l=0}^{\infty} \sum_{m=-l}^l q_{lm} Y_{lm}(\theta, \phi) \end{aligned} \quad [37]$$

The orthogonality of the spherical harmonic functions:

$$\int_0^\pi \int_0^{2\pi} Y_{l'm'}^*(\theta, \phi) Y_{lm}(\theta, \phi) \sin\theta d\theta d\phi = \delta_{ll'} \delta_{mm'} \quad [38]$$

Table 2 (See Plate 48). Directivity distribution of a longitudinal and a lateral quadrupole sound radiation

Longitudinal quadrupole radiation

$$p(r, t) = -j\rho_o \omega Q(kd)^2 \frac{e^{j\omega t - jkr}}{4\pi r} \left[\frac{1}{3} - \sin^2 \theta \sin^2 \phi \right]$$

Lateral quadrupole radiation

$$p(r, t) = \rho_o \omega Q(kd)^2 \frac{e^{j\omega t - jkr}}{4\pi r} \sin \theta \cos \theta \sin \phi$$

allows the multipole sound power radiation to be expressed as:

$$W = \frac{(\rho_o \omega)^2}{2\rho_o c_o} \sum_{l=0}^{\infty} \frac{(kd)^{2l}}{(2l+1)^2} \times \sum_{m=-l}^l \left| \int q_v(\mathbf{r}_o) (r_o/d)^l a_l Y_{lm}^*(\theta_o, \phi_o) dV_o \right|^2 [39]$$

where d may be regarded as the characteristic dimension of the sound source. It can be noted from eqn [39] that the power radiated from monopoles, dipoles, and quadrupoles is related to kd as follows:

$$W_M = \frac{(\rho_o \omega)^2}{2\rho_o c_o} \left| \int q_v(\mathbf{r}_o) Y_{00}^*(\theta_o, \phi_o) dV_o \right|^2 [40a]$$

$$W_D = \frac{(\rho_o \omega)^2}{18\rho_o c_o} (kd)^2 \times \sum_{m=-1}^1 \left| \int q_v(\mathbf{r}_o) (r_o/d) Y_{1m}^*(\theta_o, \phi_o) dV_o \right|^2 [40b]$$

and:

$$W_Q = \frac{(\rho_o \omega)^2}{450\rho_o c_o} (kd)^4 \times \sum_{m=-2}^2 \left| \int q_v(\mathbf{r}_o) (r_o/d)^2 Y_{2m}^*(\theta_o, \phi_o) dV_o \right|^2 [40c]$$

A comparison can be made between the sound-radiating efficiencies of monopoles, dipoles, and quadrupoles by comparing eqns [40a]–[40c]. The ratio of the sound power radiated by a dipole to that radiated by a monopole is:

$$\frac{W_D}{W_M} \sim (kd)^2 \sim \left\{ \frac{d}{\lambda} \right\}^2 [41a]$$

and the ratio of the sound power radiated by a quadrupole to that radiated by a monopole is:

$$\frac{W_Q}{W_M} \sim (kd)^4 \sim \left\{ \frac{d}{\lambda} \right\}^4 [41b]$$

It can be seen from eqns [41a] and [41b] that at low frequencies (long wavelengths), the dipole and the quadrupole are very much less efficient radiators of noise than at high frequencies (shorter wavelengths) when compared with a monopole of the same source strength. It can also be deduced that monopoles are the most efficient radiators of sound, whereas quadrupoles are the least efficient.

As mentioned previously, this chapter is primarily concerned with sound generation by the volume velocity input due to structural vibration. The relationships in eqns [40] and [41] can also be derived for aerodynamic-type sound sources via scaling relationships with flow velocity. In this instance, the sound power generated by a monopole scales with the fourth power of velocity, the sound power generated by a dipole scales with the sixth power of velocity, and the sound power generated by a quadrupole scales with the eighth power of velocity.

Superposition of Elementary Sources

Sound Radiation by a Tripole Sound Source

According to Huygens' principle, each point on a wavefront may be regarded as a source (Huygens' source) of secondary waves for the new wavefront at a later time. The strength of the Huygens' source consists of a dipole term for the pressure on the

surface of the wavefront, and a monopole term for the air particle velocity. Using the Helmholtz–Kirchhoff integral for sound pressure in a space enclosed by the wavefront surface and the surface at infinity, the radiated sound pressure by a Huygens' source at the wavefront \mathbf{r}' away from a point source is:

$$p_H(r, \omega) = \frac{A'}{r} [(1 + jkr') + jkr' \cos \theta] e^{-jkr} \quad [42]$$

where r is the distance from the Huygens' source to the observation point in the far field ($kr \gg 1$), θ is an angle between \mathbf{r}' and \mathbf{r} , and A' is proportional to the sound pressure at \mathbf{r}' . The sound radiation directivity can be interpreted as the superposition of the sound field radiated by a dipole and a monopole mode with the dipole vector direction perpendicular to that of \mathbf{r}' :

$$p_H(r, \omega) = \frac{\sqrt{4\pi} A'}{r} \left[(1 + jkr') Y_{00} + \frac{jkr'}{\sqrt{3}} Y_{10} \right] e^{-jkr} \quad [43]$$

Figure 4 shows the magnitude directivity of a Huygens' source for $kr' \gg 1$.

A practical tripole sound source has been invented for a limited frequency range using two loudspeakers, and is currently available. One of the loudspeakers is within an enclosure and is used as the monopole source, and the other loudspeaker is coupled with two short tubes of appropriate length at the front and rear surfaces, and is used as a dipole source. The tube diameters are the same as that of the loudspeaker.

Steering of Sound Beams

Consider an array of monopole sound sources with the same magnitude of volume velocity and equally spaced by Δz along the Z axis (**Figure 5**). A time delay τ may be introduced between neighboring monopoles. Thus, the total sound pressure at a far-field location due to the superposition of $2N + 1$ monopole sources is:

$$p(\mathbf{r}, \omega) = \sum_{n=-N}^N \frac{Q}{4\pi r_n} e^{-jkr_n - jn\omega\tau} \quad [44]$$

For sound pressure in the far field ($r \gg 2N\Delta z$), r_n in the denominators of eqn [44] is approximated by r and that in the exponential terms by $r - n\Delta z \cos \theta$. Thus, the far-field sound pressure radiated by the monopole array is:

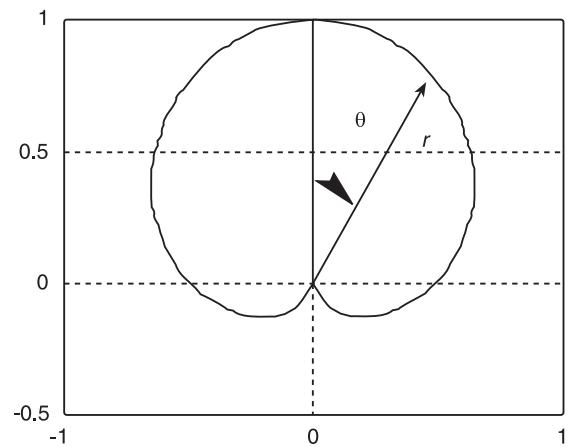

Figure 4 Magnitude directivity of a Huygens' source.

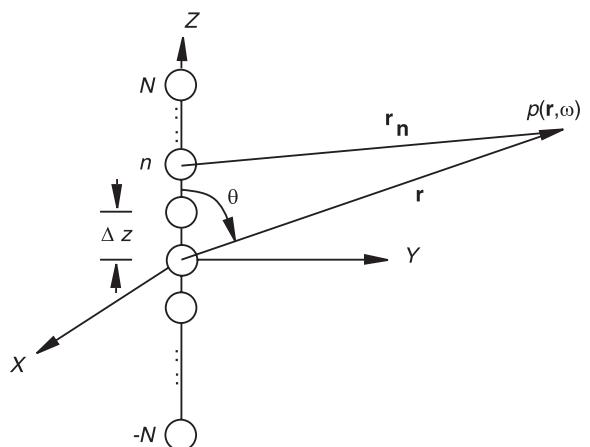

Figure 5 An array of monopole sound sources as an acoustic steering system.

$$\begin{aligned} p(\mathbf{r}, \omega) &= \frac{Q}{4\pi r} e^{-jkr} \sum_{n=-N}^N e^{jnk(\Delta z \cos \theta - \tau/c_o)} \\ &= \frac{Q}{4\pi r} e^{-jkr} \frac{\sin \left[\frac{k(2N+1)}{2} (\Delta z \cos \theta - \tau/c_o) \right]}{\sin \left[\frac{k}{2} (\Delta z \cos \theta - \tau/c_o) \right]} \end{aligned} \quad [45]$$

For far-field sound radiation, the angular distribution of the sound pressure is described by the directivity index:

$$D(\theta) = \left| \frac{\sin \left[\frac{k(2N+1)}{2} (\Delta z \cos \theta - \tau/c_o) \right]}{(2N+1) \sin \left[\frac{k}{2} (\Delta z \cos \theta - \tau/c_o) \right]} \right|^2 \quad [46]$$

The characteristics of the directivity for $\tau = 0$ are determined by the length of the array $L = 2N\Delta z$ with

respect to the wavelength, and by the total number of monopoles ($2N + 1$) in the array.

For N fixed, the compactness of the array length measured by kL determines the characteristics of the directivity. If $kL < 1$, the radiation of a compact monopole array gives rise to omnidirectional sound pressure. When kL increases, the sound field is characterized by major lobes with peak sound radiation. For $\tau = 0$, eqn [46] implies that the angular positions of the major lobes are:

$$\theta_m = \cos^{-1} \frac{m\lambda}{\Delta z} \quad [47]$$

where $m = 0, 1, 2 \dots m = 0$ corresponds to the primary major lobe, whilst $m > 0$ corresponds to the secondary major lobes. In applications where a single major lobe is required, the following condition must be satisfied:

$$\frac{\Delta z}{\lambda} < 1 \quad [48]$$

This characteristic is illustrated in Figure 6, which shows the directivity indices of an array of $2N + 1 = 5$ for various values of $\Delta z/\lambda$.

When $\Delta z/\lambda < 1$, the primary major lobe becomes narrow as the total number of monopole sources increases, which is illustrated in Figure 7 for $\Delta z/\lambda = 0.25$ and $N = 2, 6, 10$.

To steer the radiation angle of the primary major lobe, a nonzero time delay τ can be introduced. Here, the angular position of the lobe is at:

$$\theta_s = \cos^{-1} \frac{\tau}{\Delta z c_o} \quad [49]$$

which can be varied by adjusting the time delay τ .

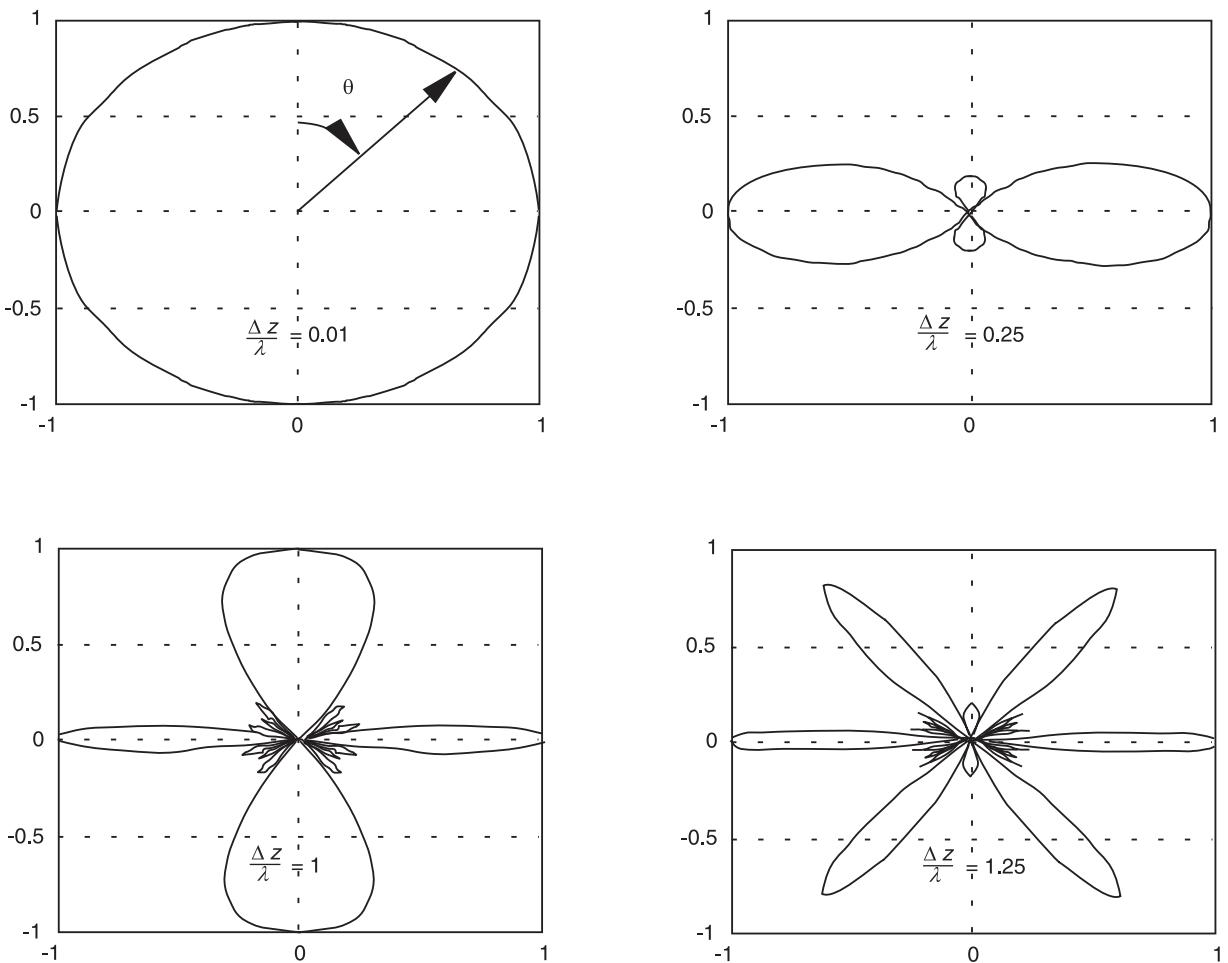

Figure 6 The directivity indices of an array of monopoles with $2N + 1 = 5$ and various $\Delta z/\lambda$.

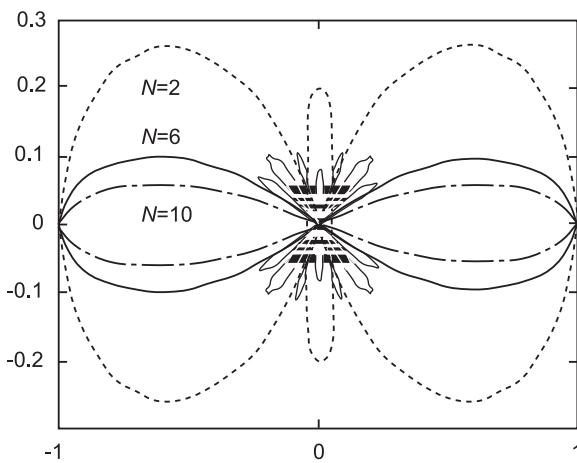

Figure 7 The primary major lobe becomes narrow as the total number of monopole sources increases ($\Delta z/\lambda = 0.25$).

Conclusions

This article has focused on the noise radiation characteristics of elementary acoustical sources. It has been limited to sound generation by the changes in the volume velocity density, specifically for structural excitation mechanisms. The noise radiation characteristics have been derived from the inhomogeneous Helmholtz equation (eqn [6]) using the Green's function and multipole expansions. Noise radiation characteristics have been quantified for the three primary sound sources (monopoles, dipoles, and quadrupoles) used in acoustic modeling. The sound power radiation characteristics of these elementary sources have also been considered together with the effects of elementary source superposition. These include the sound radiation by a tripole sound source and the effects of steering of sound beams via monopole arrays.

Nomenclature

d	distance
$p(r, t)$	sound pressure
$v(r, t)$	particle velocity
W	power
γ	ratio of specific heats
λ	wavelength
τ	time delay

Introduction

Whilst the lumped-parameter approach to mechanical vibrations is adequate to describe mode shapes and natural frequencies, it is not suitable for relating vibrations to radiated noise. One therefore has to use the fundamental wave approach to obtain an understanding of the essential features of mechanical vibrations as they relate to sound radiation and sound transmission. These interactions between sound waves and the vibrations of elastic structures form a very important part of engineering noise and vibration control.

Because elastic structures can store energy in shear and compression, all types of waves can be sustained, i.e., compressional (longitudinal) waves, flexural (transverse or bending) waves, shear waves, and torsional waves. On the other hand, since fluids can only store energy in compression, they can only sustain compressional (longitudinal) waves. Flexural waves are the only type of structural waves that play a significant part in sound radiation and transmission. Perpendicular to the surface of the structure, the flexural wave particle velocities are capable of creating volume velocities in the fluid and this results in an

effective exchange of energy between the structure and the fluid.

Acoustic loads on arbitrary surfaces are associated with the radiated sound pressure at regions in close proximity to the surfaces. This is in addition to any mechanical excitation of the surface, which could be the primary source of vibration in the first instance. If the fluid medium is air (as is usually the case in engineering noise control), then this acoustic radiation load is generally very small and the sound pressure field at regions away from the source can be estimated from the bending wave particle velocities associated with the mechanical excitation. If, however, the fluid medium is a liquid, then the acoustic radiation load can become very significant and has to be accounted for – the radiation load modifies the forces acting on the structure, a feedback coupling between the fluid and the structure is set up, and the structure subsequently becomes fluid-loaded. This article is, however, mainly concerned with structure-borne sound in the audiofrequency range with air as the fluid medium. These conditions are often representative of typical engineering noise control problems such as sound radiation from plates, shells, and cylinders in industrial-type environments and sound transmission through building partitions.

At its most fundamental level, the radiation of sound from a vibrating boundary surface can be formulated in terms of an integral equation involving Green's functions with an imposed radiation condition, i.e., the radiation condition ensures that the integral equation for the radiated sound pressure represents outward-traveling sound waves. Green's functions were introduced in the article **Noise**, Noise radiated from elementary sources on noise radiation from elementary sources and they represent solutions to the wave equation – they can also be considered to be either frequency response functions or impulse response functions between the source and receiver. In its most general form, the integral equation is attributable to Kirchhoff, although Helmholtz modified it for single-frequency (harmonic) applications. The derivation of the integral and a discussion about the radiation condition is provided in the literature. The integral is sometimes referred to as the Kirchhoff–Helmholtz integral equation (eqn [3]). The Kirchhoff–Helmholtz integral equation relates harmonic vibrational motion of the surface to the radiated sound pressure field in the enclosed fluid. It can be interpreted as representing the sound pressure field of a vibrating surface by a distribution of volume velocity sources and forces on the surface. The velocity sources and the forces are related to normal surface velocity and surface pressure respectively. It is important to note that the surface pressure and the

normal surface vibrational velocity are interrelated and not independent of each other.

For certain sound fields with simple boundary excitations, an appropriate Green's function may be constructed such that its normal derivative can be forced to be zero, thus eliminating the requirement for a knowledge of the surface pressure distributions, i.e., only a knowledge of the surface vibrational velocity is required. For complicated and three-dimensional boundary surfaces, such as truck cabins, analytical solutions are generally not possible, and the usual procedure is either to use numerical techniques to solve the integral equation, or to use experimental techniques to establish the Green's function. Rayleigh modified the Kirchhoff–Helmholtz integral equation for the specific case of a planar source located in an infinite baffle and illustrated that it is equivalent to a distribution of point sources (eqn [10]).

Sound Pressure in the Presence of Boundaries

The nature of sound fields in the presence of boundaries is described by the Helmholtz equation and the conditions of sound pressure and/or air particle velocity on the boundaries. For a steady-state sound field, the Helmholtz equation is:

$$\nabla^2 p + k^2 p = 0 \quad [1]$$

To express the sound pressure $p(\mathbf{r}, \omega)$ due to boundary vibration and reflection, a Green's function may be constructed to satisfy the following equation:

$$\nabla^2 G(\mathbf{r}|\mathbf{r}') + k^2 G(\mathbf{r}|\mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \quad [2]$$

and the relevant boundary conditions. Using eqns [1] and [2], and Green's theorem, Kirchhoff obtained the solution for sound pressure in an integral form (the Kirchhoff–Helmholtz integral):

$$p(\mathbf{r}, \omega) = \oint_s \left[G(\mathbf{r}|\mathbf{r}') \frac{\partial p}{\partial n'} - p(\mathbf{r}', \omega) \frac{\partial G(\mathbf{r}|\mathbf{r}')}{\partial n'} \right] ds' \quad [3]$$

where $\partial p / \partial n'$ represents the gradient on the boundary surface. The gradient is normal to the boundary surface and outwards positive from the volume where the sound is generated.

A special and important situation is the sound radiation from baffled plates. For this situation, the velocity of the plate in S_1 and that of the rigid baffle in S_2 (as shown in Figure 1) are:

$$v_B = \begin{cases} v_n(\mathbf{r}_p, \omega) e^{j\omega t} & \mathbf{r}_p = (x', y') \in S_1 \\ 0 & \mathbf{r}_p = (x', y') \in S_2 \end{cases} \quad [4]$$

Applying the Euler's field equation, the pressure gradient on the boundary surface is related to the boundary vibration velocity by:

$$\frac{\partial p}{\partial n'} = j\rho_0 \omega v_B \quad [5]$$

For such a boundary, where the pressure gradient on the surface is known, the Green's function to be constructed should satisfy:

$$\frac{\partial G(\mathbf{r}|\mathbf{r}')}{\partial n'} = 0 \quad [6]$$

at the boundary surface. Such a surface in **Figure 1** corresponds to $z = 0$. Thus, in this instance, the Green's function is selected as:

$$G(\mathbf{r}|\mathbf{r}') = \frac{1}{4\pi} \left(\frac{e^{-jkR_+}}{R_+} + \frac{e^{-jkR_-}}{R_-} \right) \quad [7]$$

where $R_+ = \sqrt{(x - x')^2 + (y - y')^2 + (z - z_+)^2}$, and $R_- = \sqrt{(x - x')^2 + (y - y')^2 + (z - z_-)^2}$ with z_+ and z_- being small positive and negative perturbations in the Z direction. This Green's function has a zero gradient on the boundary $z = 0$, i.e.:

$$\frac{\partial G(\mathbf{r}|\mathbf{r}')}{\partial z'}|_{z'_+, z'_- \rightarrow 0} = 0 \quad [8]$$

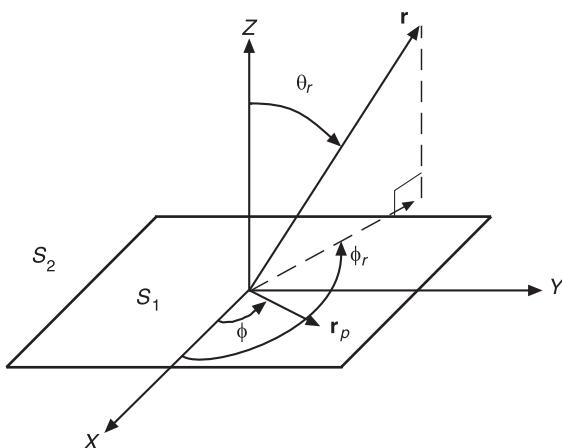

Figure 1 Coordinate system of a baffled plate.

and when the sources are limited to the boundary surface $\mathbf{r}' \rightarrow \mathbf{r}_p$, and we have:

$$G(\mathbf{r}|\mathbf{r}_p) = \frac{1}{2\pi} \frac{e^{-jkR}}{R} \quad [9]$$

where $R = |\mathbf{r} - \mathbf{r}_p| = \sqrt{(x - x')^2 + (y - y')^2 + z^2}$.

Substituting eqns [8] and [9] into the Kirchhoff-Helmholtz integral results in the Rayleigh integral for sound radiation from a baffled plate:

$$p(\mathbf{r}, \omega) = \frac{j\rho_0 \omega}{2\pi} \int_{S_1} \frac{v_n(\mathbf{r}_p, \omega)}{R} e^{-jkR} ds \quad [10]$$

where the time-dependent term $e^{j\omega t}$ is assumed for both sound pressure and plate velocity.

Modal Vibration of a Plate

The steady-state displacement $w(\mathbf{r}_p, \omega)$ of the flexural vibration of a thin plate of length L_x and width L_y at angular frequency ω is described as:

$$\frac{Eb^3}{12(1-\nu^2)} \nabla^4 w + j\omega Cw - \rho h \omega^2 w = p_p + p_e \quad [11]$$

where E , ν , and C are respectively the Young's modulus, Poisson's ratio, and damping coefficient of the plate material, whilst ρ and b are the density and thickness of the plate. p_p is the acoustic radiation loading, and p_e is the pressure due to an external excitation. The effect of acoustic loading on a baffled plate is only important when the plate is very thin or the medium of sound radiation is significantly dense (such as water). In this chapter, the acoustic loading is assumed to be second-order and is ignored.

The plate vibrational response comprises mode shape functions ψ_{mn} and natural frequencies ω_{mn} of the (m, n) th modes. They are obtained from the solution of the eigenvalue equation:

$$\frac{Eb^2}{12\rho(1-\nu^2)} \nabla^4 \psi_{mn} = \omega_{mn}^2 \psi_{mn} \quad [12]$$

with respect to the boundary conditions of the displacement at the plate edges.

The method of modal analysis begins with the expansion of the plate displacement by the mode shape functions:

$$w(\mathbf{r}_p, \omega) = \sum_{m,n} W_{mn} \psi_{mn}(\mathbf{r}_p) \quad [13]$$

The orthogonal properties of the mode shape functions allow for the solution of the modal amplitudes of the plate displacement:

$$W_{mn} = \frac{P_{mn}}{\Lambda_{mn} [\rho h (\omega_{mn}^2 - \omega^2) + jC\omega]} \quad [14]$$

where the modal force is:

$$P_{mn} = \int_{S_1} p_e(\mathbf{r}_p) \psi_{mn}(\mathbf{r}_p) \, ds \quad [15]$$

and:

$$\Lambda_{mn} = \int_{S_1} \psi_{mn}^2(\mathbf{r}_p) \, ds \quad [16]$$

Sound Power Associated with Plate Vibration

Far-field Approach

For the far-field condition ($r \gg \max[L_x, L_y]$), the R in the denominator of the Rayleigh integral (eqn [10]) is approximated by $R \cong r$, whilst the R in the phase term is approximated by:

$$R \cong r - |\mathbf{r}_p| \cos \Theta \quad [17]$$

where $\cos \Theta$ is the cosine of the angle between the surface vector \mathbf{r}_p and the observation vector \mathbf{r} and:

$$\cos \Theta = \cos \phi \sin \theta_r \cos \phi_r + \sin \phi \sin \theta_r \sin \phi_r \quad [18]$$

where θ_r and ϕ_r are the elevation and azimuth angles of \mathbf{r} , whilst ϕ is the rotation angle of \mathbf{r}_p from the x -axis. As a result of these far-field approximations, the far-field sound pressure is:

$$p(\mathbf{r}, \omega) = -\frac{\rho_o \omega^2}{2\pi r} \left[\sum_{m,n} W_{mn} \int_{S_1} \psi_{mn} e^{j|\mathbf{r}_p|k \cos \Theta} \, ds \right] e^{-jkr} \quad [19]$$

which is used to give the radiated sound power into the far-field:

$$\begin{aligned} W &= \frac{1}{2\rho_o c_o} \int_0^{2\pi} \int_0^{\pi/2} |p(\mathbf{r}, \omega)|^2 r^2 \sin \theta_r \, d\theta_r \, d\phi_r \\ &= \frac{\rho_o c_o}{2} \left(\frac{k\omega}{2\pi} \right)^2 \sum_{m,n} \sum_{m',n'} W_{mn} W_{m'n'}^* \\ &\quad \times \int_0^{2\pi} \int_0^{\pi/2} \gamma_{mn}(\theta_r \phi_r) \gamma_{m'n'}^*(\theta_r \phi_r) \sin \theta_r \, d\theta \, d\phi_r \end{aligned} \quad [20]$$

where the modal directivity term is:

$$\gamma_{mn}(\theta_r \phi_r) = \int_{S_1} \psi_{mn} e^{j|\mathbf{r}_p|k \cos \Theta} \, ds \quad [21]$$

The total sound power of the plate sound radiation is usually dominated by the self-radiation terms in eqn [20] where $(m, n) = (m', n')$. Those terms with $(m, n) \neq (m', n')$ correspond to the mutual interaction of plate modes through their radiated sound.

To describe the effectiveness of sound radiation of a vibrating plate, a nondimensional ratio between the radiated power and the quadratic velocity of the plate is used. This radiation efficiency σ is defined as:

$$\sigma = \frac{W}{\rho_o c_o S_1 \omega^2 \langle w^2 \rangle} \quad [22]$$

where

$$\langle w^2 \rangle = \frac{1}{2S_1} \int_{S_1} w^2 \, ds$$

is the space- and time-averaged quadratic displacement. The single-mode radiation efficiency can be used to study the sound power radiation in terms of the mode shape functions and the relative size of the plate with respect to the wavelength of the radiated sound (kL_x, kL_y). Here:

$$\sigma_{mn} = \left(\frac{k}{2\pi} \right)^2 \frac{\int_0^{2\pi} \int_0^{\pi/2} |\gamma_{mn}(\theta_r \phi_r)|^2 \sin \theta_r \, d\theta_r \, d\phi_r}{S_1 \langle \psi_{mn}^2 \rangle} \quad [23]$$

where $\langle \psi_{mn}^2 \rangle$ is the square of the space-averaged mode shape function.

Near-field Approach

The sound power can also be evaluated on the surface of the plate by using the plate velocity and the sound pressure on the plate:

$$\begin{aligned} W &= \frac{1}{2} \operatorname{Re}[p\dot{w}^*]_{z=0} \\ &= \frac{1}{2} \rho_o c_o \omega^2 \sum_{m,n} \sum_{m',n'} W_{mn} W_{m'n'}^* \operatorname{Re}\{Z_{mn,m'n'}\} \end{aligned} \quad [24]$$

where $Z_{mn,m'n'} = \zeta_{mn,m'n'} + j\chi_{mn,m'n'}$ is the specific acoustic radiation impedance with:

$$\zeta_{mn,m'n'} = \frac{k}{2\pi} \int_{S_1} \int_{S_1} \psi_{mn} \psi_{m'n'} \frac{\sin k|\mathbf{r}_p - \mathbf{r}'_p|}{|\mathbf{r}_p - \mathbf{r}'_p|} ds ds' \quad [25a]$$

and:

$$\chi_{mn,m'n'} = \frac{k}{2\pi} \int_{S_1} \int_{S_1} \psi_{mn} \psi_{m'n'} \frac{\cos k|\mathbf{r}_p - \mathbf{r}'_p|}{|\mathbf{r}_p - \mathbf{r}'_p|} ds ds' \quad [25b]$$

Using the near-field approach, the modal sound radiation efficiency is expressed as:

$$\sigma_{mn} = \frac{\zeta_{mn,m'n'}}{S_1 < \psi_{mn}^2 >} \quad (m, n) = (m', n') \quad [26]$$

Wave Number Representation of the Radiated Sound Field

The sound radiation from a baffled plate is characterized by the sound radiation of the individual plate modes. Each mode shape function of the flexural vibration in the plate may be wave number-transformed into numerous flexural traveling waves with wave numbers k_x and k_y in the x and y directions such that:

$$\psi_{mn}(k_x, k_y) = \int_{S_1} \psi_{mn}(\mathbf{r}_p) e^{-jk_x x - jk_y y} dx dy \quad [27]$$

The nature of the modal sound radiation can therefore be understood by the relationship between each of the traveling wave components and its induced sound field. The wave number transformation of the Helmholtz equation in semiinfinite space takes the form of:

$$P(k_x, k_y, k, z) = A e^{\pm j\sqrt{k^2 - k_x^2 - k_y^2} z} \quad [28]$$

The sign of the exponential term is selected according to the physical conditions of sound radiation of the

(k_x, k_y) traveling wave at a given k . If $k^2 > k_x^2 + k_y^2$, ‘-’ is selected, as only outgoing sound pressure waves exist. If $k^2 < k_x^2 + k_y^2$, ‘+’ has to be used, to express the sound pressure decaying exponentially with z . As the wave numbers k and $\sqrt{k_x^2 + k_y^2}$ at a given frequency are inversely proportional to the phase speed, eqn [28] shows that only plate-traveling wave components with a phase speed greater than the sound speed in air radiate sound into the far field.

The amplitude of the sound pressure is determined by the boundary conditions on the plate surface:

$$A = -\rho_o \omega^2 \frac{W_{mn} \psi_{mn}(k_x, k_y)}{\pm j \sqrt{k^2 - k_x^2 - k_y^2}} \quad [29]$$

As a result, the wave number expression for the sound pressure radiated by the (m, n) th plate mode is:

$$\begin{aligned} p(r, \omega) &= -\frac{\rho_o \omega^2 W_{mn}}{(2\pi)^2} \\ &\times \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{\psi_{mn}(k_x, k_y)}{\pm j \sqrt{k^2 - k_x^2 - k_y^2}} \\ &\times e^{jk_x x + jk_y y \pm j\sqrt{k^2 - k_x^2 - k_y^2} z} dk_x dk_y \end{aligned} \quad [30]$$

Clearly, only those values of $\psi_{mn}(k_x, k_y)$ with $k_x^2 + k_y^2 \leq k^2$ will contribute to the far-field sound pressure.

Characteristics of Sound Radiation from Baffled Plates

The preceding results of radiated sound pressure and sound power are applicable to baffled plates with arbitrary boundary conditions, provided that the orthogonal eigenfunctions of the plate vibration are available. Using the modal description of the plate vibration, the characteristics of radiation power of a vibrating baffled plate is determined by that of the self and mutual radiation of plate modes and that of the excitation of plate modes by external pressure. The self-radiation of the plate modes is described by the modal radiation efficiency σ_{mn} (as in eqns [23] and [26]). The mutual radiation terms are related to the cross-product of two different plate modes, such as:

$$\begin{aligned} &\int_0^{2\pi} \int_0^{\pi/2} \gamma_{mn}(\theta_r \phi_r) \gamma_{m'n'}^*(\theta_r \phi_r) \sin \theta_r d\theta_r d\phi_r, \\ &(m, n) \neq (m', n') \end{aligned}$$

in eqn [20] and $\zeta_{mn, m'n'}$, $(m, n) \neq (m', n')$, in eqn [25a]. The modal amplitude W_{mn} of the plate due to external pressure is not only dependent upon the orthogonality between the distributed pressure and the plate mode (eqn [15]), but also upon whether the mode is excited at its resonance or not. A quantitative discussion of the self and mutual radiation, and the excitation of the plate mode cannot, however, proceed without information about the mode shape functions of the plate. In this article, mode shape functions for simple support plates (zero deflection and free rotation at all the edges) are used for the initial discussion. The effects of different edge conditions of the plate on the mode shape functions and the characteristics of radiated sound follow qualitatively.

If the origin of the coordinate system is at the center of a simply supported plate, the mode shape functions are:

$$\psi_{mn} = \sin\left(\frac{m\pi x}{L_x} + \frac{m\pi}{2}\right) \sin\left(\frac{n\pi x}{L_y} + \frac{n\pi}{2}\right) \quad [31]$$

and the wave number of the (m, n) th mode is:

$$k_{mn} = \sqrt{\left(\frac{m\pi}{L_x}\right)^2 + \left(\frac{n\pi}{L_y}\right)^2} \quad [32]$$

For such a simply supported plate, $|\gamma_{mn}(\theta_r, \phi_r)|^2$ in eqn [23] has a closed-form solution:

$$|\gamma_{mn}(\theta_r, \phi_r)|^2 = \left(\frac{2L_x L_y}{mn\pi}\right)^2 \frac{[1 - (-1)^m \cos \alpha][1 - (-1)^n \cos \beta]}{\left[(\alpha/m\pi)^2 - 1\right]^2 \left[(\beta/n\pi)^2 - 1\right]^2} \quad [33]$$

where $\alpha = kL_x \sin \theta_r \cos \phi_r$ and $\beta = kL_y \sin \theta_r \sin \phi_r$.

Modal Radiation Efficiency

The main features of modal radiation efficiency of simply supported plates as a function of wave number ratio k/k_{mn} , modal numbers (m, n) , and phase cell area $A_{mn} = L_x L_y / mn$ can be summarized analytically. The approximate expressions of σ_{mn} for the various regions of k/k_{mn} are:

1. when $k/k_{mn} \gg 1$:

$$\sigma_{mn} \cong \frac{1}{\left[1 - (k_{mn}/k)^2\right]} \rightarrow 1 \quad [34]$$

2. just above $k/k_{mn} = 1$, σ_{mn} has a peak, and the height of the peak increases with mode number
3. below the modal critical frequency $k/k_{mn} < 1$,

when $k_n = n\pi/L_y > k$ and $k_m = m\pi/L_x < k$, and:

$$\sigma_{mn} \cong \frac{(k/k_n)^2}{kL_y} \left\{ \frac{1 + [(k_{mn}^2 - k^2)/k_n^2]}{[(k_{mn}^2 - k^2)/k_n^2]^{3/2}} \right\} \quad [35]$$

when $k_n < k$ and $k_m > k$, k_n and L_y in eqn [35] are replaced by k_m and L_x

4. well below the modal critical frequency when $k/k_{mn} \ll 1$ and $k/k_m, k/k_n \ll 1$, but $\frac{1}{2}kL_x, \frac{1}{2}kL_y > 1$:

$$\sigma_{mn} \cong 8k^2 \frac{A_{mn}^2}{\pi^5 S_1} \quad [36]$$

5. when $k/k_{mn} \ll 1$ with $\frac{1}{2}kL_x, \frac{1}{2}kL_y \ll 1$

- the σ_{mn} of odd-odd modes is proportional to the square of the phase cell area and inversely proportional to the surface area of the plate such that:

$$\sigma_{mn} \cong 32k^2 \frac{A_{mn}^2}{\pi^5 S_1} \quad [37]$$

- for odd-even modes, the superimposed contribution of the adjacent phase cell areas (cells) gives rise to more complete cancellation of sound radiation. In this case σ_{mn} is smaller by a factor of $(kL_y)^2$ ($n = \text{even}$) than that of the odd-odd modes with similar phase cell area. Here:

$$\sigma_{mn} \cong \frac{8}{3} k^2 \frac{A_{mn}^2}{\pi^5 S_1} (kL_y)^2 \quad [38]$$

For even-odd modes ($m = \text{even}$), L_y in eqn [38] is replaced by L_x

- for even-even modes, the superimposed contribution of the adjacent phase cell areas gives rise to the most complete cancellation of sound radiation. The corresponding σ_{mn} is the smallest amongst those with similar phase cell areas. Here:

$$\sigma_{mn} \cong \frac{2}{15} k^2 \frac{A_{mn}^2}{\pi^5 S_1} (kL_x)^2 (kL_y)^2 \quad [39]$$

- for long but narrow plates, $\frac{1}{2}kL_x > 1, \frac{1}{2}kL_y \ll 1$. The radiation efficiency for odd modes in the y direction is:

$$\sigma_{mn} \cong \begin{cases} \frac{4}{S_1 K_n^2} k L_x, & k/k_m > 1 \\ 16k^2 \frac{A_{mn}^2}{\pi^5 S_1}, & k/k_m < 1 \end{cases} \quad [40]$$

and that for even modes in the y direction is:

$$\sigma_{mn} \cong \begin{cases} \frac{1}{3} \frac{k L_x}{S_1 K_n^2} (k L_y)^2, & k/k_m > 1 \\ \frac{4}{3} k^2 \frac{A_{mn}^2}{\pi^5 S_1} (k L_y)^2, & k/k_m < 1 \end{cases} \quad [41]$$

The mechanism for an odd-odd plate mode to have a dominant contribution to the sound power radiation below its modal critical frequency ($k/k_{mn} \ll 1$) is the uncancelled poles (with the same phase) of sound radiation at the plate edges (form = 3, 5, 7...n = 1, or m = 1, n = 3, 5, 7...) and corners (form = 3, 5, 7...n = 3, 5, 7...). The modal radiation efficiency of simply supported plates can be obtained by numerically integrating eqn [23]. Two typical figures of modal radiation efficiency for a baffled, simply supported square plate are shown in Figure 2. In addition to the general features of modal radiation as a function of modal numbers and wave number ratios, a waviness is observed in the radiation resistance curves below the modal critical frequency.

The complexity of the curves increases, represented by increases in waviness, as the modal numbers increase.

The wave number analysis of the plate modal vibration below its modal critical frequency shows (see eqns [28] and [30]) that the nonzero far-field sound radiation is due to the truncation of an acoustically slow-bending wave at the plate-baffle junction. The near-field vibration also contributes to the sound radiation of a plate mode below its modal critical frequency. To illustrate the effects of boundary conditions on the far-field sound radiation, the wave number transformation of one-dimensional mode shape functions is analyzed. Figure 3 shows the normalized amplitudes of three modes corresponding respectively to simply supported, clamped, and free boundary conditions. These three modes have similar phase cell lengths and the same number of phase cells. The amplitudes of the phase cells near the boundaries for the C-C, and F-F modes differ from that away from the boundaries because of the near-field flexural vibration. As a result, the contributions of these modes to the far-field radiation of acoustically slow sound differ, as shown in Figure 4 for sound radiation in the acoustically slow region (e.g., $k_x/(m\pi/L) < k/(m\pi/L) = 0.5$), and the wave number components of the C-C mode have the largest value. The mode with F-F boundary conditions has the least energy in $k_x < k$.

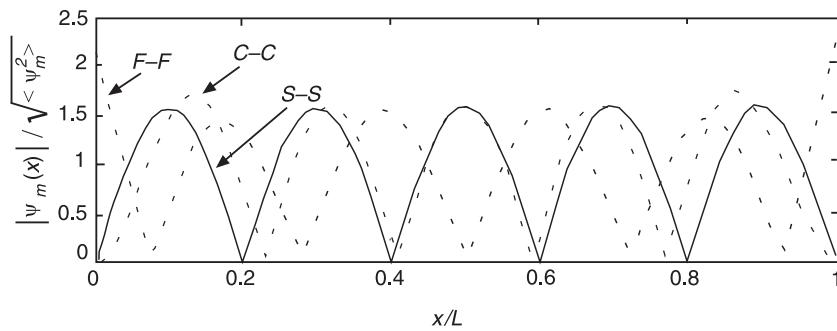

Figure 3 Normalized amplitudes of three modes corresponding respectively to simply supported (S-S), clamped (C-C), and free

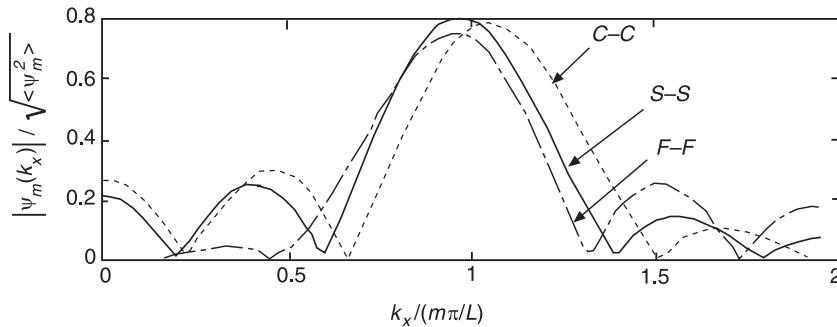

Figure 4 Normalized wave number spectrum of three modes corresponding respectively to simply supported (S-S), clamped (C-C), and free (F-F) boundary conditions.

The modal radiation efficiency of a plate with various boundary conditions has been numerically compared. The difference only occurs below the modal critical frequencies. Comparisons between simply supported plates and clamped plates show that the lower-order modes (up to the (2, 2) mode) are more efficient for the simply supported case than for the clamped case by up to 3 dB. The reverse applies for the higher-order modes.

Figure 5 shows the normalized amplitude of the three modes with only two phase cells. The corresponding wave number spectrum in Figure 6 shows that the mode with S-S boundary conditions has the largest value in the acoustically slow region $k_x/(m\pi/L) < 0.5$.

The boundary conditions with low deflection stiffness, such as free and guided boundary conditions, provide very low radiation efficiencies for the elastic modes of the plate below the modal critical frequency. However, a plate with free or guided boundary conditions also admits rigid body motion similar to the translational and rotational motions of a piston. Sound radiation from a vibrating piston in translation or rotation demonstrates the most efficient sound radiation below the modal critical frequency. When the size of the piston is much

smaller than the wavelength of sound radiation ($k_{\max}\{L_x, L_y\} \ll 1$), the approximate radiation efficiency of a vibrating piston in translation is:

$$\sigma_{pt} = \frac{1}{2\pi} k^2 L_x L_y \quad [42]$$

and that in rotation about the y -axis is:

$$\sigma_{pr} = \frac{1}{72\pi} k^2 L_x L_y (k L_x)^2 \quad [43]$$

Sound Power Radiated by Forced Vibration of a Baffled Plate

Sound radiation from forced vibration of a baffled plate involves the participation of multiple plate modes. As indicated in eqns [20] and [24], the radiated sound power not only depends upon the radiation characteristics of the individual plate modes and mutual interaction between the plate modes via their radiated sound, but also upon the excitation of each plate mode by the external forces.

If a plate is excited in such a way that the plate vibration field can be described as reverberant with equal distribution of the energy over all modes, the

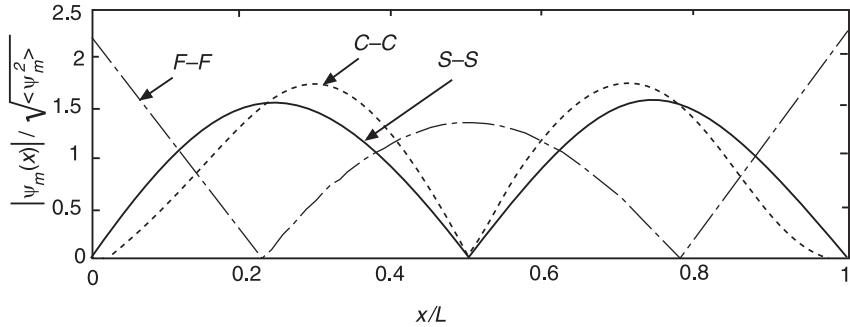

Figure 5 Normalized amplitudes of three modes corresponding respectively to simply supported (S-S), clamped (C-C), and free (F-F) boundary conditions and with two phase cells.

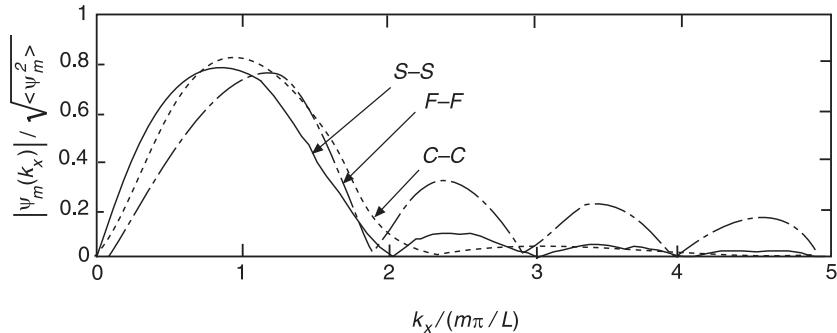

Figure 6 Normalized wave number spectrum of three modes corresponding respectively to simply supported (S-S), clamped (C-C), and free (F-F) boundary conditions and with two phase cells.

net contribution of the mutual interaction between plate modes to the total sound power may be ignored. For this case, an average radiation efficiency σ_{rad} is used to relate the sound power radiated by a plate:

$$W = \rho_o c_o S_1 \sigma_{\text{rad}} < v^2(\omega) > \quad [44]$$

where $< v^2(\omega) >$ is the space-time average mean-square velocity of the plate at the angular frequency ω and in the frequency band $\Delta\omega$. The average radiation efficiency for a simply supported plate is:

$$g_1(f/f_c) = \begin{cases} (4/\pi^2)(1 - 2\alpha^2)/\alpha(1 - \alpha^2)^{1/2}, & f < \frac{1}{2}f_c \\ 0, & f > \frac{1}{2}f_c \end{cases} \quad [46a]$$

and:

$$g_2(f/f_c) = (2\pi)^{-2} \times \{(1 - \alpha^2) \ln [(1 + \alpha)/(1 - \alpha)] + 2\alpha\} / (1 - \alpha^2)^{3/2} \quad [46b]$$

$$\sigma_{\text{rad}} = \begin{cases} 2(\lambda_c \lambda / L_x L_y)(f/f_c)g_1(f/f_c) \\ + (P \lambda_c / L_x L_y)g_2(f/f_c), & f < f_c \\ (L_x / \lambda_c)^{1/2} + (L_y / \lambda_c)^{1/2}, & f = f_c \\ (1 - f/f_c)^{-1/2}, & f > f_c \end{cases} \quad [45]$$

where $P = 2(L_x + L_y)$, $f_c = c_o^2 / 1.8c_L b$ is the critical frequency of an infinite plate with the same thickness b and material properties as that of the baffled plate, $c_L = \sqrt{E/\rho}$, $\lambda_c = c_o/f_c$:

with $\alpha = (f/f_c)^{1/2}$. Well below the plate critical frequency:

$$\sigma_{\text{rad}} \cong \frac{4L_x L_y}{c_o^2} f^2, \quad \text{for } 0 < f < f_{11} \quad [47]$$

The average radiation efficiency is graphically presented in **Figure 7**, where the effects of simply supported and clamped boundary conditions on σ_{rad} are incorporated.

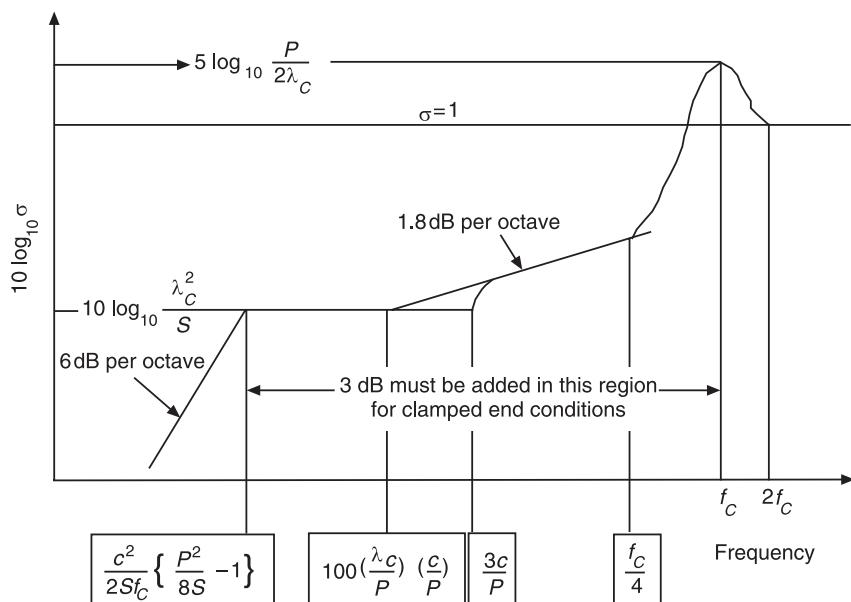

Figure 7 Average radiation efficiency of a baffled plate of perimeter $P = 2(L_x + L_y)$ and area $S = L_x L_y$ with simply supported or clamped edges. Modified with permission from Norton (1999) and Beranek (1992).

When a plate modal density is low and the frequency of sound radiation is below the critical frequency of the plate, eqns [20], [24], and [22] should be used to calculate the radiation efficiency. In this case, the total sound power produced is no longer equal to the sum of the sound powers that would be generated separately by each plate mode, and the mutual interaction of the plate modes through the radiated sound field must be taken into account. The radiated sound power is also strongly dependent, in this instance, upon the nature of the excitation force on the plate surface.

Figure 8 illustrates the radiation efficiency of a baffled plate driven by a unit point force at the center. The critical frequency of the plate is 12 kHz. The variational formulation allows calculation of free and forced plate responses for various boundary conditions, including simply supported, clamped, free, guided, and partially clamped-partially free boundary conditions.

Conclusions

In general, sound radiation from baffled plates is generated by the vibration of the various plate modes, as described by the modal radiation efficiency σ_{mn} , the mutual interaction between the modal radiation, and the degree of excitation of the plate modes by external forces. Above the modal critical frequency, the sound radiation of plate modes is effective and the mechanism of sound radiation is due to parts of the free-bending waves in the plate. In such acoustically

fast regions, the boundary conditions of the plate have little effect on the radiated sound power. Below the modal critical frequency, the mechanisms of sound radiation by the plate modes are associated with the truncation of the free-bending waves at the plate-baffle junction, and the near-field plate vibration. The mode numbers, aspect ratios, and boundary conditions control both mechanisms.

Sound radiation from free-bending waves (bending waves which are not restricted by some structural discontinuity) in a structure can thus be categorized into first, modal sound radiation at any given arbitrary frequency, including nonresonant frequencies, and second, frequency band-averaged sound radiation. However, because finite structural elements always allow for the existence of natural frequencies and their associated mode shapes, when a structure is excited by a broad-band force, this results in the resonant excitation of structural modes. Hence, frequency band-averaged sound radiation is necessarily dominated by resonant structural modes, whereas modal sound radiation is not.

In practice, when structures are mechanically excited by a broad-band force, they respond in a multimode, resonant form; many natural frequencies are excited and they resonate with the applied force. In this instance it is often – but not always – the case that these resonant modes are responsible for most of the sound radiation. It is not always the case because radiation ratios of finite structures generally increase with frequency – a situation could arise where the higher-frequency, but nonresonant, modes (i.e.,

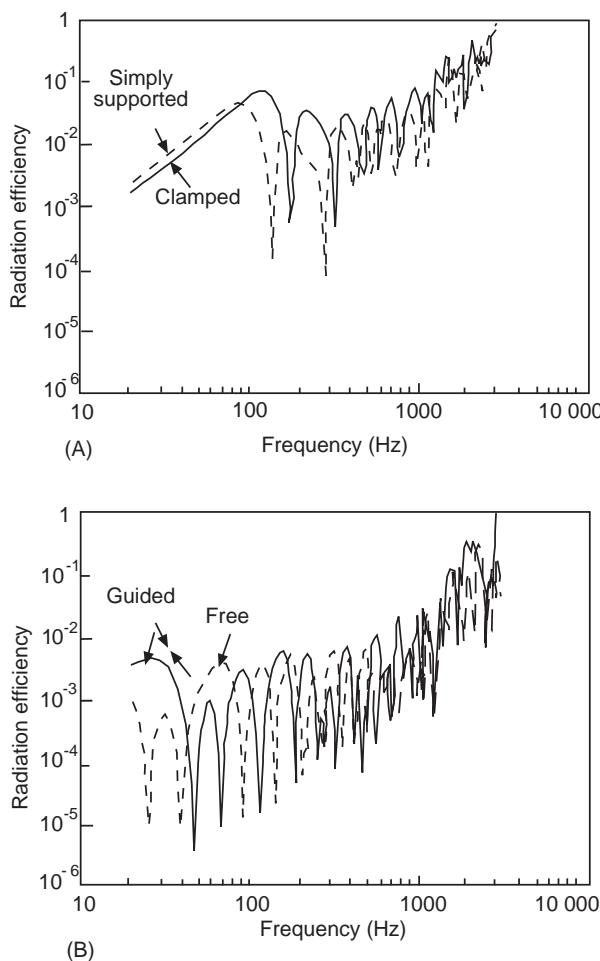

Figure 8 Radiation efficiency of a baffled plate driven by a unit point force at the center. (A) Simply supported and clamped edges; (B) free and guided edges. The plate loss factor is 0.01 and $f_c = 12\text{ kHz}$. Reproduced with permission from Berry *et al.* (1990).

modes above the excitation frequency band) with their associated higher radiation efficiency generate more sound than the lower-frequency, but resonant, modes. Generally, however, whilst these higher-frequency modes have higher radiation efficiencies, their vibrational levels are significantly reduced because they are nonresonant; thus, the net effect is that they radiate less sound than the lower-frequency, lower-radiation-efficiency, resonant modes which are within the excitation band. Hence, as a general rule, resonant structural modes tend to dominate the sound radiation from mechanically excited structures. In practice, the mechanical excitation of plates results in most of the radiated sound being produced by resonant plate modes – the sound radiated by nonresonant forced modes tends not to be very significant.

The situation is somewhat different for acoustically excited structures. The vibrational response of finite

structures to acoustic excitation (i.e., incident sound waves) is comprised of first, a forced vibrational response at the excitation frequency, and second, a vibrational response due to the excitation of the various structural natural frequencies. The former is associated with a wave that propagates through the structure at the trace wavelength of the incident sound wave. The latter is associated with the structural waves that are generated when the trace wave interacts with the boundaries; these structural waves are, in effect, free-bending waves with corresponding natural frequencies. The structural response is now both resonant and forced, and the transmission of sound through the structure (e.g., an aircraft fuselage, a partition between two rooms, or a machine cover) can be due to either one of the mechanisms or both. Thus, with acoustic excitation, it is the nonresonant forced modes, driven by the incident sound field, which match the wavelengths of the sound waves, thus transmitting sound very efficiently through the structure at frequencies below the critical frequency (but above the fundamental resonance). At frequencies above the critical frequency, both forced and resonant modes contribute to the radiated sound.

In summary, for acoustically excited plates, any sound that is radiated or transmitted (at frequencies below the critical frequency) is due to a forced response. On the other hand, for mechanically excited plates, any sound that is radiated at frequencies below the critical frequency is due to a resonant response. Above the critical frequency all the structural modes are capable of radiating sound. This conclusion is limited to regions where the bending waves are free and not restricted by structural discontinuities, i.e., regions far away from any mechanical excitation points or structural constraints such as stiffeners and joints.

When subsonic (acoustic slow) bending waves interact with a region where there are structural constraints and discontinuities (e.g., a large machine cover or an aircraft fuselage with ribs and stiffeners), reaction forces are generated on the structure. Also, there might be regions where some external mechanical excitation is transmitted to the structure via either a point or a line. Sound is radiated from regions in proximity to these various types of discontinuities. This sound is partly due to the near-field waves that are generated by the point and line reaction forces associated with some form of external mechanical excitation (a driving force) and/or any structural constraints. The other part of the sound radiation in this acoustic slow region is due to the truncation of the free-bending waves at the plate–baffle junction. This form of sound radiation from plates is produced by the uncancelled volume

velocities in regions in proximity to the structural constraint. Quite often, this sound radiation dominates over the sound radiated by the resonant corner and edge modes – the point and line forces produce sound radiation at all frequencies and not only at resonant frequencies.

Nomenclature

C	damping coefficient
E	Young's modulus
h	thickness of plate
p_e	external pressure
p_p	acoustic radiation loading
ν	Poisson's ratio
ρ	density
σ	radiation efficiency

NONDESTRUCTIVE TESTING

Sonic

S Doebling and C Farrar, Los Alamos National Laboratory, NM, USA

doi:10.1006/rwvb.2001.0138

Introduction

According to the American Society for Non-destructive Testing (ASNT), nondestructive testing (NDT) is defined as ‘the examination of an object with tech-

nology that does not affect the object’s future usefulness’. Sonic NDT (SNDT) refers to the examination of the integrity of a structure using dynamic response methods where the velocities of the excitation and response signals are significantly below the speed at which sound travels through the materials that compose the object. Thus, the measures that are commonly used to describe a structure’s vibration behavior are also frequently used in SNDT. Distinction should be made between local SNDT, used to inspect local sections of a structure for flaws, and global SNDT, used to inspect large sections of a structure for changes in mechanical properties. Global sonic nondestructive testing (GSNDT) is the focus of this article. Common synonyms for GSNDT in

recent literature include vibration-based damage identification (or damage detection) and structural health monitoring. Structural health monitoring is also used to describe the overall measurement and analysis process whereby GSNDT is used to monitor the integrity of a structure over either continuous or discrete time intervals. This article will explain the theoretical basis for GSNDT, provide an overview of the implementation process with discussion of major issues, and provide a historical context for the application of GSNDT.

Basis of Global Sonic Nondestructive Testing

The basic philosophy of GSNDT is that the dynamic mechanical response of a structure is a function of the mechanical condition of the structure. Thus, observed changes in the dynamic response can be indicative of changes in mechanical condition. The basic approach of GSNDT is the comparison of measured vibration properties for the structure from two different measurement events to assess whether the structure has changed from its original configuration. First the structure is mechanically excited, using either an excitation that occurs in the normal operation of the structure (referred to as operating or ambient excitation) or an excitation that is introduced specifically for the purposes of identifying the dynamic response properties (referred to as forced excitation). Next, the structural response is measured using vibration instrumentation (typically accelerometers or strain gauges) and the data sets are digitized, transmitted, and stored electronically (see entry on **Modal analysis, experimental, Measurement techniques**). Features of these signals are then compared from experiments conducted at different times to assess whether damage has occurred. (Modal parameters have commonly been used, but more general types of parameters and measures have also been introduced.) Using GSNDT to assess the integrity of a structure allows the operator of the structure to follow a more cost-effective condition-based maintenance strategy (i.e., maintain the structure when necessary) rather than a time-based maintenance strategy (i.e., maintain the structure at a specific time interval no matter what condition it is in).

The following example illustrates the ability to identify changes in structural condition from changes in measured vibration properties. Consider the two degrees-of-freedom (2-DOF) vibration oscillator shown in **Figure 1**. Using the methods of standard analytical modal analysis, the free equation of motion of the system can be written as:

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} 2k & -k \\ -k & 2k \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix} \quad [1]$$

Likewise, the modal frequencies, ω_n , and mode shapes, \mathbf{U}_n can be written as:

$$\begin{aligned} \omega_1 &= \sqrt{\frac{k}{m}} \quad \mathbf{U}_1 = \begin{Bmatrix} 1 \\ 1 \end{Bmatrix} \\ \omega_2 &= \sqrt{\frac{3k}{m}} \quad \mathbf{U}_2 = \begin{Bmatrix} 1 \\ -1 \end{Bmatrix} \end{aligned} \quad [2]$$

The reader will note from eqn [2] that the modal frequencies and mode shapes are functions of the mass and stiffness parameters of the system. Thus, by observing changes in these features (the modal frequencies and mode shapes), changes in the structural condition (mass and stiffness parameters) can be observed. Typically, it is assumed for practical applications that the types of damage of interest will primarily manifest as changes to the stiffness parameters while the mass parameters remain constant. Thus, for a given change in modal frequency and mode shape, information about changes to the structural stiffness parameters can be inferred.

Overview of Sonic NDT Process

The process of implementing GSNDT involves four primary steps. Each of these steps is described in detail below:

1. Operational evaluation: definition of potential damage scenarios for the system and assessment of operating conditions
2. Data acquisition and cleansing: observation of the system over a length of time using periodically spaced measurements
3. Data transformation and feature extraction; selection of parameters of interest from the data
4. Feature comparison and statistical model building: analysis of the features to determine the current mechanical state of the system

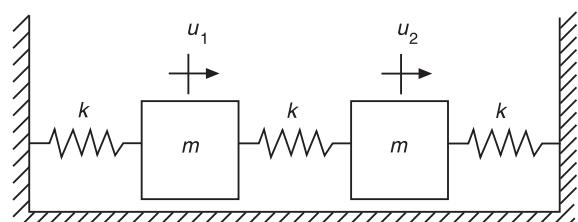

Figure 1 Two-degrees-of-freedom system.

Operational Evaluation

The first step in implementing GSNDT is operational evaluation. Operational evaluation refers to the assessment of the type of damage to be observed using GSNDT, the operational and environmental conditions under which GSNDT must be applied, the limitations which are present that will affect the GSNDT process, and the economic justification associated with GSNDT.

The first step in defining the damage that will be detected using GSNDT is to assess what level of damage is to be considered. The five levels of damage (originally presented as four levels but later modified) are:

- Level 1: Existence of damage: simple binary indication that ‘something has changed’
- Level 2: Location of damage: spatial location of damage to resolution allowed by the sensor set
- Level 3: Type of damage: classification of damage into discrete typesets, usually from application-specific knowledge base
- Level 4: Magnitude of damage: usually expressed as a percentage reduction in localized stiffness
- Level 5: Prognosis of remaining useful life of structure: requires specific knowledge of the nature of the damage, damage propagation, future loading, and the level of damage tolerance possessed by the structure

It is important to define precisely what type of damage is being sought and to select the appropriate instrumentation for that damage type. Typically it is desirable to preselect a relatively small candidate set of damage locations prior to applying the GSNDT techniques. Inclusion of too many candidate damage cases creates the danger of nonuniqueness, that is, the existence of more than one damage case that creates the same change in the measured features. Because many of the GSNDT techniques are essentially inverse modeling approaches, nonuniqueness is a major source of false-positive indications of damage.

Another factor to be considered is whether or not examples of the undamaged and damaged structure are available for GSNDT. If examples of each type of damage are available, as in the case of most rotating machinery applications, then the identification of damage can be conducted in a supervised learning mode. If examples of each type of damage are not available, as in most civil engineering applications, then the identification of damage must be conducted in an unsupervised learning mode. The implication of the learning mode is explained under the section on feature comparison and statistical model building, below.

Data Acquisition and Cleansing

Sensor and excitation selection and placement The data acquisition phase of GSNDT involves selecting the types of sensors to be used, selecting the location where the sensors should be placed, determining the number of sensors to be used, and defining the data acquisition/storage/transmittal hardware. This process will be application-specific. Economic considerations will play a major role in making these decisions. Another consideration is how often the data should be collected. In some cases it may be adequate to collect data immediately before and at periodic intervals after a severe event. However, if fatigue crack growth is the failure mode of concern, it may be necessary to collect data almost continuously at relatively short time intervals.

Because data can be measured under varying conditions, the ability to normalize the data becomes very important to the GSNDT process. One of the most common procedures is to normalize the measured responses by the measured inputs. When environmental or operating condition variability is an issue, the need can arise to normalize the data in some temporal fashion to facilitate the comparison of data measured at similar times of an environmental or operational cycle. Sources of variability in the data acquisition process and with the system being monitored need to be identified and minimized to the extent possible. In general, all sources of variability cannot be eliminated. Therefore, it is necessary to make the appropriate measurements such that these sources can be statistically quantified.

Data acquisition, processing, and storage Data acquisition for GSNDT involves scaling and antialias filtering the data, converting the data to digitized samples, and storing the samples in electronic form on a magnetic or optical medium. Transmission of the data is a significant issue, because many schemes for GSNDT of large structures such as bridges and buildings require large distances (1 km and greater) between the sensor and the storage medium. Historically, long cables have been used to bring the sensor signals back to a central location for scaling, filtering, digitization, and storage. This approach has significant drawbacks as a result of signal loss and noise in the cables as well as monitoring of cable integrity. Alternatives have been proposed that use wireless systems. Some wireless systems perform a local ‘clustering’ of transducer signals via cables to a ‘local’ data acquisition system. With several of these ‘local’ systems across a large structure, the need to run cables along the entire structure is eliminated. Another approach is to make an integrated sensing, signal

conditioning, digitizing and storage unit, then deploy one such unit at each desired measurement point on the structure. A master unit at a centralized location queries each of the remote units via wireless connection to retrieve the data.

Data cleansing and validation Data validation is the process of deciding whether or not the data are generally acceptable and suitable for use in GSNDT. Data cleansing is the process of selectively choosing data to accept for, or reject from, the feature selection process. Filtering is a type of data cleansing where one rejects data in certain frequency bands. The data validation and cleansing process is usually based on knowledge gained by individuals directly involved with the data acquisition. Judgment of individuals based on experience and consistency across channels and data sets are some of the criteria that are commonly used. Finally, it should be noted that the process of data acquisition and cleansing is not static, but involves feedback from the feature extraction and feature comparison steps.

Data Transformation and Feature Extraction

Once the data have been acquired and validated, the process of condensing useful GSNDT information from the data begins. Usually the raw data time series are not directly indicative of changes in the structural properties. Thus, GSNDT requires the use of transforms and features to determine the state of the structure. A transform is a mathematical operation that is applied to the data to change the domain under which the data are viewed. A transform may include assumptions about the form of the data, but does not inherently add or remove information from the data. (Thus, for each transform there is also an inverse transform.) An example is the Fourier transform, which assumes that the data can be represented by superposed sinusoids, then computes the required coefficients for these sinusoids. The inverse Fourier transform returns the data back to the time domain without loss of information.

Feature extraction is the process of extracting information from the data (or a transform of the data) such that the overall quantity of data is reduced. Thus, it is through feature extraction that the GSNDT analyst seeks to reduce the (usually very large) set of raw data to the few parameters that are of interest. Note that there is a tradeoff when extracting features as information is typically lost in the process. Take, for example, the harmonic sine wave shown in Figure 2. It is composed of 1024 data points. However, if it is noted that the signal is simply a sine wave of amplitude 2, frequency 4 Hz, and phase 0, the 1024 data points have been reduced to three para-

meters, in this case without much loss of information about the signal.

Selection of the features to be identified is crucial to the GSNDT process. There are three basic characteristics of the features that must be considered:

1. Sensitivity: the feature must be relatively sensitive to the type of damage that was selected in the operational evaluation step. Also, the feature must be relatively insensitive to the measurement interference defined in the operational evaluation step.
2. Observability: the feature must be observable by the measurements defined in the data acquisition and cleansing step. In other words, the measurements obtained must contain information that the feature can be extracted from.
3. Dimensionality: it is desirable to minimize the length of the feature vector (defined as the dimensionality of the feature). In the example presented above, if the magnitudes of the individual data points had been the feature of interest, the feature vector would have dimension 1024 (or 1026 after including the starting point and spacing of the time axis). However, upon converting to the modal properties, the feature vector has dimension 3. Low dimensionality is crucial to ensuring that the multidimensional parameter spaces defined in the statistical model-building section below are well populated. (For example, in a multivariate Gaussian distribution, it is important to have low enough dimensionality such that the data set is adequate to populate the tails of the distribution.)

This so-called curse of dimensionality is demonstrated as shown in Figure 3. For a univariate (dimension 1) standard normal distribution, 90% of the data

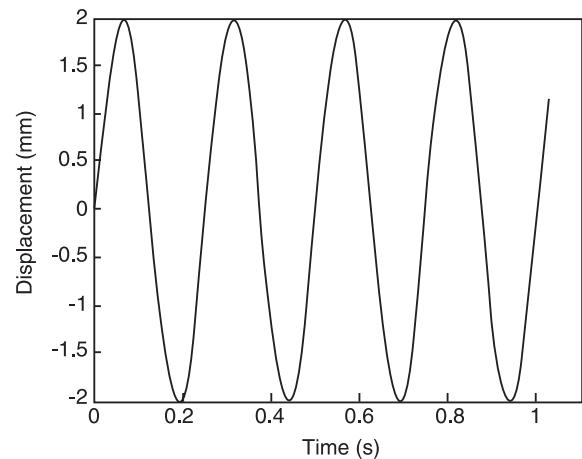

Figure 2 Sine wave for example of feature extraction.

in the distributions falls between -1.6 and $+1.6$. However, for a 10-dimensional standard normal distribution, less than 1% of the data falls within a distance 1.6 from the origin. Thus, a tremendous amount of data is required to describe the features accurately with so many dimensions.

Feature computation techniques can be defined as regressive or nonregressive. Regressive features are computed by curve-fitting (regression) of a parametric formula to the data or a transform of the data. Examples of regressive features are modal parameters, autoregressive moving average (ARMA) coefficients, and finite element model perturbations. Features computed directly from the data without the use of parametric curve-fitting are called nonregressive. Maximum/minimum values, root-mean-square values, and zero-crossing counts are examples of nonregressive features. In general, regressive features are more computationally intensive to extract, but are generally desirable because of the ability to incorporate an understanding of the underlying mechanics into the model.

Modal parameters are commonly used features in GSNDT because the GSNDT field grew to a great extent out of the community that practices experimental modal analysis (see **Modal analysis, experimental, Measurement techniques**). Techniques for extracting modal parameters (and for defining the data acquisition necessary to do so) are well defined and both software and hardware are available commercially. Modal parameters are determined by regression of parameters to the frequency response function or its time domain equivalent, the impulse response function.

Another issue to note is that some features are computed directly from the data or its transforms, whether by regression or not (such as modal parameters), whereas some features are themselves computed from other features. Perturbations to finite element model parameters based on regression to identified modal parameters are examples of ‘features of other features’.

Nonregressive features Nonregressive features are attractive for GSNDT because they can give insight about the state of the structure without the need for detailed computations or model assumptions. Examples of nonregressive features include simple mathematical functions of the time series, such as the maximum value and the root-mean-square value. Another commonly used nonregressive feature is the comparison of the error in the frequency response function or the coherence function between the undamaged and damaged data sets. Advanced nonlinear signal-processing techniques can also be used as nonregressive features for GSNDT. Examples include higher-order spectra, beat phenomena, time-frequency transforms, and wavelet transforms.

In the rotating machinery industry, almost all GSNDT is performed using nonregressive features of the signal. Examples include the root-mean-square value of the response signal, increase of power spectral density magnitude at particular resonant frequencies, and the existence of harmonic resonances at multiples of the rotational speed. In applications where the damage can be distributed across a large spatial region (such as in civil infrastructure), nonregressive features are mainly useful for performing a quick check on the data. Detailed insight into the nature of the structural damage in such cases generally requires some sort of regression in order to bring knowledge of the underlying geometry and mechanics into the diagnosis process.

In many GSNDT applications, it is acceptable to treat the measurement set as representing the response of a purely linear system. In other situations, it may not be acceptable to assume linearity, but it is often mathematically convenient to do so anyway. For some applications, assumption of linear structural response is simply not valid. This situation occurs when the materials that compose the structure are inherently nonlinear (such as polymers or foams), or when the damage itself introduces nonlinearity. In the latter case, features that detect the onset of nonlinearity are used to conduct level 1

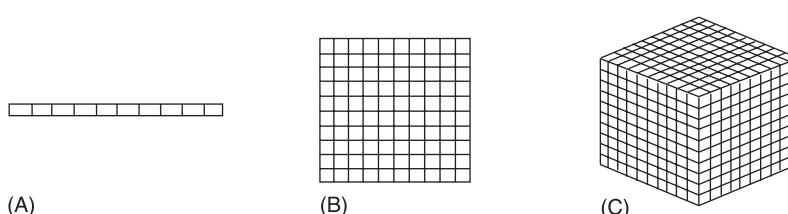

Figure 3 Illustration of the ‘curse of dimensionality’. (A) 1-D: 10 bins; (B) 2-D: 100 bins; (C) 3-D: 1000 bins.

GSNDT. Changes in the coherence function and estimated probability density function can be used in this way.

Regressive features By far the most commonly used regressive feature in GSNDT applications are modal parameters, specifically the modal frequency, modal damping ratio, and mode shape. Also, functions of these features are among the most commonly used features in GSNDT. While modal parameters are typically not the best features to use for GSNDT from a sensitivity standpoint, there is widespread belief in the community that they are useful indicators of damage. Their popularity is owed to the physical insight that they provide and the large number of commercial software packages that are available to compute them.

Modal frequency is the most commonly used linear feature, followed by the mode shape and functions of the mode shape, such as mode shape curvature, bending strain energy, modal flexibility, and load-dependent Ritz vectors. Modal damping has been used for GSNDT, but due to a high level of experimental variability it tends not to be a very indicative feature. Finite element method updating (see **Finite element methods**), which was originally developed to tune linear finite element models to measured modal parameters, is also used to estimate changes in the finite element material and geometric parameters, which can be used as features in GSNDT. In the case of nonlinear response, general-purpose regression techniques include ARMA coefficients, polynomial fits, and the update of finite element method parameters using nonlinear data.

Feature Comparison and Statistical Model Building

Once features have been extracted from the data, they are compared with features extracted from previous data sets to assess whether or not structural damage has occurred. In some cases, such as rotating machinery applications, examples of ‘undamaged’ and ‘damaged’ feature sets are available, and thus the GSNDT problem reduces to classification of the measured feature into the appropriate damage set. This situation is referred to as supervised comparison. The alternative, when only undamaged feature sets or damaged feature sets are available, is referred to as unsupervised learning. In unsupervised learning, it is not possible to make a set classification, but only a hypothesis about the likelihood that the new feature is a member of the existing feature set. Feature comparison techniques can be categorized as being either deterministic (i.e., features are considered to be absolute values that are measured exactly) or statistical

(i.e., features are considered to be samples from a random parent population).

Most deterministic feature comparisons are simple error comparisons (either absolute error or normalized in some way). For features such as modal frequency, the error comparison can be done for each value in the feature vector. However, for features with spatial distribution such as mode shapes, comparison metrics that reduce the aggregate comparison to a set of scalar values is desirable. An example of such a metric for mode shapes is the modal assurance criterion (MAC).

Using the results of the feature comparison to assess whether or not damage has occurred requires the definition of whether the damage identification will be unsupervised or supervised. In the case where examples of data from the damaged structure are not available, unsupervised methods must be used to detect clustering in the data and then look for outliers to the cluster to detect damage. Examples of clustering techniques include density estimation, expectation maximization, and k -means algorithms. In the case where examples of data from the damaged structure are available, supervised methods can be used to classify what damage case the current features most closely represent, or to use regression to assess the location and magnitude of damage. Examples of classification techniques include Fisher’s discriminant, quadratic classification, and k -nearest neighbors. Regression techniques include linear, polynomial, and k -nearest neighbors. Neural networks can be utilized in both classification and regression techniques. The field of statistical process control also offers techniques for trending the data to track the onset of damage and predict future behavior.

Consideration of variability An important issue in the comparison of features is the variability that is present in the features as a result of factors other than structural damage. These factors can include environmental effects (such as temperature, wind, humidity, etc.), operational interference (such as acoustic loads or extraneous vibration excitations), and electrical noise. Often these effects cannot be mitigated, but the quantification of the effects is nevertheless crucial to produce a credible GSNDT result. If the effect is cyclical, observation of the feature variability over one or more complete cycles of the effect can give an approximation of the perturbation in the feature value due to this effect. Including a measure of the effect in the feature vector (such as a measurement of temperature differential or automotive traffic flow) can be an effective technique for accounting for the source of variability.

An example of the effect of temperature-induced variability in features is shown in Figure 4. Pictured in this figure are measurements of the first modal frequency of a bridge structure taken over a 24-h period at 2-h intervals. Superimposed are measurements of temperature differential between the eastern and western edges of the bridge. Clearly indicated is a strong variability of this feature (first modal frequency) as a function of deck temperature differential.

False-positive and false-negative indicators A key aspect of GSNDT is the elimination of false-positive and false-negative indicators from the damage diagnosis process. False-positive refers to the situation where damage is indicated when in fact none is present. False-negative refers to the situation where damage is not indicated, even though it is present. Although false-negative indicators pose the larger problem in terms of life safety, false-positive indicators are a significant issue in that they can irreparably damage the credibility of the GSNDT technique being applied or the engineer applying it. When developing or implementing a GSNDT technique on a set of data, it is important to compare two data sets from the undamaged structure under different experimental and environmental conditions to study false-positive indicators. It is also important to compare data sets from the undamaged structure and the damaged structure at various levels of damage to study false-negative indicators and to define the threshold at which damage can be detected.

GSNDT History and Applications

Early Work

It is the authors' speculation that damage or fault detection, as determined by changes in the dynamic properties or response of systems, has been practiced in a qualitative manner, using acoustic techniques, since modern human beings have used tools. More recently, this subject has received considerable attention in the technical literature and a brief summary of the developments in this technology over the last 30 years is presented below. Specific references are not cited.

The development of vibration-based damage detection technology has been closely coupled with the evolution, miniaturization, and cost reductions of fast Fourier transform (FFT) analyzers and digital computing hardware. To date, the most successful application of vibration-based damage detection technology has been for monitoring rotating machinery. The rotating machinery application has taken an almost exclusively nonregressive approach to damage detection. The detection process is based strictly on pattern recognition applied to time histories or spectra generally measured at a single point on the housing of the machinery during normal operating conditions. Often this pattern recognition is only performed in a qualitative manner. Databases have been developed that allow specific types of damage to be identified from particular features of the vibration signature. For these systems the approximate location of the damage is generally known, making a single-channel

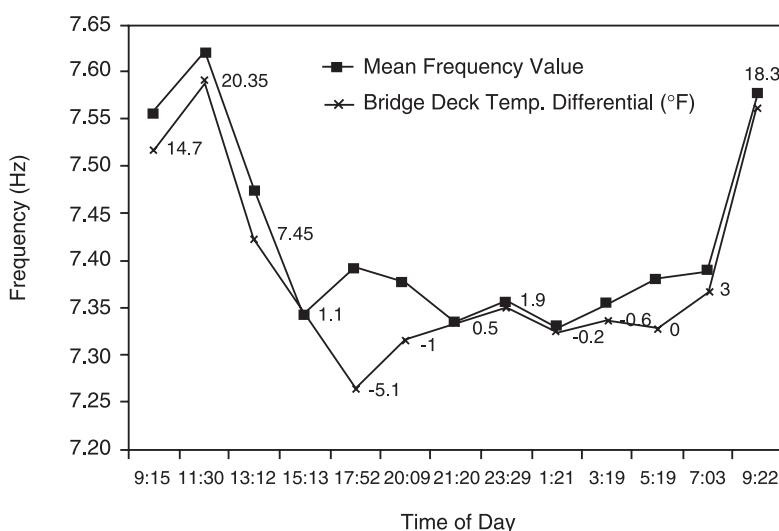

Figure 4 Example of feature variability as a function of temperature change.

FFT analyzer sufficient for most periodic monitoring activities. Typical damage that can be identified includes loose or damaged bearings, misaligned shafts, and chipped gear teeth. Today, commercial software integrated with measurement hardware is marketed to help the user systematically apply this technology to operating equipment.

During the 1970s and 1980s the oil industry made considerable efforts to develop vibration-based damage detection methods for offshore platforms. This damage detection problem is fundamentally different from that of rotating machinery because the damage location is unknown and because the majority of the structure is not readily accessible for measurement. To circumvent these difficulties, a common methodology adopted by this industry was to simulate candidate damage scenarios with numerical models, examine the changes in resonant frequencies that were produced by these simulated changes, and correlate these changes with those measured on a platform. A number of very practical problems were encountered, including measurement difficulties caused by platform machine noise, instrumentation difficulties in hostile environments, changing mass caused by marine growth and varying fluid storage levels, temporal variability of foundation conditions, and the inability of wave motion to excite higher vibration modes. These issues prevented adaptation of this technology and efforts at further developing this technology for offshore platforms were largely abandoned in the early 1980s.

Applications to Rotating Machinery

The rotating machinery application represents a mature technology where vibration-based damage detection has made the transition from a research topic to industry practice. Vibration-based damage detection for rotating machinery has been repeatedly applied with success to a variety of machinery elements such as roller bearings and gears. In the past, the greatest emphasis has been on the qualitative interpretation of vibration signatures both in the frequency and, to a lesser extent, in the time domain. Numerous summaries and reviews of this approach are available in textbook form, including detailed charts of machinery fault analysis. The approach taken has generally been to consider the detection of damage qualitatively on a fault-by-fault basis by examining acceleration signatures for the presence and growth of peaks in spectra at certain frequencies, such as multiples of shaft speed. A primary reason for this approach has been the inherent nonlinearity associated with damage in rotating machinery. Recently, more general approaches to damage detec-

tion in rotating machinery have been developed. These approaches utilize formal statistical methods to assess both the presence and level of damage on a statistical basis.

Aerospace Applications

The aerospace community began to study the use of vibration-based damage detection during the late 1970s and early 1980s in conjunction with the development of the space shuttle. This work has continued, with current applications being investigated for the National Aeronautics and Space Administration's space station and reusable launch vehicle. The shuttle modal inspection system (SMIS) was developed to identify fatigue damage in components such as control surfaces, fuselage panels, and lifting surfaces. These areas were covered with a thermal protection system, making them inaccessible and, hence, impractical for conventional local nondestructive examination methods. This system has been successful in locating damaged components that are covered by the thermal protection system. All orbiter vehicles have been periodically subjected to SMIS testing since 1987. Space station applications have primarily driven the development of experimental/analytical damage identification methods. These approaches are based on correlating analytical models of the undamaged structure with measured modal properties from both the undamaged and damaged structure. Changes in stiffness indices as assessed from the two model updates are used to locate and quantify the damage. Since the mid-1990s, studies of damage identification for composite materials have been motivated by the development of composite fuel tank for a reusable launch vehicle.

Civil Structure Applications

The civil engineering community has studied vibration-based damage assessment of bridge structures since the early 1980s. Modal properties and quantities derived from these properties, such as mode shape curvature and dynamic flexibility matrix indices, have been the primary features used to identify damage in bridge structures. Environmental and operating condition variability present significant challenges to the bridge-monitoring application. The physical size of the structure also presents many practical challenges for vibration-based damage assessment. Regulatory requirements in some eastern Asian countries, which mandate the companies that construct the bridges periodically to certify their structural health, are driving current research and commercial development of vibration-based bridge-monitoring systems.

Concluding Remarks

The field of GSNDT, while composed of well-developed technologies such as dynamic sensing, digital signal processing, modal testing, experimental modal analysis, and statistical pattern recognition, is still in its infancy. Only in the field of rotating machinery inspection has GSNDT crossed the chasm between research and application. Open research issues still exist in the areas of operational evaluation, data acquisition and cleansing, data transformation and feature extraction, and feature comparison. Nevertheless, the potential economic and societal benefits of effective GSNDT are of significant enough magnitude that research continues so that these hurdles may be overcome.

shows the instrumentation of a typical ultrasonic flaw inspection setup. In such an inspection, a pulser generates very short repetitive pulses of electrical energy that are used to drive an ultrasonic transducer. A piezoelectric crystal in the transducer converts the electrical pulses into mechanical motion, producing an elastic wave which then propagates into the component and interacts with any flaws present. Waves scattered from the flaws can be received by another piezoelectric transducer and converted back to electrical signals. These received signals are amplified by the receiver section of the pulser/receiver, captured and displayed as a voltage vs time trace on a digital oscilloscope, and transferred to a computer for signal processing and data interpretation. An oscilloscope display of the flaw signals is one of the most common types of ultrasonic displays, called an A-scan. A typical A-scan voltage vs time display is shown in **Figure 2** for a pulse-echo setup where the same transducer is used as both a transmitter and receiver. In contrast, the two-transducer setup shown in **Figure 1** is called a pitch-catch setup. In an A-scan display, one normally sees, in addition to the flaw signal(s), other responses from the geometry, such as the back surface reflection shown in **Figure 2**, and a large negative response at the beginning of the time trace, called the ‘main bang’. This main bang signal comes from some of the electrical energy generated while the pulser is firing leaking through into the receiving section. This signal produces a ‘dead zone’ close to the transducer that is unusable for inspection purposes since other responses are buried in this large signal. In addition to the A-scan, there are two other commonly-used types of display in the nondestructive testing field. The B-scan, shown in **Figure 3**, uses a position sensor to measure the location (*x*-position) of the transducer as it moves along a linear scan path. When a signal is received from a flaw or a part of the geometry, the arrival time of this signal is used to generate a corresponding depth (*z*-position) from which the signal arose in the component being inspected. A response that is proportional to the amplitude of the signal received is then recorded on a computer display at these measured *x*- and *z*-positions. As the transducer moves, a complete cross-sectional display is then generated on the computer screen, as shown in **Figure 3**, producing in effect a side view of the interior of the component. Only a black and white B-scan image is shown in **Figure 3** but in practice these images may be gray-scale or color-coded.

Another type of flaw response display used in nondestructive testing is called a C-scan. In this case, a transducer is mechanically moved in a two-dimensional plane, typically in a raster-like scan as shown in **Figure 4**. Both the *x*- and *y*-coordinates of

High-frequency propagating sound waves are commonly used in industry as a means for nondestructively evaluating a component for flaws. **Figure 1**

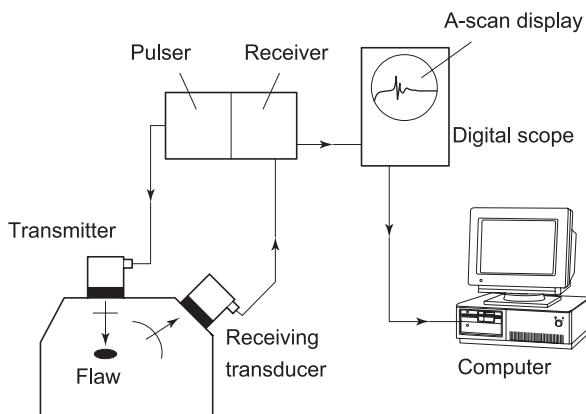

Figure 1 Components of an ultrasonic nondestructive testing measurement system.

the transducer are measured and a response proportional to the amplitude of the signal received is recorded and displayed on a computer screen at this location, producing a two-dimensional (2-D) C-scan image as the transducer scans over the surface. In some cases, only signals received in a particular time range (corresponding to a depth range in the component being inspected) are displayed, giving a 2-D image of flaws only in a selected section of the part. If this depth range is taken as the full width of the component in the z -direction, then all the flaw responses are displayed, as shown in **Figure 4**. However, unlike the black and white image shown in **Figure 4**, the amplitude responses of many C-scans are often displayed as color-coded images on a computer screen.

Producing A-, B-, or C-scan images of flaw responses is not difficult to achieve. What is difficult is to quantitatively interpret those images in terms of flaw type, size, orientation, etc. Such interpretation requires a more detailed knowledge of the basic physics involved in the inspection process. The following sections describe some of that fundamental physics, including the types of ultrasonic waves used for testing purposes (bulk waves, Rayleigh waves, plate waves), and basic wave phenomena (reflection/transmission, mode conversion, critical angles, attenuation) that are often present in ultrasonic inspections. Since ultrasonic transducers play a very important role in tests, several sections discuss the types of ultrasonic transducers commonly used in

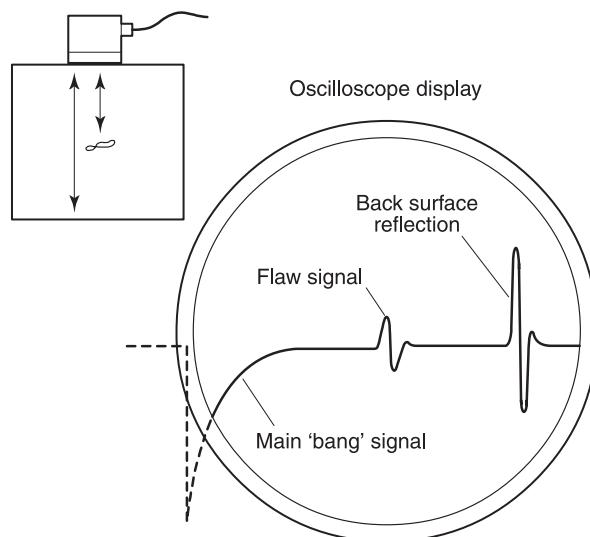

Figure 2 A-scan voltage vs time display for a simple pulse-echo inspection setup.

practice and consider the basic parameters that describe the radiated sound fields of transducers.

Ultrasonic Bulk Waves

Ultrasonic bulk waves are the type of waves most commonly used in nondestructive testing applications. The governing equations that describe bulk waves for a homogeneous, isotropic elastic solid are Navier's equations, given by:

$$G\nabla^2\mathbf{u} + \frac{E}{2(1+v)(1-2v)}\nabla(\nabla \cdot \mathbf{u}) = \rho \frac{\partial^2 \mathbf{u}}{\partial t^2} \quad [1]$$

where $\mathbf{u}(x, t)$ is the displacement in the solid at point x and time, t , ρ is the density, G is the shear modulus, and E and v are Young's modulus and Poisson's ratio, respectively. Through the use of the Helmholtz decomposition theorem, the displacement can be expressed in terms of a scalar potential, ϕ , and a vector potential, ψ , as:

$$\mathbf{u} = \nabla\phi + \nabla \times \psi \quad [2]$$

This Helmholtz decomposition reduces Navier's equations to two separate wave equations for the potential functions given by:

$$\begin{aligned} \nabla^2\phi - \frac{1}{c_p^2} \frac{\partial^2\phi}{\partial t^2} &= 0 \\ \nabla^2\psi - \frac{1}{c_s^2} \frac{\partial^2\psi}{\partial t^2} &= 0 \end{aligned} \quad [3]$$

The scalar potential ϕ represents compressional waves traveling with the wave speed c_p while the vector potential ψ represents shear waves traveling with a wave speed, c_s , where:

$$\begin{aligned} c_p &= \sqrt{\left[\frac{E(1-v)}{(1+v)(1-2v)\rho} \right]} \\ c_s &= \sqrt{\left(\frac{G}{\rho} \right)} = \sqrt{\left[\frac{E}{2(1+v)\rho} \right]} \end{aligned} \quad [4]$$

For most structural materials the wave speed of compressional waves is approximately twice the wave speed of shear waves (see Table 1). Both compressional and shear waves are referred to as bulk waves since they propagate in the volume (bulk) of a solid. Compressional bulk waves are also called P-waves, pressure waves, longitudinal (L) waves, dilatational

waves, or irrotational waves. Bulk shear waves are also called S-waves, transverse (T) waves, distortional waves, equivoluminal waves, or rotational waves.

An elastic solid admits plane harmonic bulk wave solutions of the form:

$$\begin{aligned} \phi &= \Phi \exp [ik_p(x - c_p t)] \\ \psi &= \Psi \exp [ik_s(x - c_s t)] \end{aligned} \quad [5]$$

where $k_\alpha = \omega/c_\alpha$ is the wave number for a wave of type α ($\alpha = p, s$) and ω is the circular frequency. Since both bulk wave speeds in eqn [4] are independent of frequency, harmonic wave solutions of the type given by eqn [5] represent nondispersive waves. This is strictly true, however, only if the solid is perfectly elastic so that no frequency dependent energy attenuation or dissipation mechanisms are present.

Rayleigh Waves

At a free surface of an elastic solid, waves can propagate that are confined primarily to that surface. These surface waves are called Rayleigh waves. At the stress-free plane surface ($y = 0$) of a semi-infinite elastic solid occupying the region $y \geq 0$, for example, harmonic Rayleigh waves of the form:

$$\begin{aligned} \phi &= A \exp(-\alpha y) \exp[ik(x - ct)] \\ \psi &= Be_z \exp(-\beta y) \exp[ik(x - ct)] \end{aligned} \quad [6]$$

can propagate and satisfy the stress-free surface boundary conditions if the Rayleigh wave speed, $c = c_R < c_s$, is a real root of the equation:

$$\left(2 - \frac{c^2}{c_s^2}\right)^2 - 4\sqrt{\left(1 - \frac{c^2}{c_p^2}\right)}\sqrt{\left(1 - \frac{c^2}{c_s^2}\right)} = 0 \quad [7]$$

A simple equation that gives a good fit for this root in terms of Poisson's ratio, ν , and the shear wave speed, c_s , is:

$$c_R = \frac{0.862 + 1.14\nu}{1 + \nu} c_s \quad [8]$$

The depth of penetration of Rayleigh waves into the solid ($y \geq 0$), is controlled by the frequency. This can be seen from the expressions for the decay coefficients α, β of eqn [6] which are given by:

$$\begin{aligned} \alpha &= |k| \sqrt{\left(1 - \frac{c^2}{c_p^2}\right)} \\ \beta &= |k| \sqrt{\left(1 - \frac{c^2}{c_s^2}\right)} \end{aligned} \quad [9]$$

where $k = \omega/c$ is the wave number and $c = c_R$ is the wave speed of the Rayleigh wave. Although the solutions in eqn [6] are for 2-D disturbances propagating on a planar interface, similar Rayleigh waves can be propagated on the curved surfaces of 3-D geometries, allowing their use in the inspection of surface areas of a component that might not be directly accessible. Rayleigh waves are nondispersive provided that the solid behavior is perfectly elastic, and provided that the predominant wavelengths present in the propagating wave are large, relative to both the principal radii of the surface and the surface roughness.

Plate Waves

In thin geometries such as plates, potentials of the form:

$$\begin{aligned} \phi &= f(y) \exp [ik(x - ct)] \\ \psi &= g(y)\mathbf{e}_z \exp [ik(x - ct)] \end{aligned} \quad [10]$$

can satisfy the governing equations of motion and boundary conditions of zero stress on the faces of the plate. These solutions correspond to plate waves, also called Lamb waves. It is usually convenient to consider separately the case of symmetrical extensional motions of the plate and antisymmetrical flexural motions (Figure 5). The wave speeds of both the extensional and flexural motions are found as roots of the equation:

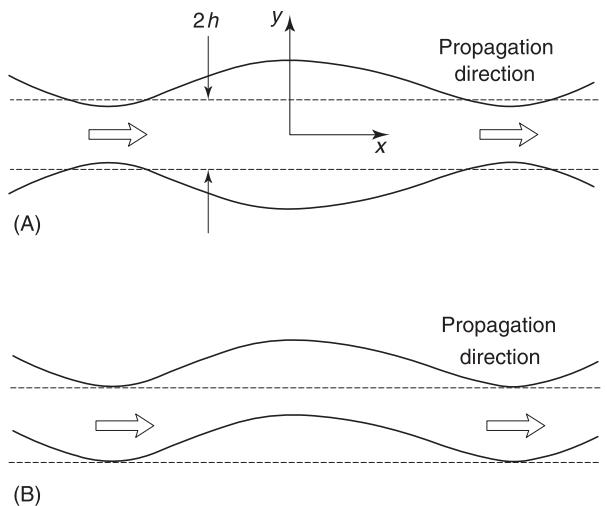

Figure 5 Displacements associated with (A) symmetrical and (B) antisymmetrical plate (Lamb) waves.

$$\frac{\tanh(\beta h)}{\tanh(\alpha h)} = \left[\frac{4k^2\alpha\beta}{(k^2 + \beta^2)^2} \right]^{\pm 1} \quad [11]$$

where the plus/minus sign in eqn [11] corresponds to extensional/flexural plate waves, respectively. The thickness of the plate is $2h$ and $\alpha\beta$ are given by eqn [9] where now c is the wave speed of the plate wave. Unlike the case of Rayleigh surface waves, the wave speeds corresponding to the roots of eqn [11] are frequency-dependent so that plate waves in general are dispersive. Also, at a given frequency, there are multiple roots of eqn [11] possible, each of which corresponds to a particular plate wave 'mode'. Figure 6 shows some of the dispersion curves for

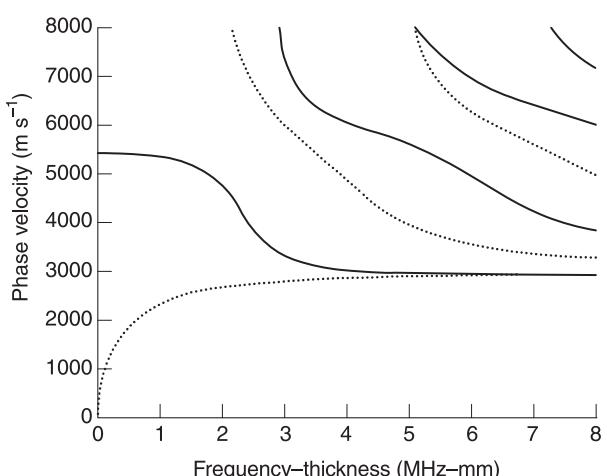

Figure 6 Phase velocity vs frequency for some of the lowest-order symmetrical (continuous lines) and antisymmetrical (dotted lines) plate Lamb waves.

various symmetrical and antisymmetrical plate wave modes. Because Lamb waves are very sensitive to changes of geometry, they are frequently used in pipe and plate inspections to detect cracks and corrosion-induced thinning and to inspect bonds in multi-layered structures.

Reflection and Refraction of Ultrasonic Waves

When an ultrasonic bulk wave of a particular type is incident on a solid interface, reflected and refracted waves of different types can be generated through the process of mode conversion. For example, in nondestructive immersion testing applications, a transducer located in a fluid generates compressional waves that then can be transmitted into an immersed solid component. An idealized model of this case is shown in Figure 7 where the incident wave is a plane P-wave and the fluid–solid interface is planar.

The incident wave generates only a reflected plane P-wave in the fluid but both a plane P-wave and a mode-converted plane S-wave are transmitted into the solid. At oblique incidence, the directions of propagation of the reflected and transmitted waves are controlled by generalized Snell's law, given by:

$$\frac{\sin \theta_{p1}}{c_{p1}} = \frac{\sin \theta_{p2}}{c_{p2}} = \frac{\sin \theta_{s2}}{c_{s2}} \quad [12]$$

where c_{p1} , c_{p2} are the compressional wave speeds in the fluid and solid, respectively, and c_{s2} is the shear wave speed of the solid. The polarization direction for the velocity of each wave is shown as a bold arrow in

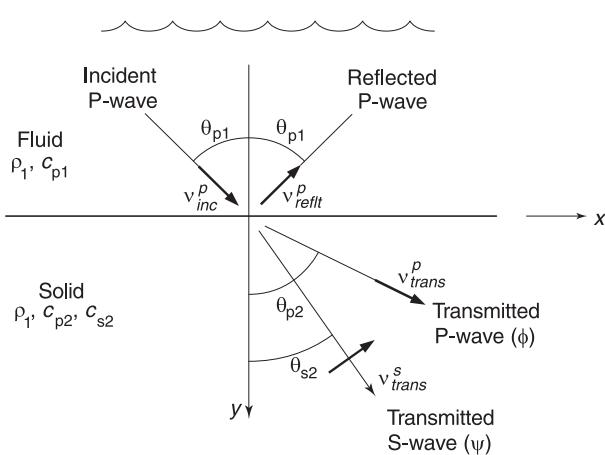

Figure 7 Reflected and transmitted plane waves at a plane fluid–solid interface due to an incident plane wave in the fluid, illustrating the process of mode conversion. Polarizations of the wave velocity vectors are shown as bold arrows.

Figure 7. Plane P-waves are longitudinally polarized along their directions of propagation while plane S-waves have a polarization in a plane perpendicular to the direction of propagation. If the polarization of an S-wave lies in a vertical plane, as is the case shown in Figure 7, then the S-wave is a vertically polarized (SV) wave. If the polarization is in a horizontal plane instead, then the S-wave is called a horizontally polarized (SH) wave.

The amplitudes of the reflected and transmitted waves at an interface are usually expressed as the amplitude of the incident wave multiplied by an appropriate reflection or transmission coefficient. Amplitudes can be expressed in terms of many different physical quantities (pressure, stress, velocity, displacement, energy, etc.) so that it is important to specify the physical quantity on which a particular reflection or transmission coefficient is based. For example, the reflection and transmission coefficients based on ratios of the reflected/transmitted wave velocities to the incident wave velocity at the fluid–solid interface are given by:

$$\begin{aligned} R^{PP} &\equiv \frac{v_{reflt}^P}{v_{inc}^P} = \frac{\Delta_2 - \Delta_1}{\Delta_1 + \Delta_2} \\ T^{PP} &\equiv \frac{v_{trans}^P}{v_{inc}^P} = \frac{2 \cos \theta_{p1} [1 - 2(\sin \theta_{s2})^2]}{\Delta_1 + \Delta_2} \\ T^{PS} &\equiv \frac{v_{trans}^S}{v_{inc}^P} = \frac{-4 \cos \theta_{p1} \cos \theta_{p2} \sin \theta_{s2}}{\Delta_1 + \Delta_2} \end{aligned} \quad [13]$$

where:

$$\begin{aligned} \Delta_1 &= \cos \theta_{p2} \\ \Delta_2 &= \frac{\rho_2 c_{p2}}{\rho_1 c_{p1}} \left[4 \left(\frac{c_{s2}}{c_{p2}} \right)^2 \sin \theta_{s2} \cos \theta_{s2} \sin \theta_{p2} \cos \theta_{p2} \right. \\ &\quad \left. + 1 - 4(\sin \theta_{s2} \cos \theta_{s2})^2 \right] \end{aligned} \quad [14]$$

Eqns [12]–[14] show that in general, these reflection and transmission coefficients are controlled by the incident angle, the wave speeds of the fluid and the solid and the acoustic impedance, Z_α , for a wave of type α ($\alpha = p, s$), defined by:

$$Z_\alpha = \rho c_\alpha \quad [15]$$

In the SI system, the unit of Z_α is $\text{kg m}^{-2}\text{s}^{-1} = 1 \text{ rayl}$. A rayl is a very small quantity so that acoustic impe-

dance values are often quoted in terms of Mrayl = 10^6 rayl (Table 2). At normal incidence ($\theta_{p1} = 0$) eqn [13] reduces to:

$$\begin{aligned} R^{PP} &= \frac{\rho_2 c_{p2} - \rho_1 c_{p1}}{\rho_1 c_{p1} + \rho_2 c_{p2}} = \frac{Z_{p2} - Z_{p1}}{Z_{p1} + Z_{p2}} \\ T^{PP} &= \frac{2\rho_1 c_{p1}}{\rho_1 c_{p1} + \rho_2 c_{p2}} = \frac{2Z_{p1}}{Z_{p1} + Z_{p2}} T^{PS} = 0 \end{aligned} \quad [16]$$

Equation [16] shows that there is no mode conversion at normal incidence and the reflection and transmission coefficients are controlled solely by the ratio of the compressional wave acoustic impedances of the two media.

From generalized Snell's law (eqn [12]), it follows that at oblique incidence there are two critical angles where the waves which characterize the transmission/reflection process change from the purely plane waves shown in Figure 7. The first of these critical angles occurs when the transmitted P-wave grazes along the interface ($\theta_{p2} = \pi/2$) which occurs at an incident angle, θ_{p1} , given by:

$$\theta_{p1} = \sin^{-1} \left(\frac{c_{p1}}{c_{p2}} \right) \quad [17]$$

Such a critical angle always exists as long as $c_{p2} > c_{p1}$. For incident angles greater than this first critical angle, the transmitted plane P-wave disappears entirely and becomes instead an inhomogeneous wave traveling along the interface whose amplitude decays exponentially with depth from the interface. If the incident angle is increased to the point where the transmitted shear wave grazes the interface, a second critical angle, θ_{c2} , occurs where the incident angle is:

Table 2 The acoustic impedance of compressional and shear waves for some common materials

Material	Z_p (Mrayls)	Z_s (Mrayls)
Air	0.0004	–
Aluminum	17.3	8.21
Brass	40.6	18.1
Copper	44.7	20.3
Glass	12.6	7.35
Lucite (perspex)	3.11	1.27
Magnesium	57.7	30.5
Nickel	49.5	26.5
Nylon	2.91	1.23
Polyethylene	1.79	0.50
Steel, mild	46.6	25.3
Steel, stainless	45.4	24.3
Titanium	27.3	13.9
Water	1.48	–

$$\theta_{c2} = \sin^{-1} \left(\frac{c_{p1}}{c_{s2}} \right) \quad [18]$$

This second critical angle also always can exist as long as $c_{s2} > c_{p1}$. For incident angles beyond the second critical angle, the transmitted plane shear wave also disappears and becomes an exponentially decaying inhomogeneous wave traveling along the interface. Critical angles are very important in ultrasonic nondestructive testing applications since they are used in the construction of angle beam shear wave transducers and Rayleigh wave transducers (see the section below on ultrasonic transducers).

Attenuation of Ultrasonic Waves

Navier's equations or the wave equations derived from it in terms of potentials describe the propagation in an ideal (lossless) material. However, waves in all real materials exhibit a loss of amplitude due to attenuation mechanisms such as grain scattering (also called metal 'noise'), and absorption. If the amplitude of a plane wave traveling in the x -direction in an attenuating medium is A_1 at a location x_1 and A_2 at a location $x_2 = x_1 + d$, then to account for attenuation losses we may write:

$$\frac{A_2}{A_1} = \exp [-\alpha(f)d] \quad [19]$$

where $\alpha(f)$ is the attenuation coefficient, measured in nepers per unit length (where a neper (Np) is a dimensionless quantity). In general the attenuation coefficient will be a function of the frequency, f , of the ultrasound. For example, in water at room temperature, the attenuation has been measured as:

$$\alpha(f) = 25.3 \times 10^{-15} f^2 \text{ Np m}^{-1} \quad [20]$$

where f is the frequency in Hz. Frequently, attenuation measurements are given on a decibel (dB) scale instead. Attenuation measured in terms of dB/unit length, $\alpha_{dB/l}$, can be related to the linear attenuation coefficient, α , through the relationship:

$$\alpha_{dB/l} = 8.686\alpha \quad [21]$$

In highly attenuative materials such as rubbers or filled materials, material attenuation may also affect the wave speed in a frequency-dependent manner. These effects are called material dispersion effects to distinguish them from frequency-dependent wave

speeds arising from geometric dispersion, as found in plate waves.

Ultrasonic Transducers

One of the most common ways to generate ultrasound in ultrasonic tests is with the use of a contact P-wave transducer of the type shown in **Figure 8**. The contact transducer consists of a very thin piezo-electric crystal plate that is electroplated on both faces. Those faces are in turn connected electrically to the external input/output connector of the transducer. In some cases a small electrical network may be present for ‘tuning’ purposes. The front face of the plated crystal is attached to a ceramic wear plate and the back face is attached to an attenuative backing material that is used to control the vibrational characteristics of the crystal. During ultrasonic inspections, a thin fluid couplant layer is normally used between the wear plate and the part being tested to ensure good mechanical coupling of the transducer to the part. Water, oil, and glycerin are some examples of common fluid couplants used in practice. When the voltage pulse generated by the pulser excites the faces of the crystal, mechanical motion of the piezo-electric crystal is produced. Normally, the characteristics of the piezo-electric crystal plate are chosen so that this motion is generated primarily normal to the crystal faces, causing its thickness to expand and contract. This motion then launches a compressional (P)-wave through the wear plate and couplant into the adjacent material.

Contact transducers of similar construction can also be designed to launch shear waves. However, the special permanent or semi-permanent couplants required for a contact S-wave transducer prevents one from using those transducers where scanning motion of the transducer over a component is required. Instead, shear wave scanning inspections normally

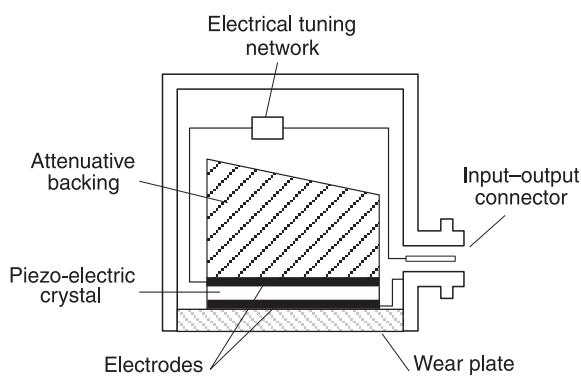

Figure 8 Elements of a contact, plane P-wave transducer.

employ an angle beam shear wave transducer as shown in **Figure 9**. In this configuration the elements of a P-wave transducer (crystal, backing, etc.) are placed on the angled surface of a plastic wedge that is then coupled to the component with an ordinary fluid couplant. The angle of the wedge is chosen so that the first critical angle is exceeded. In this case the refracted P-wave is an inhomogeneous wave and does not propagate as a bulk wave into the component, leaving only a mode-converted bulk SV-wave propagating at an angle θ_{s2} as shown in **Figure 9**. Transducers of this same type can be used to generate Rayleigh surface waves as shown in **Figure 10**. In this case the wedge angle must be chosen so that one phase matches to the Rayleigh wave speed of the component being inspected. From generalized Snell’s law, this occurs when:

$$\theta_{p1} = \sin^{-1}(c_{p1}/c_{R2}) \quad [22]$$

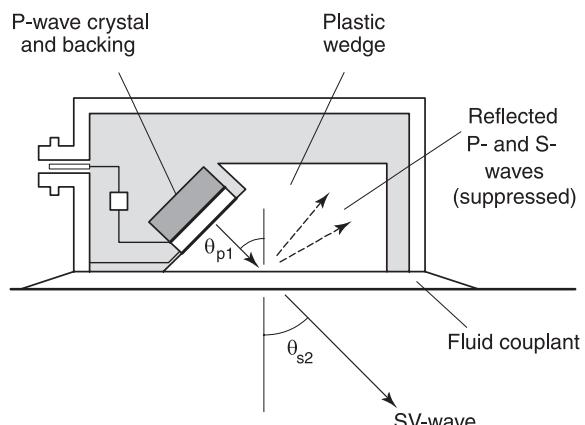

Figure 9 Elements of an angle beam shear wave transducer.

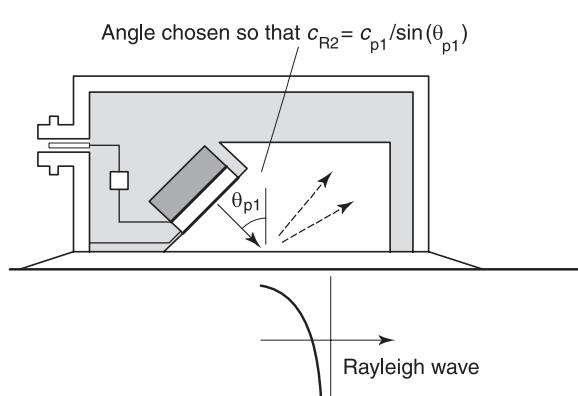

Figure 10 An angle beam transducer constructed so as to generate a Rayleigh surface wave.

where c_{p1} is the wave speed of P-waves in the plastic wedge and c_{R2} is the Rayleigh wave speed of the component.

Immersion transducers (Figure 11) have a construction that is very similar to that of a contact P-wave transducer. These transducers and the component to be inspected are both placed in a fluid. The transducer launches a P-wave into the fluid which propagates in the fluid and then into the component. In the immersion probe the wear plate is replaced by a facing plate, called a quarter-wave plate, that serves to improve the transmission of energy from the crystal to the water. Immersion transducers are often attached to a mechanical scanning apparatus at the end of a metal tube (called a wand) as shown in Figure 11.

Other types of ultrasonic piezo-electric transducer include focused transducers (Figure 12) and arrays (Figure 13). Focused transducers often employ an acoustic lens to concentrate the ultrasound at a particular depth while arrays use electronically controlled phasing of many small elemental transducers to produce both beam steering and focusing.

Devices other than piezo-electric transducers have also been used to both generate and receive ultrasound. Electromagnetic acoustic transducers (EMATS), for example, generate ultrasound through the use of eddy currents generated in an electrically conducting component interacting with a magnetic field to cause a mechanical motion of the surface of the component (Figure 14). In laser ultrasonics, a laser beam can be used to locally heat a small region of a surface impulsively and produce a propagating wave.

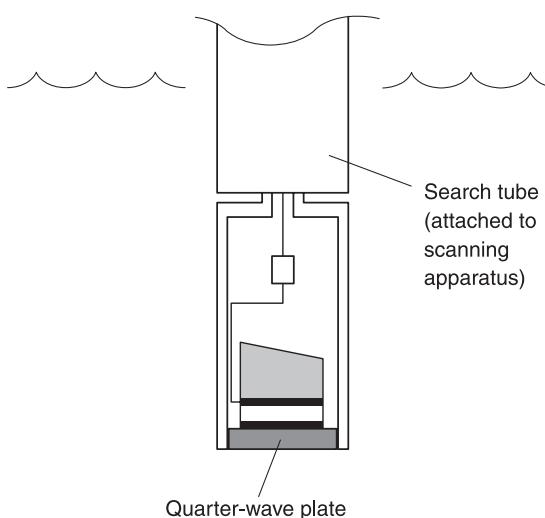

Figure 11 Elements of a plane P-wave transducer used in immersion testing.

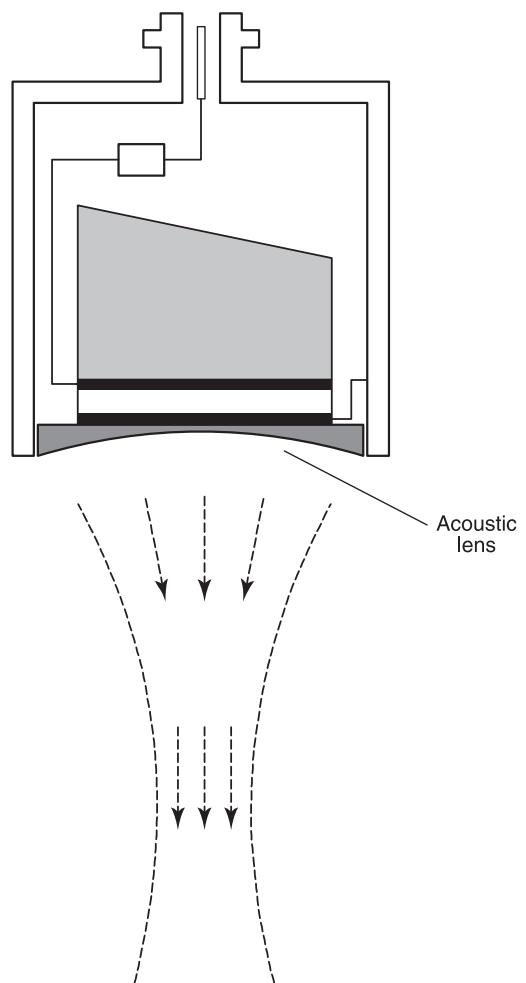

Figure 12 A focused P-wave transducer for immersion testing which uses an acoustic lens to concentrate the sound beam.

Electrostatic (capacitive), magnetostrictive and flexible polymeric transducers are also used in particular applications.

Transducer Radiated Wave Fields

The beam of sound generated by an ultrasonic transducer controls many of the important aspects of the signals received in an ultrasonic nondestructive testing measurement. Although a transducer is excited by a voltage pulse and therefore generates a short acoustical pulse of sound in the propagation medium, many of the important aspects of a transducer wave field can be studied by modeling the case when the transducer is driven by a sinusoidal input at a single frequency. One commonly used model to evaluate transducer wave fields at a single frequency is the Rayleigh–Sommerfeld integral, which models the pressure, p , generated by a planar (unfocused) trans-

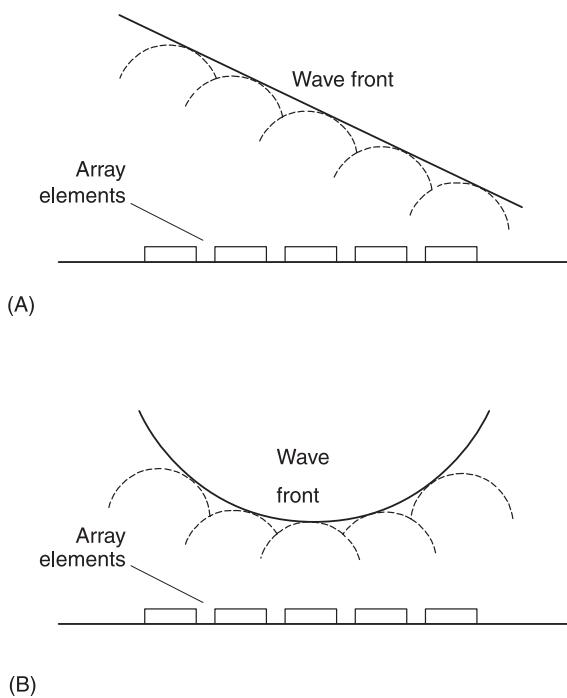

Figure 13 Elements of an array transducer where the elements are phased to produce (A) beam steering and (B) beam focussing.

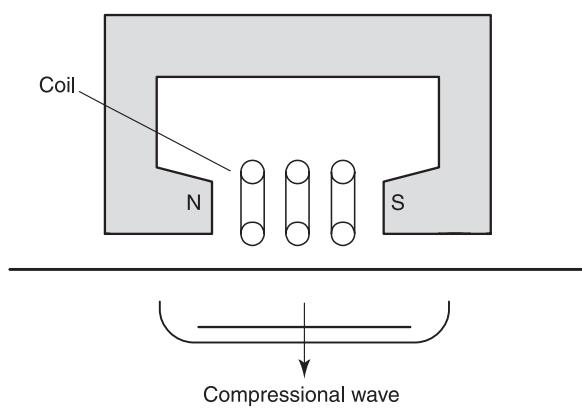

Figure 14 An electromagnetic-acoustic (EMAT) transducer for generating P-waves in an electrically conducting component.

ducer radiating into a fluid as a superposition of point sources of $\exp(-i\omega t)$ time dependency acting over a planar aperture, S , of an otherwise baffled (motionless) plane (Figure 15). The Rayleigh–Sommerfeld integral is given by:

$$p(\mathbf{x}, \omega) = \frac{-i\omega\rho}{2\pi} \int_S v(\mathbf{y}, \omega) \frac{\exp(ikr)}{r} dS(y) \quad [23]$$

where ρ is the density, $k = \omega/c$ is the wave number and $r = |\mathbf{x} - \mathbf{y}|$ is the distance between a point, \mathbf{x} , in the fluid and a point, \mathbf{y} , on the aperture, S , of the

transducer. The velocity $v(\mathbf{y}, \omega)$ is the normal velocity field acting over the aperture, S . In general the Rayleigh–Sommerfeld integral can only be evaluated numerically but there are a number of important special cases where analytical results can be obtained.

Circular Planar Piston Transducer

If the velocity field is uniform over the entire aperture, i.e., $v(\mathbf{y}, \omega) = v_0(\omega)$, then the Rayleigh–Sommerfeld integral models the wave field of a piston transducer. For a circular piston transducer of radius a , the pressure along the central ($z-$) axis can be found exactly in the form:

$$p(z, \omega) = \rho c v_0 \left\{ \exp(ikz) - \exp[ik\sqrt{(z^2 + a^2)}] \right\} \quad [24]$$

A plot of the magnitude of this on-axis pressure is shown in Figure 16. It can be seen from that figure that in a region close to the transducer there are a series of maxima and nulls in the wave field while far from the transducer the pressure simply decays monotonically. The nulls are located along the axis at locations given by:

$$z_n = \frac{a^2}{2n\lambda} - \frac{n\lambda}{2} \quad [25]$$

for the values of $n = 1, 2, 3, \dots$, where z_n is positive. The quantity $\lambda = 2\pi/k$ is the wavelength. Similarly, the on-axis maxima of a piston transducer are located at:

$$z_m = \frac{a^2}{(2m+1)\lambda} - \frac{(2m+1)\lambda}{4} \quad [26]$$

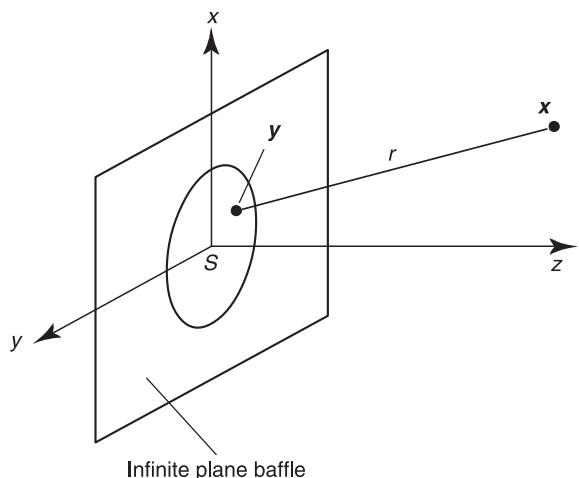

Figure 15 Plane aperture in an infinite plane baffle for modeling the waves radiated from a planar transducer into a fluid which occupies the region $z \geq 0$.

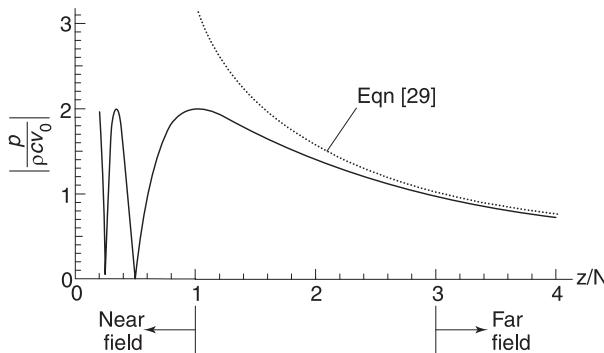

Figure 16 On-axis normalized pressure vs normalized distance for a circular, planar piston transducer ($ka = 100$), showing the near- and far-field behaviors.

for the values of $m = 0, 1, 2, \dots$, where z_m is positive. In many ultrasonic nondestructive testing the approximate near-field distance, N , given by:

$$N = \frac{a^2}{\lambda} \quad [27]$$

is large compared to the wavelength so that the second terms in eqns [25] and [26] can be neglected. In this case the nulls and maxima locations are given approximately by:

$$\begin{aligned} z_n &\cong \frac{a^2}{2n\lambda} = \frac{N}{2n} \quad (n = 1, 2, 3, \dots) \\ z_m &\cong \frac{a^2}{(2m+1)\lambda} = \frac{N}{(2m+1)} \quad (m = 0, 1, 2, \dots) \end{aligned} \quad [28]$$

As eqn [28] shows, the on-axis maximum that is the farthest from the transducer occurs for $m = 0$ at one near field distance, N , from the transducer. Distances $z < N$ are said to be in the transducer near field. Distances given approximately by $z > 3N$ are said to be in the transducer far field. In the far field the on-axis pressure is approximately given by:

$$p(z, \omega) \cong \frac{-ik\rho cv_0 a^2}{2} \frac{\exp(ikz)}{z} \quad [29]$$

Eqn [29] shows that the pressure in the far field exhibits a $1/z$ decay, the form of which is typical of a propagating spherical wave. Thus, the far-field region is also called the spherically spreading region of the transducer (Figure 16). In the far field, it is also possible to analytically evaluate the Rayleigh-Sommerfeld integral for points in the transducer wave field off the z -axis (Figure 17). The result is:

$$p(\mathbf{x}, \omega) = -i\omega\rho v_0 a^2 \frac{\exp(ikR)}{R} \frac{J_1(k\alpha \sin \theta)}{ka \sin \theta} \quad [30]$$

The first term in eqn [30] is just a frequency-dependent amplitude coefficient. The second term represents a spherically spreading wave, a result that is expected since the expression is for the pressure in the far field. The last term in eqn [30] represents the angular dependent amplitude term that is plotted in Figure 18. From Figure 18 we see that there is typically a main lobe of the transducer radiated wave field centered around the transducer axis as well as other smaller side lobes. The first null away from the axis occurs approximately at an angle:

$$\theta_{\text{null}} \cong \frac{3.83}{ka} = \frac{0.61\lambda}{a} \quad [31]$$

which is an expression that can be used to evaluate the angular beam spread of the transducer in the far field.

Together, the near field distance, N , and the angle, θ_{null} , define the main characteristics of a planar piston

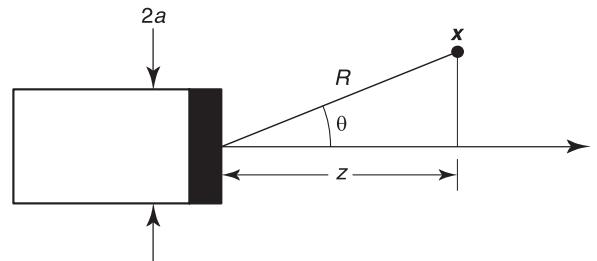

Figure 17 Geometry for defining the off-axis pressure wave field of a circular, planar piston transducer.

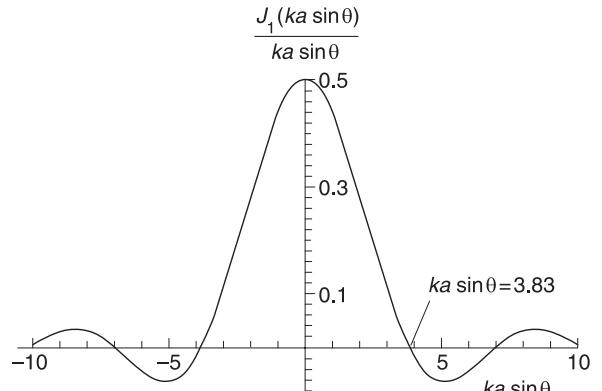

Figure 18 The far-field angular diffraction pattern for a circular, planar piston transducer showing the main lobe and side lobes of the radiated wave field.

transducer since for distances $z < N$, the beam of the transducer stays well collimated (like a flashlight beam), but with both on- and off-axis near-field variations in the pressure, while for $z > N$ the pressure in the beam simply decays monotonically and the beam spreads at an angle that can be characterized by the angle θ_{null} . This overall behavior of the transducer wave field is shown schematically in Figure 19.

Focused Transducer

The Rayleigh–Sommerfeld integral can also be used to model the wave field of a focused transducer if the planar aperture, S , is replaced by a curved surface aperture over which the normal velocity is specified (Figure 20). For a circular aperture of radius a and a spherical surface of radius R_0 the on-axis pressure can again be obtained analytically for a constant velocity (piston) transducer as:

$$p(z, \omega) = \frac{\rho c v_0}{q_0} [\exp(ikz) - \exp(ikr_e)] \quad [32]$$

where $q_0 = 1 - z/R_0$, $r_e = \sqrt{(z-h)^2 + a^2}$, and $h = R_0 - \sqrt{(R_0^2 - a^2)}$. As seen in Figure 21 there are again nulls and maxima in the response, with the largest maximum found at a distance somewhat less than the location of the geometric focus ($z = R_0$). The true focus distance, R_f , (where the on-axis response is the largest) is always smaller than the geometrical focus distance, R_0 , because of diffraction effects, becoming equal to R_0 only in the limit of very large frequencies (Figure 21). The location of the true focus can be found numerically by evaluating eqn [32]. The on-axis nulls are located at:

$$z_n = \frac{(a^2 + b^2) - n^2 \lambda^2}{2h \pm 2n\lambda} \quad (n = 1, 2, 3, \dots) \quad [33]$$

for all values of n where $z_n > 0$. The plus sign in eqn [33] corresponds to nulls that satisfy $z_n < R_0$ and the minus sign corresponds to nulls (if they exist) for $z_n > R_0$. There is not a simple analytical expression for the location of the maxima as found in the planar

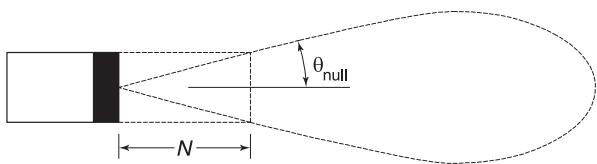

Figure 19 Characterization of the wave field of a circular, planar piston transducer by the near-field distance, N , and the angular beam spread of the main lobe, θ_{null} .

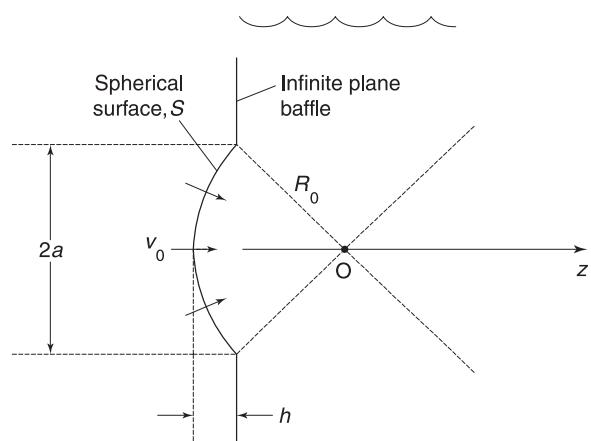

Figure 20 A spherically focused circular piston transducer modeled as a spherical aperture in an infinite plane baffle over which a normal velocity field is specified.

piston probe case. Instead, the maxima for the focused probe must be obtained as the roots of the transcendental equation:

$$\cos(k\delta/2) = \frac{2(\delta+z)\sin(k\delta/2)}{(\delta+h)q_0 k R_0} \quad [34]$$

where $\delta = r_e - z$. Analytical results for the off-axis pressure in the plane of the geometrical focus ($z = R_0$) can also be obtained (Figure 22). It is found that:

$$p(x, \omega) = -i\omega\rho v_0 a^2 \frac{\exp(ik\bar{R}_0)}{\bar{R}_0} \frac{J_1(ka \sin \theta)}{ka \sin \theta} \quad [35]$$

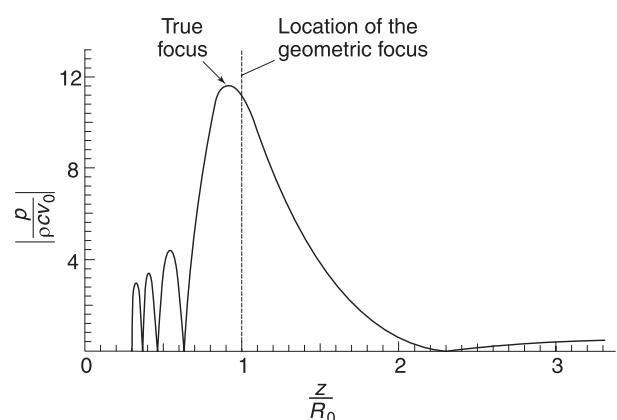

Figure 21 On-axis normalized pressure vs normalized distance for a 10 MHz, 12.7 mm diameter, 76.2 mm focal length spherically focused piston transducer radiating into water. In this case, an on-axis null exists for $z > R_0$.

which is identical in form to the far-field off-axis pressure for the planar piston probe (eqn [30]). Eqn [35] can be used to estimate the lateral spot size of the ultrasonic beam in the plane of the geometrical focus by evaluating the distance, W_f , between nulls. It is found that:

$$W_f = 7.66 \frac{R_0}{ka} \quad [36]$$

One can also estimate the focal point spot size based on either a 3 dB or a 6 dB decrease of the pressure from its maximum on axis value. In those cases, the spot size estimates are:

$$\begin{aligned} W_f|_{3 \text{ dB}} &= 3.20 \frac{R_0}{ka} \\ W_f|_{6 \text{ dB}} &= 4.43 \frac{R_0}{ka} \end{aligned} \quad [37]$$

Similarly, it is desirable to have a simple estimate of the depth of focus, D_f , of the transducer, which is defined to be the axial length over which there is a specified drop off in pressure from the maximum value. One approximate depth of focus estimate is given by:

$$D_f|_{3 \text{ dB}} \cong 3.5 \frac{R_0}{a} W|_{3 \text{ dB}} = 1.8 \frac{R_0^2 \lambda}{a^2} \quad [38]$$

based on the assumption that the beam is highly focused. A more exact value can be obtained directly

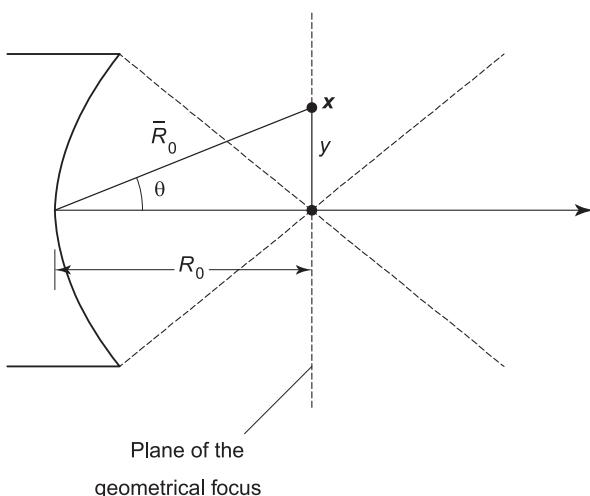

Figure 22 Geometry for defining the off-axis pressure wave field of a circular, spherically focused piston transducer in the plane of the geometrical focus.

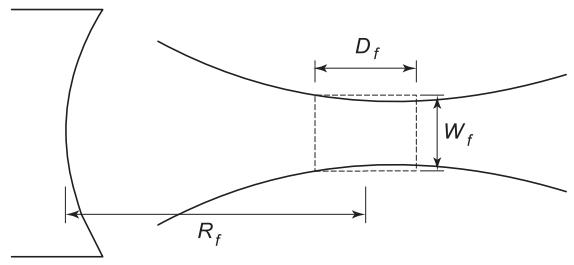

Figure 23 The three parameters that define the focussing characteristics of a circular, spherically focussed piston transducer: the location of the true focus, R_f , the lateral spot size of the beam, W_f , and the depth of focus, D_f .

from eqn [32] by numerical means. The true focal length, R_f , the focal spot size, W_f , and the depth of focus, D_f , describe the location and size of the region over which the pressure in the focused beam is concentrated (Figure 23). These are the three key parameters needed when setting up an ultrasonic inspection with a focused probe.

Nomenclature

A	amplitude
c	wave speed
D	depth of focus
E	Young's modulus
G	shear modulus
R	true focal length
S	aperture
W	focal spot size
Z	impedance
ϕ	scalar potential
ψ	vector potential
ρ	density
v	Poisson's ratio

NONLINEAR NORMAL MODES

A F Vakakis, University of Illinois, Urbana, IL, USA

doi:10.1006/rwvb.2001.0046

Introduction

The concept of nonlinear normal mode (NNM) can be considered as a nonlinear extension of the linear normal mode of classical vibration theory. Although the principle of linear superposition does not apply in nonlinear theory, NNMs can be used to predict resonances of forced nonlinear systems and to study localization (spatial confinement) of vibrational energy in periodic systems. Hence, the NNM is a valuable theoretical tool for better modeling and understanding the dynamics of nonlinear oscillators. Moreover, NNMs can find additional applications in modal analysis, model reduction, and vibration and shock isolation designs.

Definition of an NNM

Engineers and physicists traditionally associate normal modes with linear vibration theory and regard them as closely related to the principle of linear superposition. Indeed, the modes of vibration of a discrete or continuous linear system can be used to express arbitrary free or forced oscillations of the system as superpositions of modal responses. On the other hand, it is a well-known result that the principle of linear superposition generally does not apply to nonlinear systems. Hence, an NNM must be carefully defined as a nonlinear extension of the classical linear normal mode, that accounts for the restrictions imposed by nonlinear theory and respects the individualistic nature of nonlinear systems. In what follows we show that the concept of ‘normal mode’ can be successfully extended to nonlinear theory where it finds numerous applications.

All practical engineering structures are to some extent nonlinear, the nonlinearities being kinematic, material, or geometric. For example, in rotating

bladed disk assemblies, dynamic unbalances or pressure differentials due to fluid–structure interactions may excite structural resonances that lead to finite-amplitude motions where nonlinearities are strongly affecting the response. Similarly, vibrations of large-scale truss structures may be strongly influenced by clearance nonlinearities of the joints connecting individual components, or by geometric nonlinearities arising from finite deflections of oscillating structural members. In such cases the concept of NNM can be used to understand and model nonlinear dynamic phenomena that might have no counterparts in linear theory. Ignoring the nonlinear effects and using linear modes to model the dynamics, although permissible in certain cases, may lead to poor modeling and incomplete characterization of the dynamics.

An NNM can be considered as the nonlinear extension of the linear normal mode of classical vibration theory. One defines an NNM of an undamped discrete or continuous system as a synchronous periodic oscillation where all material points of the system reach their extreme values or pass through zero simultaneously. The corresponding oscillation is represented by a modal line in the configuration space of the system, which represents the synchronous oscillation. In contrast, however, to linear systems that possess straight modal lines, the modal lines of a nonlinear system can be either straight or curved. Hence, for discrete systems we define as similar NNMs those corresponding to straight modal lines in configuration space, and as nonsimilar NNMs those corresponding to curved modal lines. Nonsimilar NNMs are typical in nonlinear oscillators, whereas similar NNMs exist only under certain symmetry conditions.

As an example, consider the two-degree-of-freedom (DOF) symmetric nonlinear system of Figure 1 with governing equations of motion given by:

$$\begin{aligned}\ddot{x}_1 + x_1 + x_1^n + K(x_1 - x_2)^n &= 0 \\ \ddot{x}_2 + x_2 + x_2^n - K(x_1 - x_2)^n &= 0\end{aligned}\quad [1]$$

where n is an integer and K a coupling stiffness

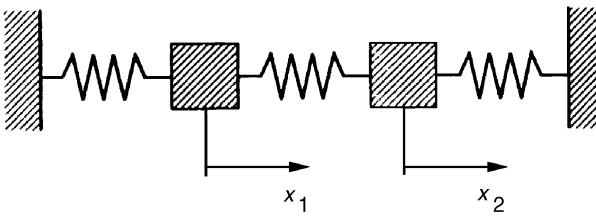

Figure 1 The two-degree-of-freedom nonlinear oscillator. Reproduced with permission from Vakakis AF (1997) Nonlinear normal modes and their applications in vibration theory: an overview. *Journal of Mechanical Systems and Signal Processing* 11: 3–22.

coefficient. This system possesses only similar NNM, corresponding to a linear relation between the dependent variables x_1 and x_2 :

$$x_2(t) = cx_1(t) \quad [2]$$

where c is termed the modal constant. Clearly, eqn [2] represents a straight modal line in the (x_1, x_2) configuration plane of the system. Using eqn [2] we eliminate x_2 from the equations of motion (eqn [1]) as follows:

$$\begin{aligned} \ddot{x}_1 + x_1 + [1 + K(1 - c)^n]x_1^n &= 0 \\ \ddot{x}_1 + x_1 - (1/c)[K(1 - c)^n + c^n]x_1^n &= 0, \quad c \neq 0 \end{aligned} \quad [3]$$

For motion on a NNM both equations [3] must provide identical solutions $x_1 = x_1(t)$, a requirement that is satisfied by matching the respective coefficients of the nonlinear terms:

$$K(1 - c)^n + c^n = 1 + K(1 - c)^n, \quad c \neq 0 \quad [4]$$

The algebraic eqn [4] always possesses the solutions $c = \pm 1$, which correspond to inphase and antiphase similar NNM. These are the only normal modes that the linear system ($n = 1$) can possess. Depending on n , the nonlinear system can have additional modes which are depicted in Figure 2. These additional NNM bifurcate from the antiphase mode $c = -1$ and exist for values of the coupling parameter $K < 1/4$. Clearly, such bifurcations cannot take place in the linear system (which has as many modes as DOF), and, thus, the bifurcating NNM are essentially nonlinear modes which cannot be regarded as analytic continuations of any linear ones. Hence, the normal modes of a nonlinear system can be more numerous than its degrees of freedom – a feature which is in contrast to linear theory. As indicated in Figure 2, some of the NNM are unstable, i.e., are not maintained under small perturbations of their initial conditions. This is another exclusive feature of non-

linear modes, since linear normal modes are always neutrally stable (as are all linear periodic motions).

When the symmetry of the system of Figure 1 is perturbed, the NNM generally become nonsimilar. This type of NNM is more difficult to compute, as demonstrated by the following example. We consider again eqn [1] with $n = 3$, and perturb the symmetry by adding linear coupling terms and cubic grounding terms:

$$\begin{aligned} \ddot{x}_1 + x_1 + \nu_1 x_1^3 + k_1(x_1 - x_2) + \nu_2(x_1 - x_2)^3 &= 0 \\ \ddot{x}_2 + (1 + \alpha_1)x_2 + \nu_1(1 + \alpha_3)x_2^3 + k_1(x_2 - x_1) \\ + \nu_2(x_2 - x_1)^3 &= 0 \end{aligned} \quad [5]$$

Furthermore, we assume that weak coupling between the two masses exists, and rescale the coupling stiffness coefficients as, $k_1 = \varepsilon K_1$, $\nu_2 = \varepsilon N_2$, where ε is a small parameter, $|\varepsilon| \ll 1$. The nonsimilar NNM of the oscillator (eqn [5]) are then sought in the form (compare with the requirement for similar NNM; eqn [2]):

$$x_2 = \hat{x}_2(x_1) \quad [6]$$

where the modal function $\hat{x}_2(\cdot)$ governs the trajectory of the mode in the configuration plane (x_1, x_2) . Asymptotic methods for analytically approximating the modal curve (eqn [6]) have been presented in the literature; they are based on perturbation expansions in terms of the small parameter ε , and will not be discussed here. In contrast to similar NNM which do not depend on the energy of the motion, nonsimilar NNM are energy-dependent, and the modal function (eqn [6]) depends on the specific level of the energy of oscillation. Again, the number of nonsimilar modes of a nonlinear dynamical system may exceed in number its degrees of freedom.

NNM can also be defined for systems with damping. In this case, the NNM oscillation is not synchronous and nontrivial phase differences exist between the positional variables. Shaw and Pierre reformulated the concept of NNM for a general class of nonlinear discrete oscillators, by defining NNM invariant manifolds of the motion where the damped free oscillation takes place. The parametrization of the NNM invariant manifolds was performed by employing two independent reference positional variables, a displacement and a velocity. An extension of this invariant manifold approach to a complex framework was performed by Nayfeh and coworkers.

To demonstrate the NNM invariant manifold formulation, consider the following n -DOF oscillator:

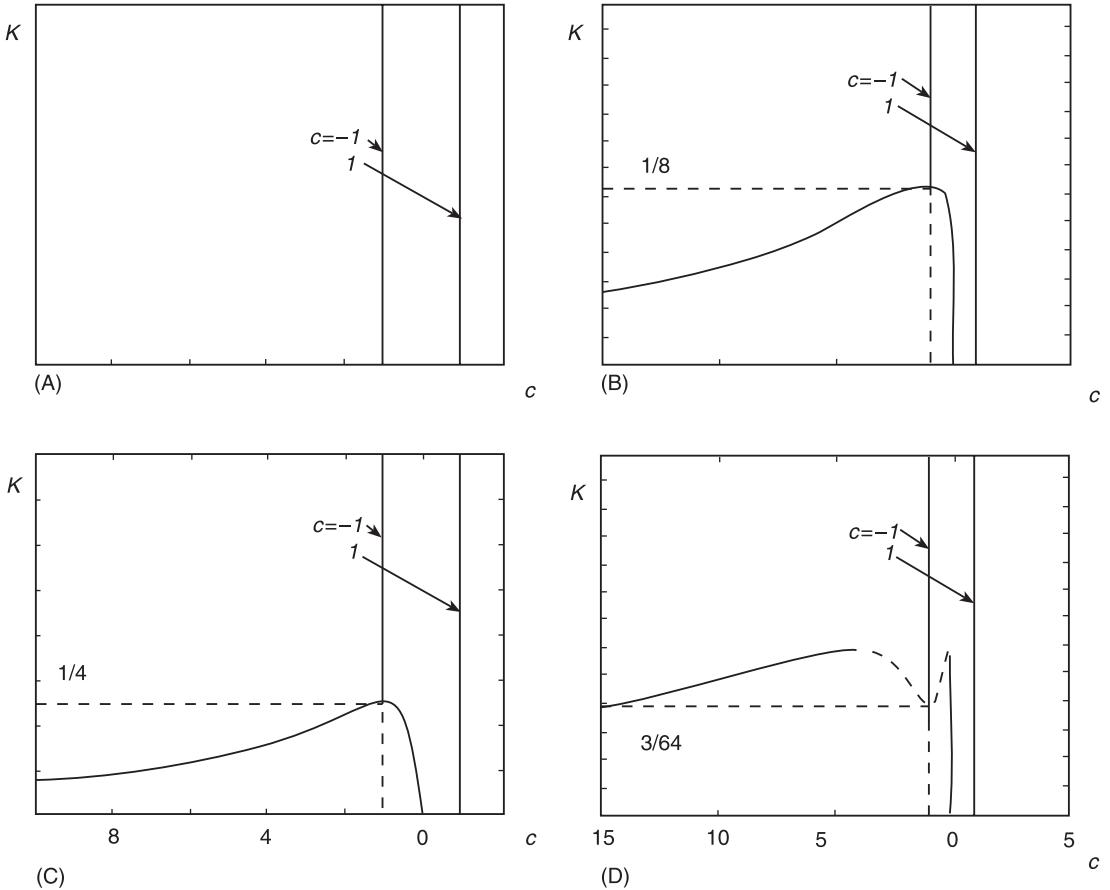

Figure 2 Nonlinear normal modes (NNMs) of the system with stiffness nonlinearities. (A) Balance of linear terms; (B) balance of fifth-order terms; (C) balance of cubic terms; (D) balance of seventh-order terms. Continuous line, stable; dashed line, unstable NNMs.

$$\ddot{x}_i + f_i(x, \dot{x}) = 0, \quad i = 1, 2, \dots, n \quad [7]$$

where \mathbf{x} is an $(n \times 1)$ vector of positional variables, and $f_i(\mathbf{x}, \dot{\mathbf{x}})$ is a vector with smooth nonlinearities. Alternatively, eqn [7] is expressed in the following form:

$$\begin{aligned} \dot{x}_i &= y_i \\ \dot{y}_i &= -f_i(\mathbf{x}, \mathbf{y}), \quad i = 1, 2, \dots, n \end{aligned} \quad [8]$$

An NNM of (eqn [7]) or (eqn [8]) is a free oscillation where all displacements and velocities are parameterized by a reference displacement-velocity pair, say $(x_1, y_1) \equiv (x, y)$:

$$x_i = X_i(x, y), \quad y_i = Y_i(x, y), \quad i = 1, 2, \dots, n \quad [9]$$

This relation defines a two-dimensional surface in the $2n$ -dimensional phase space of the dynamical system which is the two-dimensional NNM invariant mani-

fold. The NNM invariant manifold is approximated by substituting eqn [9] into eqn [8], eliminating the explicit time dependence, and solving a set of differential equations for $X_i(x, y)$ and $Y_i(x, y)$, $i = 2, \dots, n$:

$$\begin{aligned} Y_i - \frac{\partial X_i}{\partial x} y &= \frac{\partial X_i}{\partial y} f_1(x, X_2, \dots, X_n, y, Y_2, \dots, Y_n) \\ \frac{\partial Y_i}{\partial x} y + \frac{\partial Y_i}{\partial y} f_1(x, X_2, \dots, X_n, y, Y_2, \dots, Y_n) &= f_i(x, X_2, \dots, X_n, y, Y_2, \dots, Y_n), \\ i &= 2, \dots, n \end{aligned} \quad [10]$$

Methods for solving eqn [10] have been published in the literature.

We note at this point that the previous formulations for computing NNMs are valid only in systems where no modal interactions due to internal resonances exist. When such nonlinear interactions take place, the synchronicity of the NNMs is eliminated and the ensuing periodic motion takes place in higher-

dimensional invariant manifolds. In this case, nonlinear modal interactions can be analytically studied either by performing the analysis in terms of canonical modal coordinates, or by constructing NNM invariant manifolds of higher dimensions.

Applications of NNMs in vibrations

NNMs can be used better to model and understand the nonlinear vibrations of mechanical oscillators. As mentioned earlier, a nonlinear system can possess more modes than degrees of freedom and, hence, not all NNMs can be regarded as nonlinear extensions of linear modes. Indeed, in nonlinear mechanical systems mode bifurcations may occur, generating NNMs having no analogs in linear theory. Thus, a vibration analysis based purely on linearized methods may omit certain NNMs, and result in incomplete modeling of the dynamics of the system under consideration. This indicates that extending concepts such as modal analysis or forced resonance to nonlinear systems must be performed with care. In the following sections two main applications of NNMs are discussed, namely, their influence on forced resonances and on nonlinear localization and motion confinement. Potential new applications of NNMs to vibration analysis are also discussed.

Nonlinear Forced Resonances

An important property of NNMs relates to forced resonances. It has been shown in the literature that forced nonlinear resonances occur in neighborhoods of NNMs, similarly to the resonances of classical linear theory. This fact indicates that knowledge of the structure of the normal modes of a nonlinear system can provide valuable insight on its resonances, a feature that is of importance when designing for vibration isolation. We note that, depending on its modes, a nonlinear system can possess more forced resonances than the ones predicted by a linearized approach, since a subset of the resonances can be essentially nonlinear, with no counterparts in linear theory. In such cases a ‘linearization’ of the system might miss certain resonances, with obvious consequences in the success of the vibration isolation design.

To illustrate better the previous points we present an example with a cyclic flexible assembly consisting of N identical uniform cantilever beams, coupled by means of linear stiffnesses (cf. Figure 3). Assuming beam inextensibility and finite-amplitude oscillations, nonlinear inertia and curvature terms give rise to geometric nonlinearities which affect significantly the dynamics. The governing equations of motion are of the following form:

$$\begin{aligned}
 & v_{itt} + v_{ixxxx} + \varepsilon c_i v_{it} \\
 & + \varepsilon \left\{ v_{ix} [v_{ix} v_{ixx}]_x + \frac{1}{2} \int_1^x \left[\int_0^s v_i \xi^2(\xi, t) d\xi \right] ds \right\}_x \\
 & = -\varepsilon \frac{KL^4}{EI} \{2v_i(1/L) - v_{i-1}(1/L) - v_{i+1}(1/L)\} \\
 & \times \delta(x - 1/L) + \frac{P_i(x, t)}{\varepsilon^{1/2}}, \quad i = 1, \dots, N
 \end{aligned} \tag{11}$$

where K is the nonlinear coupling stiffness, c_i is the coefficient of distributed viscous damping for the i th beam, $\delta(\cdot)$ is Dirac's function, $P_i(x, t)$ is the distributed excitation applied to the i th beam, and $v_0 \equiv v_N, v_{N+1} \equiv v_1$ due to cyclicity. It is assumed that the coupling linear stiffnesses and viscous damping coefficients are small, $O(\varepsilon)$ quantities (with $|\varepsilon| \ll 1$), and that the beam deflections are of $O(\varepsilon^{1/2})$. It is additionally assumed that the distributed excitations $P_i(x, t)$ possess harmonic time dependence with frequency $(\omega_1 + \varepsilon\sigma)$ and identical spatial distribution to the first linearized cantilever mode of each beam:

$$P_i(x, t) = \Phi_1(x) \cos(\omega_1 + \varepsilon\sigma)t, \quad 0 < x < 1, \quad i = 1, \dots, N \tag{12}$$

In eqn [12], $\Phi_1(x)$ is the spatial distribution and ω_1 the natural frequency of the first linearized cantilever mode of each beam. We approximate the fundamen-

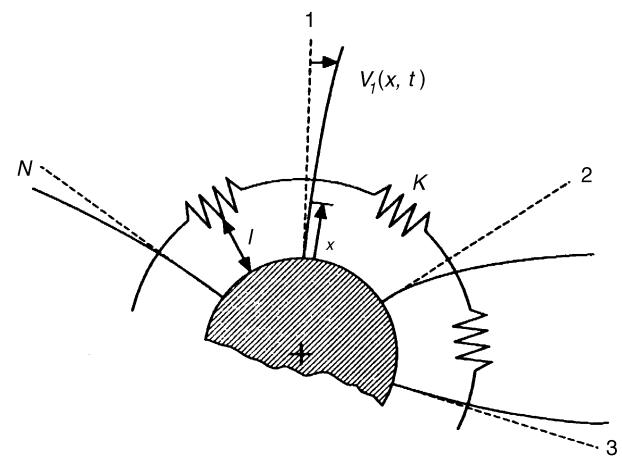

Figure 3 The cyclic assembly of N geometrically nonlinear beams. Reproduced with permission from Vakakis AF (1997) Nonlinear normal modes and their applications in vibration theory: an overview. *Journal of Mechanical Systems and Signal Processing* 11: 3–22.

tal (at the frequency of excitation) steady-state responses of the beams as:

$$v_i(x, t) = \Phi_1(x)a_i \cos [(\omega + \varepsilon\sigma)t + \beta_i] + O(\varepsilon), \quad [13]$$

$$i = 1, \dots, N$$

In **Figure 4** the resonance branches of the system with $N = 4$ beams are depicted, when harmonic excitation is applied only to beam 1. In the unforced system there are essentially nonlinear modes with no counterparts in linear theory. As a result, the nonlinear system exhibits a very complicated structure of resonances, with as many as 12 stable coexisting branches; linear theory would predict at most four resonances.

This result indicates that stiffness nonlinearities can drastically alter the topology of the steady-state response curves of a structure. This finding is especially critical in applications where precise knowledge of the resonance regimes is important for vibration isolation. Since forced resonances occur in neighborhoods of NNMs, one can optimize the topological picture if the NNMs of the unforced system before forcing is applied. This procedure can eliminate dangerous nonlinear resonances from certain frequency ranges and induce steady-state responses in other frequency domains that are beneficial to the design objectives. Hence, optimizing the structure of NNMs of the unforced system can lead to more predictable forced dynamics and improved performance of the forced system.

Nonlinear Mode Localization

NNMs provide an excellent framework for studying nonlinear mode localization in vibrating systems. Indeed, a subset of NNMs in a system can be localized, with vibration energy spatially confined to a small part of the system. This can be realized from **Figure 2** where the NNMs of the 2-DOF symmetric system of **Figure 1** are depicted. We note that as the coupling stiffness decreases (K small), there always exists a pair of NNMs with small or large values of c ; these modes are stable and localize to either one of the masses the system. Similarly, considering the resonance plots of **Figure 4** for the cyclic assembly, the branch 1 of resonances is strongly localized, with the directly forced beam vibrating with considerably larger amplitude than the other beams of the assembly. This strongly localized branch exists in the neighborhood of a strongly localized NNM of the undamped unforced system, and has no counterpart in linear theory. There also exist weakly localized resonances with more than one beam oscillating with relatively large amplitudes (for example, see branches 7 and 8 in **Figure 4**).

These examples demonstrate some typical features of nonlinear mode localization, namely, that it can occur in weakly coupled, perfectly periodic systems. This is in contrast to linear-mode localization that occurs only in weakly coupled and disordered periodic systems. Hence, localization in nonlinear systems occurs even in the absence of structural disorder. Nonlinear localization can greatly influence the transient response of a structure since it can lead to passive motion confinement of disturbances generated by external forces: in a structure with localized NNMs, motions generated by external impulsive excitations remain passively confined close to the point where they are initially generated, instead of spreading through the entire structure. This passive confinement phenomenon in periodic systems is in contrast to linear theory where energy is transferred from one mass to another through the classical beat phenomenon. Hence, localized NNMs can provide a novel tool for vibration and shock isolation designs of mechanical systems, since a system whose inherent dynamics leads to motion confinement of external disturbances is more amenable to active or passive control than a system with no such dynamical properties.

Additional Applications

NNMs can find additional applications in other areas of vibration theory. Starting from modal analysis and system identification (MA-SI), the majority of currently available techniques rely on linearity, and SI methods for nonlinear systems assume weak nonlinearities and modal structures similar to that of an underlying linearized system. As shown above, even a simple 2-DOF can have more normal modes than its DOF, which shows that nonlinear MA-SI techniques should account for the possibility that certain of the sought modes have no counterparts in linear theory. In that context, NNMs coupled with nonparametric SI methods such as orthogonal mode decomposition (Karhunen–Loeve method) can provide a valuable tool for understanding the effects of structural nonlinearities on the dynamics, and for developing new nonlinear MA-SI methodologies. The need for the development of such techniques is evident when one considers that most engineering structures exhibit to some extent nonlinear behavior due, for example, to dry friction, clearances, or vibroimpacts.

As mentioned previously, NNMs provide an excellent framework for localization designs in structures. Inducing localization in a structure can be very beneficial as far as its controllability is concerned since it can lead to passive confinement of externally induced disturbances. In addition, using NNMs to study

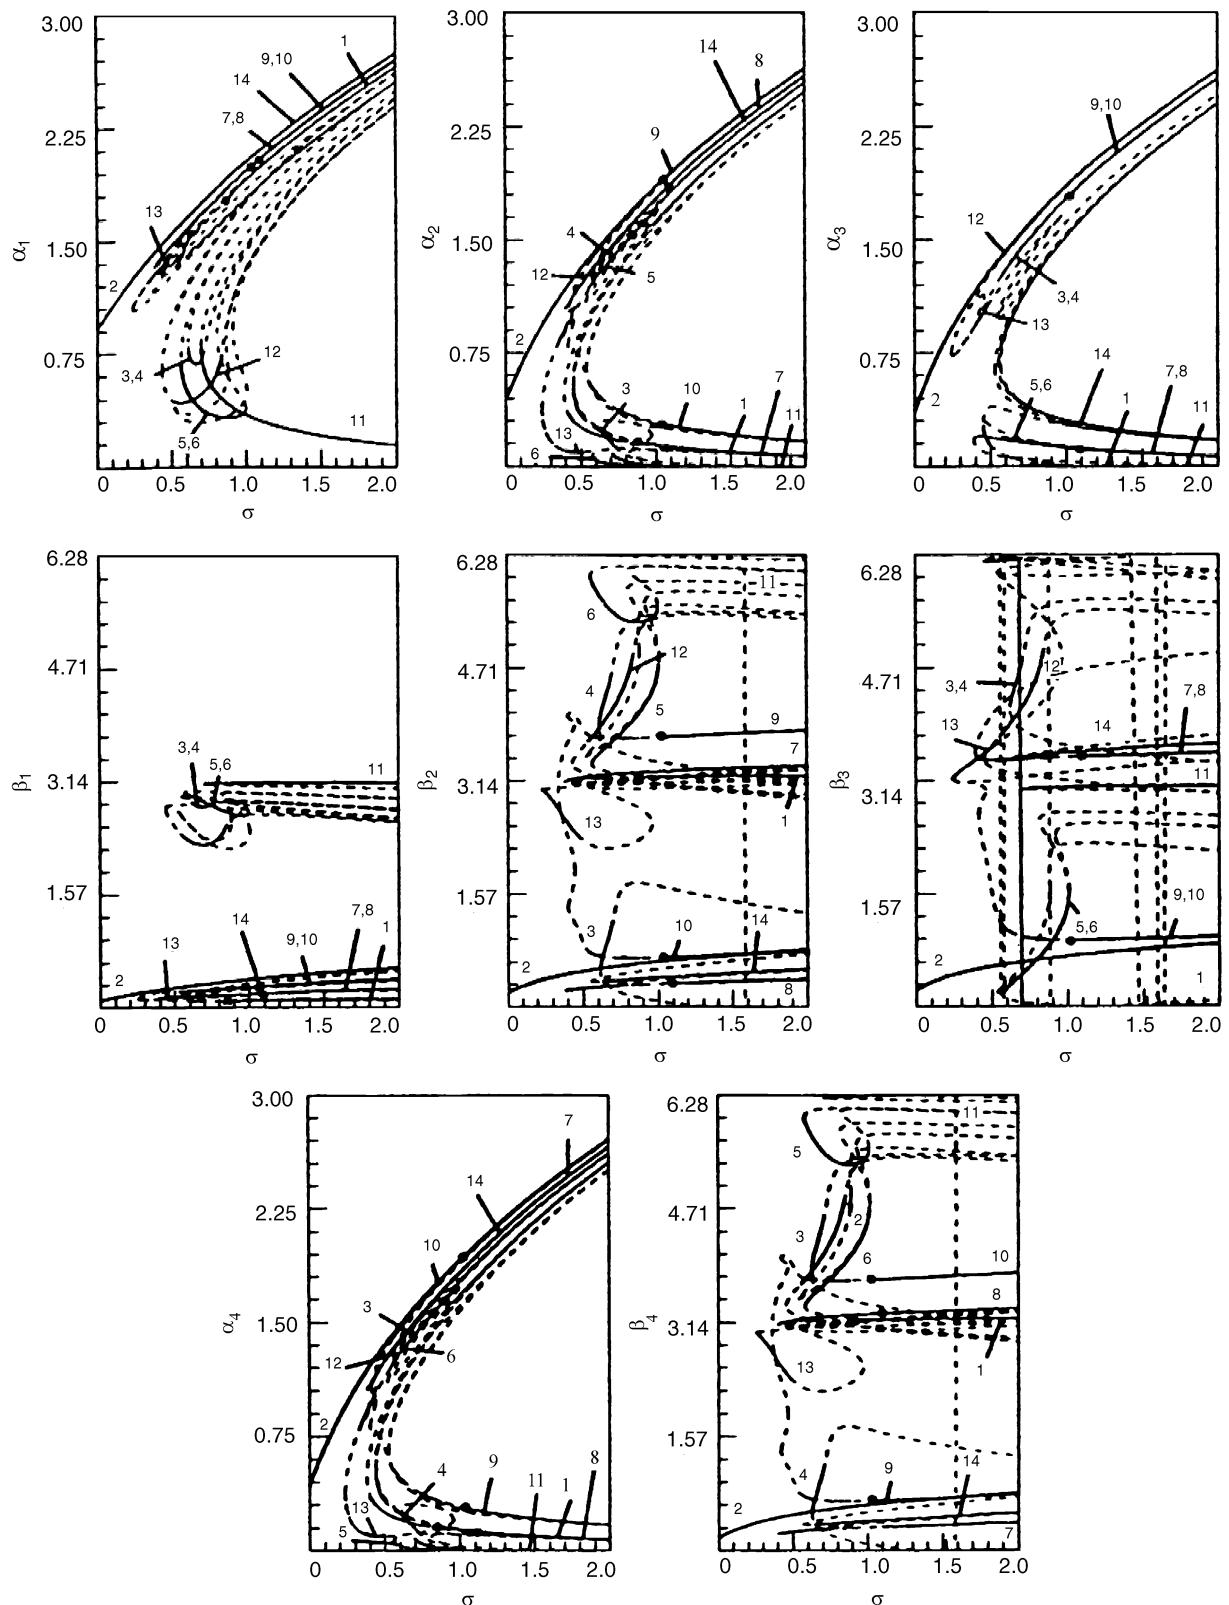

Figure 4 Fundamental resonances for $N = 4$ beams. Continuous line, stable; dashed line, unstable steady states. Reproduced with permission from Vakakis AF (1997) Nonlinear normal modes and their applications in vibration theory: an overview. *Journal of Mechanical Systems and Signal Processing* 11: 3–22.

motion confinement phenomena due to nonlinearities can be beneficial in applications where such localization phenomena are unwanted. For example, localization of vibrational energy in rotating turbine blade assemblies can be catastrophic since it may lead to failure of highly rotating blades. Understanding the mechanisms (such as structural disorder and nonlinearities) that lead to motion confinement can prevent such failures and prolong the operational life of mechanical components. To give an indication of the diverse applications that nonlinear localization has, we mention that in a recent interesting work nonlinear localization was used to explain certain dynamic phenomena in a steelpan musical instrument.

On a more theoretical level, localized NNMs can be related to certain solitary waves and solitons encountered in nonlinear partial differential equations. Hence, NNMs can provide a theoretical link between solitary waves and nonlinear localized vibrations in discrete or continuous oscillators. Of additional interest would be the development of nonlinear superposition principles that express general nonlinear transient responses as nonlinear superpositions of individual NNM responses; then a nonlinear analog to the principle of classical linear superposition of linear vibration theory could be derived.

Finally, the NNMs of elastic structures can be used as bases for Galerkin projections that reduce the number of DOF required for vibration analysis (model reduction). In recent works it was found that a basis consisting of NNMs can capture more accurately the structural dynamics than a similar basis composed of purely linearized modes. Hence, NNMs can also be used for order reduction of nonlinear systems, and for decoupling the equations of motion of nonlinear oscillators.

Nomenclature

c	modal constant
$f_i(\mathbf{x}, \dot{\mathbf{x}})$	nonlinear coupling stiffness
x_1, x_2	dependent variables
\mathbf{x}	($n \times 1$) vector of positional variables
δ	Dirac's function
$\Phi_1(x)$	spatial distribution
ω	natural frequency

Introduction

Nonlinear system identification is the art of determining a model of a nonlinear dynamical process by

combining information obtained from data with that of physical insight or *a priori* knowledge. The system to be modeled may be an experiment, a natural process, or even a large-scale computer simulation. Dynamic responses of such deterministic systems may be periodic or nonperiodic.

Nonlinear system identification is a broad subject. At the most basic level, the goal might be to merely identify how many states or modes are needed to construct a model of the system. With such information at

hand, a more detailed system identification can begin. At the more refined extreme is parametric system identification, for which the form of the differential equations of motion that model the system is known, but unknown parameters need to be identified. In between these two extremes lie techniques of nonparametric identification and nonlinear prediction, where the goal might range from revealing a nonlinear restoring force characteristic, to modeling the dynamic behavior without determining the differential equations of motion.

This article summarizes some ideas spanning this range of problems. We start with the most basic case of estimating the number of active states or modes, since in the most raw situation, this is where the analyst may start. We then discuss nonparametric identification methods, and finally, parametric system identification. There are many approaches to system identification in the literature, and we only touch on some of them. The goal here is to introduce basic ideas. Our focus is on deterministic systems, although methods are available for systems with random components. The tools discussed should enable system identification for a variety of nonlinear response regimes, be they periodic, quasiperiodic, or chaotic. Periodic responses may be more tractable for standard analyses, while nonperiodic responses tend to explore the response space and produce a large amount of information.

Estimating the Active States

When aiming for a state-space description of a vibration system, the estimation of the number of active states can be helpful in identifying low-order order models, either by reducing a high-order model, or by building a lumped-parameter model from scratch.

We can subdivide this section into two basic groups. The first group is emphasized when the modeler has access to a single time-history of data from a single observable, for example from a single sensor on the experimental rig. The second group is applicable when the analyst has access to several time histories of sensor data.

Extracting Dynamics from a Single Observable

Many of the ideas summarized here are well suited for nonperiodic data, and can be found in detail elsewhere.

The first step is to reconstruct the dynamics of the active states, i.e., to take, typically, a single sampled measurement history and view it in a higher-dimensional space, which can somehow accommodate the dynamics that generated the signal. The fully

reconstructed state space can then be used for estimating a bound on the number of active states in the system.

The method of delays is the most common method for reconstructing the phase space. Suppose we have a measurement y which is essentially a smooth function of the states x , i.e., $y = f(x)$, and suppose further that the measurement is sampled at a sampling interval h , generating a series producing sampled quantities y_n , with $n = 1, \dots, M$. According to the method of delays, we build vectors $\mathbf{y}_n = (y_n, y_{n+1}, \dots, y_{n+(d_E-1)l})$, where l is a delay index, and d_E is the dimension of y_n . The delay time is $\tau = hl$. The pseudo vectors \mathbf{y}_n can then be plotted in a d_E -dimensional space. The sequence of points \mathbf{y}_n traces out a sampled curve in this pseudo phase space. This forms the reconstructed phase space, in which the next stage of data analysis and modeling can be pursued. According to Takens' embedding theorem, the dynamics in the reconstructed phase space qualitatively represent the dynamics in the true phase space for 'smooth' systems.

The method of delays can be intuitively justified by considering that the delay coordinates represent a linear transformation from coordinates that represent finite differences in time. Since mechanical systems have states which can be represented by displacements and velocities, the choice of discretized derivatives as pseudo states seems a natural one. Incidentally, derivatives of the observable have also been considered for performing reconstructions, and while this idea does produce a pseudo phase space in theory, it has the problem of noise amplification, and is not considered practical.

Practical problems associated with the method of delays are the choice of delay, and the choice of dimension d_E . If the delay is too large, and the system is chaotic, then measurement errors grow, and successive samples in the reconstructed phase space become statistically unrelated. If the delay is too small, then successive samples in the reconstructed phase space are too similar, and little information is gained. The happy medium is usually chosen by finding the delay which minimizes the average mutual information between the observable and its delay.

The choice of d_E is what we are after, as it tells us how many delay coordinates are necessary to describe the dynamics in the reconstructed space. The supposition is that this number is similar (but not exactly the same) as the number of active states. The method of false nearest neighbors (FNN) is a common choice for determining d_E . In this method, the reconstructed phase space is examined for artificial crossings of trajectories. When two trajectories cross, the phase space is too small. The first dimension for which there seems to be no trajectory

crossings is the dimension of the reconstructed space. Variations of the method have since been developed. Usually, the dimension of the reconstructed space represents an upper bound on the number of active states in the system.

Also useful is a computation of the fractal dimension, d_0 . An object of dimension d_0 need be described by a maximum of $2d_0 + 1$ coordinates, which also provides a hint as to the number of delay variables needed to describe the data.

Extracting Empirical Modes

If simultaneous time-histories of many sensors are available, these can be used to look for empirical modes by using proper orthogonal decomposition (or Karhunen–Loëve decomposition, or principal components analysis).

Application of proper orthogonal decomposition (POD) to structures typically requires sensed dynamical quantities at M locations within the system. For this discussion, these quantities are taken to be displacements $x_1(t), x_2(t), \dots, x_M(t)$, although other states can be used. When the displacements are sampled N times, we can form displacement-history arrays $\mathbf{x}_i = (x_i(t_1), x_i(t_2), \dots, x_i(t_N))^T$, for $i = 1 \dots M$. (The means are sometimes subtracted from the displacement histories.) In performing the POD, these displacement histories are used to form an $N \times M$ ensemble matrix:

$$\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M]$$

Each row of \mathbf{X} represents a point in the measurement space at a particular instant in time. The $M \times M$ correlation matrix $\mathbf{R} = (1/N)\mathbf{X}^T\mathbf{X}$ is then formed. Since \mathbf{R} is real and symmetric, its eigenvectors are orthogonal. The eigenvectors \mathbf{v} of \mathbf{R} are the proper orthogonal modes (POMs), and the eigenvalues λ are the proper orthogonal values (POVs).

The POMs are the principal axes of inertia of the data in the measurement space, and the POV's indicate the mean squared values of the data in the directions of the corresponding POMs. Equivalently, the POMs are the optimal distributions of signal power, and the POV's indicate the signal power associated with the corresponding POMs.

Using the POV's, the POMs can be ranked in descending order of signal power. The cumulative power is then the truncated sum of the POV's. It has been customary to say that the number of dominant, or active, modes are those of largest energy that contain, say, 99% or 99.9% of the total signal power. This is a prescription. These modes can then be used as an empirical modal basis for projecting the

original large-order equations of motion to obtain a lower-order model. In linear vibrations, the POMs represent the linear normal modes only under specific circumstances.

Nonparametric Identification

In nonparametric identification, vibration behavior is modeled or predicted by means other than differential equations. Some approaches include Volterra series (or Weiner series) modeling, neural networks, and nonlinear time-series prediction, or merely the identification nonlinear stiffness characteristics.

First we mention the Volterra series approach. The response of a linear system to an input can be represented by a convolution integral, in which the input is convolved with the impulse response function. In the Volterra series approach, this convolution integral is a first-order Volterra functional. The impulse response is the kernel. For modeling nonlinear input-output dynamics, a series of Volterra functionals is constructed, the k th term consisting of a k -fold nested convolution integral involving k delays of the input and a k th order kernel, which acts as a weighting function in the integral. In identifying the system, these kernels are to be identified, typically with a least-squares fit in the time-series response. (The time-series values of the kernels or weighting values are identified). The Weiner G-functionals, which are orthogonal functionals constructed from the Volterra functionals, can be used in place of the Volterra functionals in the system identification.

Backpropagation artificial neural networks can be applied to model discrete-time dynamics of sampled dynamic systems. The artificial neural networks are basically curve-fits to the dynamics. If input-output dynamics are written as $y_{k+1} = h(y_k, y_{k-1}, \dots, y_{k-n_y}; u_k, u_{k-1}, \dots, u_{n_u})$ and if state-space dynamics are expressed as $x_{k+1} = f(x_k, u_k)$ and $y_{k+1} = g(x_k, u_k)$, where y_k is an output, u_k is an input, and x_k are the states, then the artificial neural network would be used to fit the functions h or f and g , i.e., the dynamics between samples, by using the arguments of the functions as inputs to the artificial neural network. In the learning process, the inputs and outputs are applied to the neural network, and a steepest descent (for example) with respect to network parameters, is used to minimize the error. The neural networks are highly nonlinear, and may have many local minima in the error. The aim would be to settle on a suitable local minimum.

The problem of identifying h in the input-output description is akin to nonlinear time-series prediction, for which the sampled output represents the time

series to be predicted. In time-series prediction, the goal is to take recent samples of an output, and predict the input for the near future. Time-series prediction can be done in the phase space reconstruction of the time series. When the reconstruction is in the appropriate dimension, as described earlier, and trajectories do not cross, then there is a unique short-time dynamical evolution for any point in the reconstructed phase space. That is, there is a well defined function that maps a given point in the phase space to its iterate, a few samples later. This function is to be identified. One way to do it is to find localized dynamics near reference trajectories in the dynamics. These localized dynamics are good within a specified distance of the reference trajectory, and are often modeled with linear functions. This can also be done by dividing the phase space into cells. Thus, when identified, the dynamics are approximated with piecewise linear maps.

The nonlinear dynamics of single-input/single-output dynamical systems and control systems can be modeled by setting up equivalent reverse multiple-input/single-output linear systems to represent the system at hand. When the system input and output are reversed, the nonlinearities can then be treated as additional correlated inputs.

Parametric Nonlinear System Identification

In this scenario, the ordinary differential equations of motion are known, and the forms of nonlinear terms are known. However, parameters in the equations of motion remain unknown and need to be identified. Among the approaches to consider in this situation are time-domain analysis, frequency-domain analysis, and bifurcation analysis.

The basic idea in time domain analysis is to take measured time histories of displacements, velocities and accelerations, and find parameters such that the equations of motion best accommodate the measured response for all time samples. This ultimately amounts to a least-squares solution with a minimized cost function based on a residual. One perspective is the direct evaluation of terms in the differential equation based on measured quantities. Here, the optimal parameters can be chosen to best balance the equation of motion at each time sample, for example by singular value decomposition. Another method is to use an analytical expression of the time response, written in terms of unknown parameters, and compare it with the measured response of the system to be identified. Then just one measurement signal is needed. Such methods have been reviewed by

Stry and Mook, who in turn proposed the use of a correction term to accommodate modeling errors, which is then recast into a two-point boundary-value problem for the solution of the correction term. The correction term is then used to fit the nonlinear functions to be identified.

The idea in frequency-domain analysis is to take the Fourier transforms of the measured time histories, insert them into the differential equations of motion, and find parameter values that balance harmonics in the least-squares sense. If the system is linear in its parameters, i.e., the parameters are external coefficients on the nonlinearities in the equations of motion, then the balance equations are linear in the parameters, and a straightforward least squares solution suffices. Differentiation can be done by multiplying the transformed signal by $i\omega$. As such, for example, only measurements of displacements are needed, and velocities and accelerations can be obtained in the frequency domain. If the system response is periodic, then the Fourier coefficients can be computed by Fourier series or Fourier transforms. If the system response is chaotic, then numerous saddle-type unstable periodic orbits are ‘visited’ during the response. These periodic orbits can be approximately extracted and treated similarly to the way the stable periodic responses were treated, thus extending the idea to handle chaotic responses as well as stable periodic responses. The numerous periodic orbits from the chaotic response provide ample redundancy for the least-squares approximation of the parameters.

Bifurcation behavior can be exploited by finding parameters such that bifurcation events occur at the right parameter values. Bifurcations are considered to be rather sensitive to parameters, which is good for parameter identification. The bifurcation behavior is usually determined by using perturbation methods (see **Perturbation techniques for nonlinear systems**), such as multiple scales, averaging, and normal forms; to obtain analytical expressions of the bifurcation events as functions of parameters, which can then be used for the purposes of identification. In order to use bifurcations in system identification, bifurcations need to be observed experimentally. This means that the parameter space must be explored in the experiments, and parameter values for which sudden qualitative changes in the dynamical behavior must be recorded. The type of bifurcation must be recognized. As a cautionary note, bifurcation behavior is usually analyzed for steady-state, constant-parameter behavior. Experimental sweeps of parameter space really mean that the system has nonconstant, slowly varying parameters. Systems with slowly

varying parameters may have significantly different bifurcation occurrences than systems with truly constant parameters. Thus, the experimenter must be patient in the exploration of parameter space.

Conclusions

There are a range of options in nonlinear system identification, and choosing a particular method depends on the needs of the analysts, as well as the analyst's comfort with the fundamental ideas underlying a given tool.

Along with system identification should come model verification. Models can be verified by comparing responses of the model with responses of the system to be identified. If possible, it is a good idea to use data separate from those used in the identification calculation. Nonlinear system responses can be compared by characterizations of the responses, which is another subject for study. Nonlinear responses can be very sensitive to parameter errors, modeling errors, and even initial conditions. As such, validation based on responses should be performed with caution. Another possible perspective is to compare the model more directly with the system to be identified. This can be done by examining the differences in vector fields. What is meant here is that the terms in the model, say in the differential equation, approximate the flow of states in the state space. If the flow of states can be ascertained in the data, for example by finite differences of short-term sampled data, then the geometry of the phase flow can be verified. The geometry of the phase flow may turn out to be agreeable, even if the parameter sensitive and initial conditions sensitive responses seem to be off base.

In system identification there is always concern about noise and robustness, issues that we have not covered here. These issues are addressed in many of the cited references.

Nomenclature

d	delay index
d_o	fractal dimension
d_E	dimension of y_n
R	$M \times M$ correlation matrix
λ	eigenvalue
τ	time delay

Introduction

Nonlinear models arise for most real systems and their presence in one form or another is generally the rule. The source of nonlinearity in structural and mechanical systems may be geometric, inertial, or

material in nature. Geometric nonlinearities typically arise from large deflections or rotations, or from other purely kinematical characteristics. Inertial nonlinearities can arise due to boundary or displacement dependent constraints. For example, when a thin elastic beam with movable supports undergoes transverse vibrations, the transverse oscillations are accompanied by small horizontal displacements of the movable end-mass. Thus, a large transverse motion of the beam leads to an axial inertial force that contributes to moments acting at the neutral axis of the beam. Examples of material nonlinearities include those arising due to nonlinear stress-strain relations, elastoplastic material behavior, etc. Other sources of nonlinearities include body forces (magnetic or electric fields), dry friction, and solid-fluid interactions.

In single-degree-of-freedom systems, the presence of nonlinear terms results in a vast variety of phenomena including: multiple periodic solutions, jumps in periodic responses, limit cycles, frequency entrainment, variation of natural frequencies with amplitude of response, subharmonic, superharmonic, combination and ultrasubharmonic resonances, period-doubling, and chaotic motions. While most of these responses are exhibited by systems subject to a single harmonic excitation, combination resonances arise only when the excitations involve more than one frequency. Many more interesting effects are generated when multiple excitations with distinct frequencies act on the system. All these types of behavior are classified as ‘resonance phenomena’ and arise when the linear natural frequency of the single-degree-of-freedom system and the frequencies of external or parametric excitations satisfy certain ‘frequency relationships’. A large system response amplitude resulting from a small perturbation force characterizes a resonance condition. It can be explained in terms of nonzero virtual work done by the perturbing forces over a cycle of the particular mode under consideration. The simplest resonance condition is that of ‘primary resonance’ and it occurs when $\omega_n \approx \Omega$, where ω_n and Ω are, respectively, the linear natural frequency and the excitation frequency. In this case, the amplitude of the excitation has to be small and it is called a soft excitation. All other resonance cases arising due to external excitations involve amplitudes of excitation called hard excitations.

As an example of resonant phenomena exhibited by a single-degree-of-freedom system, consider a mathematical pendulum with a point mass attached at the end of a massless rigid rod. The rod is pinned to a support which is oscillated horizontally transverse to the gravity direction in the plane of the pendulum. In the absence of the base excitation, the pendulum

rests in the bottom equilibrium position and this position is stable. When disturbed slightly, the pendulum oscillates about this static equilibrium position in its linear mode with a natural frequency determined by the length of the pendulum. When the pendulum is excited with a harmonic base displacement, the response depends on both the amplitude and the frequency of excitation. For an excitation frequency near the natural frequency, the pendulum does not need much excitation to undergo large amplitude motions. Interestingly, for frequencies below the natural frequency, there are two stable periodic motions, only one of them being large. For frequencies above the natural frequency, however, the pendulum has a unique periodic response.

We should note that if the displacement of the point of suspension of the pendulum also has a component along the vertical direction, this excitation component results in an equation of motion with time-periodic coefficients. This is an example of parametrically excited systems. For certain combinations of system and excitation parameters, these systems can exhibit parametric resonances and instabilities. These systems are considered elsewhere in the Encyclopedia and will not be addressed in this article.

Multiple-degree-of-freedom nonlinear systems can exhibit additional resonances including internal resonances and combination resonances. In an internal resonance, the system natural frequencies satisfy a certain frequency relation. In a combination resonance, both the system and excitation frequencies are involved in the frequency relation. These situations are generally called modal interactions, and they provide a mechanism for energy exchange among the modes of the system through some nonlinearity. The type of internal resonance exhibited by a system depends on the nature and degree of the nonlinearity present in it. For systems with cubic stiffness nonlinearities, an internal resonance can arise if:

$$\begin{aligned} \omega_n &\approx 3\omega_m, \quad \omega_n \approx |\pm 2\omega_m \pm \omega_k| \quad \text{or} \\ \omega_n &\approx |\pm \omega_m \pm \omega_k \pm \omega_l| \end{aligned} \quad [1]$$

where ω_n , ω_m , etc. are the linear natural frequencies of the system. When the nonlinearities in the system are quadratic, an internal resonance may additionally arise if:

$$\omega_n \approx \omega_m \quad \text{or} \quad \omega_n \approx |\pm \omega_m \pm \omega_k| \quad [2]$$

Systems with a single harmonic excitation may exhibit a combination resonance when:

$$\begin{aligned}\Omega &\approx \frac{1}{2} |\pm \omega_m \pm \omega_k|, \quad \Omega \approx |\pm 2\omega_m \pm \omega_k| \quad \text{or} \\ \Omega &\approx |\pm \omega_m \pm \omega_k \pm \omega_l|\end{aligned}\quad [3]$$

and the nonlinearities are cubic. For systems with quadratic nonlinear terms, the additional possible combination resonances involve frequency relations of the form:

$$\Omega \approx |\pm \omega_m \pm \omega_k| \quad [4]$$

When modal interactions occur due to the existence of an internal or combination resonance, modes that are not directly excited by an external forcing can also undergo large-amplitude oscillations. These motions arise, however, only when the excitation amplitude reaches a minimum critical level and a ‘pitchfork’ bifurcation transition occurs from a single mode to a coupled mode response. Also, these motions are predominant, that is, the energy transfer mechanism is effective, when the excitation frequency is in the vicinity of an exact resonance with a suitable system natural frequency. A further consequence of these modal interactions is the existence of complex amplitude-modulated dynamics for the system modes. These amplitude-modulated motions are similar to the well-known beating motions that arise in linear systems with two closely spaced natural frequencies.

As an example of modal interactions in multi-degree-of-freedom systems, consider the response of a stretched string to a transverse harmonic excitation. Suppose that the excitation is constrained to the vertical plane while the string can oscillate in both the vertical and horizontal planes. For small oscillations, the motions in the two orthogonal directions are uncoupled and are each governed by the wave equation. Thus, in each plane of motion, there is an infinity of natural modes of response and the associated natural frequencies. Every mode of oscillation in the vertical plane has an identical counterpart in the horizontal plane. For larger-amplitude motions, if the lowest-order nonlinearities are retained in the model, the equations of motion for the two identical modes of oscillation in the two orthogonal directions are coupled through cubic stiffness nonlinearities. Thus, the two identical modes of vibration of the string are in ‘one-to-one’ internal resonance. For a small harmonic forcing near a linear natural frequency of the string, the string responds harmonically in the vertical plane. Very near primary resonance, however, the response in the vertical plane becomes unstable and the string starts oscillating periodically in a three-dimensional motion. This is the well-known ballooning response of the string.

This article is focused on resonances arising in externally excited discrete dynamic systems. Quite often, these models also arise as a result of discretization of continuous models for strings, beams, rods, plates, arches, etc. Most of the analytical techniques for the study of resonance phenomena are based on constructing asymptotic or perturbation expansions for periodic and almost periodic solutions. These expansions require a small parameter, usually associated with the smallness of the nonlinearity. The asymptotic methods utilized here include the method of averaging and the method of multiple time scales. Results are described first for single-degree-of-freedom systems with quadratic and cubic nonlinearities. They are followed by some results for resonances arising in two-degree-of-freedom systems.

Resonant behavior also occurs when self-excited systems are subjected to periodic external forces or disturbances. Since the natural system itself has limit cycle motions, the external excitation frequency can interact with the self-oscillation frequency to give frequency entrainment, phase-locked motions, as well as amplitude-modulated oscillations. These motions are not discussed here.

Single-Degree-of-Freedom Systems

Consider the equation of motion for the nonlinear harmonically excited model:

$$\ddot{x} + \omega_n^2 x + 2\epsilon\zeta\dot{x} + \epsilon\alpha_1 x^2 + \epsilon^2\alpha_2 x^3 = F \cos \Omega t, \quad 0 < |\epsilon| \ll 1 \quad [5]$$

consisting of a restoring force with linear, quadratic as well as cubic terms, and a linear velocity proportional damping. Here, ϵ is a small parameter usually introduced to characterize the relative order of nonlinearity and other effects in the model. Such equations frequently arise in modeling single-degree-of-freedom mechanical systems. They also arise as one-mode truncations of continuous structural systems. Here, only position-dependent restoring forces have been considered. They are usually a result of nonlinear stress-strain (or force-deflection) relations, or kinematical constraints. Nonlinear inertial terms can also be included in the model without much difficulty.

For small-amplitude motions, the response of the system can be constructed as a power series in the small parameter ϵ . To eliminate the presence of unbounded components in the solution (secular terms), terms that are a result of only the expansion procedure, and to develop solutions that are uniformly valid in time, many techniques have been

developed. In one popular technique, known as the method of multiple time scales, new independent time-like variables are introduced and the solution is assumed in the form:

$$\begin{aligned} x(t; \varepsilon) &= x_0(T_0, T_1, \dots) + \varepsilon x_1(T_0, T_1, \dots) \\ &\quad + \varepsilon^2 x_2(T_0, T_1, \dots) + \dots \end{aligned} \quad [6]$$

where $T_0 = t$ is the fast time, and $T_1 = \varepsilon t$, $T_2 = \varepsilon^2 t$, ... etc., are the various slow times. The various time derivatives can be written in terms of the new independent time scales as:

$$\begin{aligned} \frac{dx}{dt} &= D_0 + \varepsilon D_1 + \varepsilon^2 D_2 + \dots, \\ \frac{d^2x}{dt^2} &= (D_0 + \varepsilon D_1 + \varepsilon^2 D_2 + \dots)^2 \\ &= D_0^2 + 2\varepsilon D_0 D_1 + \varepsilon^2 (2D_0 D_1 + D_1^2) + \dots, \end{aligned} \quad [7]$$

where $D_n \equiv \partial/\partial T_n$. Then, substituting in eqn [5] and collecting terms of like powers in ε gives (up to second-order):

$$D_0^2 x_0 + \omega_n^2 x_0 = F \cos \Omega T_0 \quad [8a]$$

$$D_0^2 x_1 + \omega_n^2 x_1 = -2D_0 D_1 x_0 - 2\zeta D_0 x_0 - \alpha_1 x_0^2 \quad [8b]$$

$$\begin{aligned} D_0^2 x_2 + \omega_n^2 x_2 &= -2D_0 D_1 x_1 - 2D_0 D_2 x_0 - D_1^2 x_0 \\ &\quad - 2\zeta D_0 x_1 - 2\zeta D_1 x_0 - 2\alpha_1 x_0 x_1 - \alpha_2 x_0^3 \end{aligned} \quad [8c]$$

The solution of eqn [8a] is of the form:

$$\begin{aligned} x_0 &= A(T_1, T_2) e^{i\omega_n T_0} + \Lambda e^{i\Omega T_0}/2 + \text{c.c.}, \\ \Lambda &= F/(\omega_n^2 - \Omega^2) \end{aligned} \quad [9]$$

where ‘c.c.’ indicates the complex conjugate of the preceding terms. Here, A is an arbitrary function of the slow times, and it is determined by imposing solvability requirements for the elimination of secular terms at the next level of approximation. Note that the solution (eqn [9]) contains a small-divisor term that leads to unbounded response when $\Omega \approx \omega_n$, and this is the case of primary resonance.

Primary Resonance

To develop a uniformly valid approximation to the solution when $\Omega \approx \omega_n$, the excitation force and the damping are rescaled by $F = \varepsilon^2 \hat{F}$ and $\zeta = \varepsilon \hat{\zeta}$. Clearly, there are then the corresponding changes in eqns [8a–c]. The solution (eqn [9]) at the lowest order reduces

to $x_0 = A(T_1, T_2) e^{i\omega_n T_0} + \text{c.c.}$, where A has to be determined at the next order of approximation. The equation for the next approximation is:

$$\begin{aligned} D_0^2 x_1 + \omega_n^2 x_1 &= -2D_0 D_1 x_0 - \alpha_1 x_0^2 \\ &= -2i\omega_n D_1 A e^{i\omega_n T_0} - \alpha_1 A^2 e^{2i\omega_n T_0} - \alpha_1 A \bar{A} + \text{c.c.} \end{aligned} \quad [10]$$

For bounded solutions to exist, the resonance terms on the right-hand side of eqn [10] must vanish, that is, $D_1 A = 0$ and A does not depend on the slow time T_1 . The solution for eqn [10] is then:

$$x_1 = (\alpha_1 A^2 / 3\omega_n^2) e^{i\omega_n T_0} - (\alpha_1 / \omega_n^2) A \bar{A} + \text{c.c.} \quad [11]$$

where A is still an unknown variable. The equation for the second approximation is now:

$$\begin{aligned} D_0^2 x_2 + \omega_n^2 x_2 &= -2D_0(D_1 x_1 - 2D_2 x_0) - D_1^2 x_0 \\ &\quad - 2\hat{\zeta} D_0 x_0 - 2\alpha_1 x_0 x_1 - \alpha_2 x_0^3 + \hat{F} \cos \Omega T_0 \\ &= -\left\{ 2i\omega_n (D_2 + \hat{\zeta}) A + (3\alpha_2 - 10\alpha_1^2 / 3\omega_n^2) A_2 \bar{A} \right\} \\ &\quad \times e^{i\omega_n T_0} + \hat{F} e^{i\Omega T_0} / 2 + \text{c.c.} + \text{NST} \end{aligned} \quad [12]$$

where NST stands for terms that do not produce any secular terms in the solution for x_2 . Since $\Omega \approx \omega_n$ for primary resonance, letting $\Omega = \omega_n + \varepsilon^2 \sigma$, where σ is the frequency mistuning, and eliminating terms that give rise to secular terms, gives:

$$\begin{aligned} a' &= -\hat{\zeta} a + \hat{F} \sin \gamma / (2\omega_n) \\ a\gamma' &= \sigma a - \left\{ (3\alpha_2 / 8\omega_n) - 5\alpha_1^2 / 12\omega_n^3 \right\} a^3 \\ &\quad + \hat{F} \cos \gamma / (2\omega_n) \end{aligned} \quad [13]$$

where $A = a e^{i\beta} / 2$ and $\gamma = \sigma T_2 - \beta$. These eqns [13] are known as the amplitude equations and they determine the amplitude a and the phase β of the first term in the asymptotic expansion (eqn [6]). The two-term response of the nonlinear system is then given by:

$$\begin{aligned} x(t; \varepsilon) &= a \cos (\omega_n t + \beta) + \varepsilon (\alpha_1 a^2 / 6\omega_n^2) \\ &\quad \times \{ \cos (2\omega_n t + 2\beta) - 3 \} + \dots \end{aligned} \quad [14]$$

The above solution is periodic with period $2\pi/\Omega$ and contains higher harmonic components. In the presence of quadratic nonlinearities ($\alpha_1 \neq 0$), a constant term is also generated. The system thus oscillates around a nonzero mean.

For steady-state periodic solutions, we set $a' = 0, \gamma' = 0$. Then, squaring and adding the two equations in eqn [13], and eliminating the angle γ , gives the frequency-response equation

$$\begin{aligned}\sigma &= \left\{ (3\alpha_2/8\omega_n) - (5\alpha_1^2/12\omega_n^3) \right\} a^2 \\ &\pm \sqrt{\left(\hat{F}^2/4\omega_n^2 a^2 - \hat{\zeta}^2 \right)}\end{aligned}\quad [15]$$

that relates the amplitude of response a to the frequency and amplitude of excitation, σ and \hat{F} , and the system model parameters $\hat{\zeta}, \omega_n, \alpha_1$ and α_2 . Note that σ represents the deviation of the excitation frequency from the system linear natural frequency. For $\sigma > 0$, the excitation frequency is above the natural frequency and vice versa. Also note that the frequency of response is expressed as a function of the amplitude of response. This is quite different from the form conventionally utilized for frequency response functions of linear systems.

It is very instructive to study solutions of eqn [15] in various special cases. Figures 1–6 show a representative set of response curves beginning with the response for a linear undamped ($\hat{\zeta} = 0$) system excited near primary resonance.

1. *Linear system:* The corresponding frequency-response relationship is:

$$\sigma = \pm \sqrt{\left(\hat{F}^2/4\omega_n^2 a^2 - \hat{\zeta}^2 \right)} \quad [16]$$

In the absence of damping ($\hat{\zeta} = 0$), eqn [16] reduces to $a = |\hat{F}|/2\omega_n\sigma$. As seen in Figure 1, the response for zero damping is unbounded at $\sigma = 0$. The response amplitude depends on the excitation amplitude \hat{F} . Actually, the response curves are rectangular hyperbolas in the (σa) plane. The important curves for $\hat{F} = 0$ are the line $a = 0$ and the vertical line at $\sigma = 0$. Thus, at $\sigma = 0$ the response amplitude is undefined in the free response case, whereas for any external forcing the response is unbounded.

2. *Nonlinear undamped free system:* The response amplitude a for zero damping is:

$$\sigma = \left\{ (3\alpha_2/8\omega_n) - (5\alpha_1^2/12\omega_n^3) \right\} a^2 \quad [17]$$

The response (Figure 2) depends on the sign of the coefficient $\alpha_e \equiv \{(3\alpha_2/8\omega_n) - (5\alpha_1^2/12\omega_n^3)\}$, which is sometimes called the effective nonlinearity. For positive values of this coefficient, the response exists only for $\sigma \geq 0$, the frequency of response is greater than the linear natural frequency ω_n , and the nonlinearity is called hardening. This sign

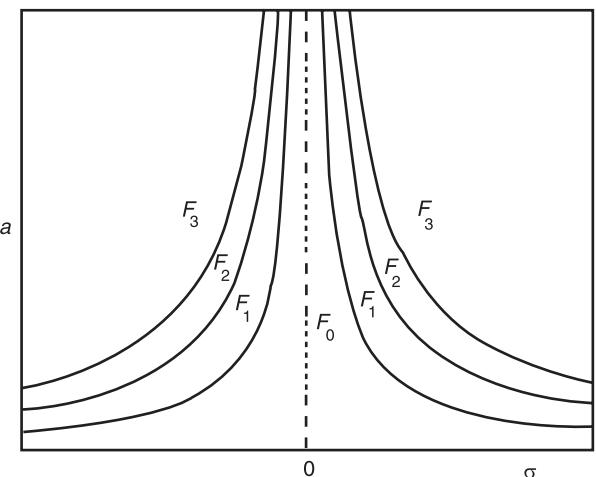

Figure 1 Response curves for the single-degree-of-freedom undamped linear system defined by eqn [16].

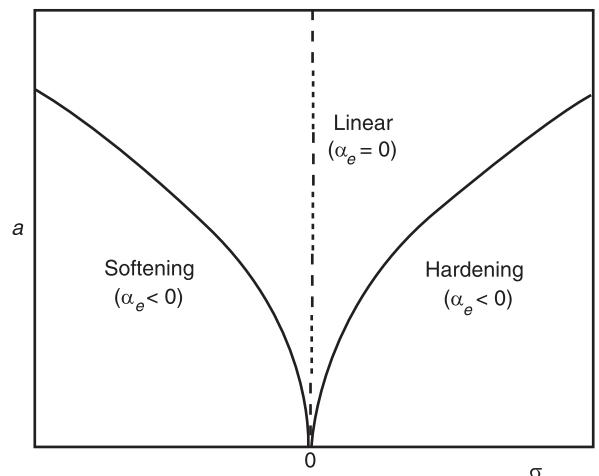

Figure 2 Free-response curves and variation of the frequency of response with amplitude for an undamped nonlinear single degree-of-freedom oscillator (eqn [17]).

depends on a combination of the nonlinear coefficients of the quadratic and cubic nonlinear terms. Similarly, the nonlinearity is called softening when the sign of α_e is negative so that the response exists only for $\sigma \leq 0$.

3. *Forced nonlinear undamped system:* The response amplitude in this case is:

$$\sigma = \{\alpha_e\} a^2 \pm \hat{F}/(2\omega_n a) \quad [18]$$

These responses for the softening and hardening nonlinearities are shown in Figures 3 and 4 respectively. Effectively, the presence of nonlinearities bends the response curves in Figure 1 in either a forward or a backward direction. This results in

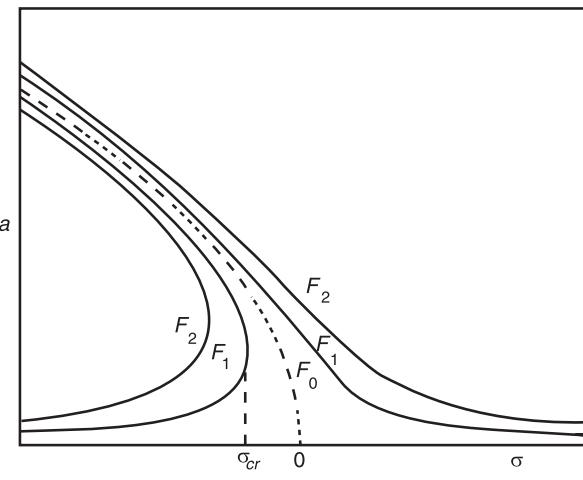

Figure 3 Response curves for resonantly excited and un-damped single-degree-of-freedom nonlinear system with softening nonlinearity ($\alpha_e < 0$) (eqn [18]).

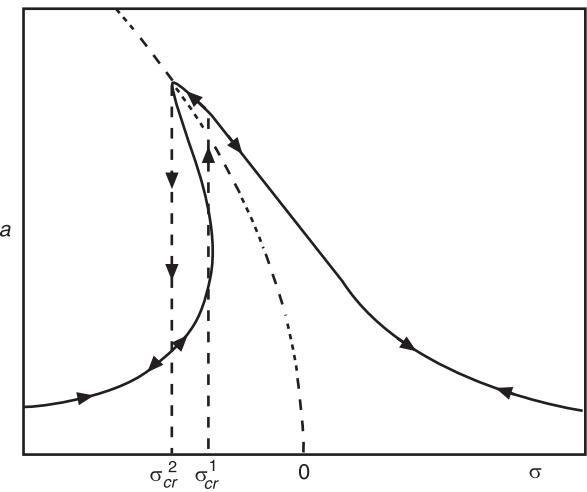

Figure 5 Response curves for resonantly excited and damped single-degree-of-freedom nonlinear system with softening nonlinearity ($\alpha_e > 0$) (eqn [15]).

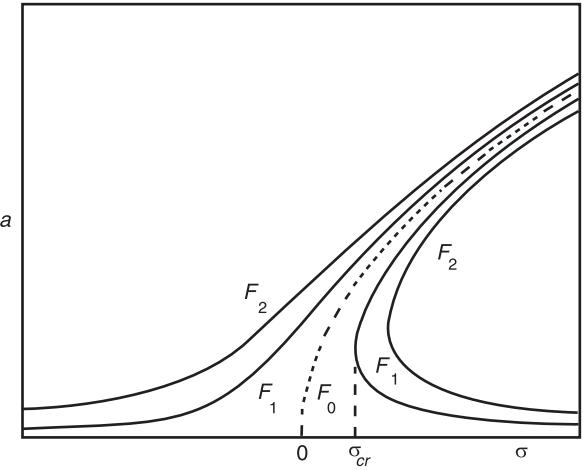

Figure 4 Response curves for resonantly excited and un-damped single-degree-of-freedom nonlinear system with hardening nonlinearity ($\alpha_e > 0$) (eqn [18]).

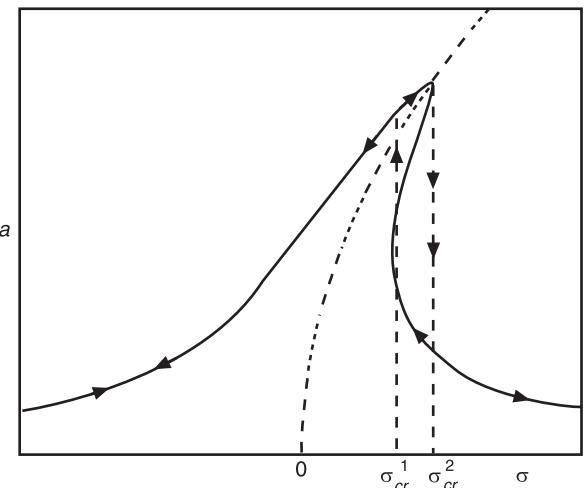

Figure 6 Response curves for resonantly excited and damped single-degree-of-freedom nonlinear system with hardening nonlinearity ($\alpha_e > 0$) (eqn [15]).

regions of frequency σ for which three distinct response amplitudes exist for the system at the same excitation frequency. For a softening nonlinearity, the three solutions region exists for frequencies below some critical value $\sigma_{cr} < 0$. Just the opposite situation arises for the hardening nonlinearity. The critical σ_{cr} is a function of the force amplitude and the nonlinearity parameters, and is a point of vertical tangency for the response curves. Furthermore, the response amplitude for the nonlinear system is finite at every excitation frequency, contrary to the linear case where the response is unbounded at exact linear resonance ($\sigma = 0$). The response of the unforced system

(Figure 2) is shown by dotted lines in Figures 3 and 4. These are known as the backbone curves.

4. *Damped nonlinear system:* The response amplitudes for the two cases of softening and hardening nonlinearities are shown in Figures 5 and 6, respectively. Note here that the amplitude of response is bounded and there now exist two critical frequencies σ_{cr}^1 and σ_{cr}^2 . Only between these two frequencies does the system have three distinct periodic responses. If the frequency of excitation is slowly changed monotonically past a critical value, the response amplitude suddenly jumps up or down. This is the classical jump phenomenon in

nonlinear vibrations. There also arises the associated hysteresis in nonlinear vibrations theory due to the different paths followed in forward and backward variations in the excitation frequency.

The stability of any of the periodic solutions, which are given by the equilibrium points of the amplitude equations, can be evaluated by a linearized analysis of these equations (eqns [13]). The characteristic equation for the linearized system, around an equilibrium point given by a root of eqn [15], is:

$$\lambda^2 + 2\hat{\zeta}\lambda + \hat{\zeta}^2 + \{\sigma - 3a^2\alpha_e\}\{\sigma - a^2\alpha_e\} = 0 \quad [19]$$

Using this equation it can be shown that, when there are three solutions of eqn [15], the middle solution is unstable with a positive and a negative eigenvalue. Furthermore, at the critical values of the frequency, σ_{cr}^1 and σ_{cr}^2 , also the points of vertical tangency in the response curves, one of the roots of eqn [19] vanishes, thus indicating a saddle-node bifurcation. This essentially completes the discussion of the primary resonance case and we return to the zeroth-order solution in eqn [9] for the possibility of other resonances.

Secondary Resonances

When $\Omega \neq \omega_n$, and the excitation frequency is away from the linear natural frequency, the solution (eqn [9]) at the lowest order is uniformly valid. Now consider the equation for the next approximation, eqn [8b]. Substituting the solution (eqn [9]) into the right-hand side gives:

$$\begin{aligned} D_0^2x_1 + \omega_n^2x_1 &= -2i\omega_n(D_1 + \zeta)Ae^{i\omega_n T_0} - i\zeta\Omega\Lambda e^{i\Omega T_0} \\ &\quad - \alpha_1 \left\{ A^2 e^{2i\omega_n T_0} + \Lambda^2 e^{2i\Omega T_0} / 4 \right. \\ &= A\Lambda e^{i(\omega_n + \Omega)T_0} \\ &\quad \left. + A\bar{\Lambda} + A\Lambda e^{i(\omega_n - \Omega)T_0} + \Lambda^2 / 4 \right\} / + c.c. \end{aligned} \quad [20]$$

The solution of eqn [20] contains additional secular terms when either $\Omega \approx 2\omega_n$ or $\Omega \approx \omega_n/2$. One can then proceed, as in the case of primary resonance above, and derive the amplitude equations that determine the response of the nonlinear system under appropriate resonance conditions. Since the small divisor or secular terms arise at first order, these are called secondary resonances. Secondary resonances also arise when either $\Omega \approx 3\omega_n$, or $\Omega \approx \omega_n/3$, though their appearance only becomes apparent when one considers solutions at the second-order approximation.

Subharmonic resonance of order one-half In this case, when $\Omega \approx 2\omega_n$, one assumes that:

$$\Omega = 2\omega_n + \varepsilon\sigma \quad [21]$$

where σ is the frequency mistuning away from the exact subharmonic resonance condition. Then, the two-term approximation to the solution of eqn [5] is:

$$\begin{aligned} x &= a \cos (\omega_n t + \beta) + \Lambda \cos \Omega t \\ &\quad - \varepsilon \left[\alpha_1 \left\{ (a^2 + \Lambda^2) / 2\omega_n^2 \right. \right. \\ &\quad \left. \left. - (a^2 / 6\omega_n^2) \cos (2\omega_n t + 2\beta) \right. \right. \\ &\quad \left. \left. + (\Lambda^2 / 2(\omega_n^2 - 4\Omega^2)) \cos 2\Omega t \right. \right. \\ &\quad \left. \left. - (\Lambda a / \Omega(\Omega + 2\omega_n)) \cos ((\omega_n + \Omega)t + \beta) \right. \right. \\ &\quad \left. \left. - (2\zeta\Omega\Lambda / (\omega_n^2 - \Omega^2)) \sin \Omega t \right] + \dots \right. \end{aligned} \quad [22]$$

where the amplitude a and the phase $\beta = (\varepsilon\sigma t - \gamma + \nu)/2$, are defined by solutions of the amplitude equations:

$$\begin{aligned} a' &= -(\zeta + \alpha_1\Lambda\Gamma \sin \gamma)a \\ a\gamma' &= a \left[\sigma - 2\alpha_1\Lambda\Gamma \cos \gamma \right. \\ &\quad \left. - \varepsilon \left\{ -\zeta^2 + (3\alpha_2/2 - 5\alpha_1^2/8\omega_n^2)\Lambda^2 \right\} / \omega_n - 2\varepsilon\alpha_e a^2 \right] \end{aligned} \quad [23]$$

Here, the constants ν and Γ are defined by the relation $2\omega_n\Gamma e^{i\nu} = 1 - \varepsilon(\sigma - 8i\zeta/3)/2\omega_n$.

The steady-state solutions of eqns [23] define the amplitude and phase of the subharmonic component of the total response (eqn [22]), that is, with frequency $\Omega/2$. Clearly, $a = 0$ is a solution for all values of the parameters and it corresponds to the solution with frequency Ω . A linearized stability analysis for the zero solution determines its stability as a function of the system parameters. It may also be possible to find nonzero equilibrium solutions of eqns [23]. Then, the response period for the solution in eqn [22] is twice that of the excitation period. Note that because of the relation between the phase angles β and γ , and the modulo 2π nature of angular variables, there are two distinct values of β for every solution for γ and they are phase-shifted by π . Thus, for every nonzero amplitude a , there exist two subharmonic solutions that are π phase apart. No distinction is made here between these two solutions.

The important features for the subharmonic solutions are their numbers, the parameter combinations for which they arise, and the stability of the various solutions. These can be represented in the form of a bifurcation set that gives the parameter values at

which solutions change their stability. A typical bifurcation set for eqns [23], in the (σ, F) plane, is shown in **Figure 7**. In region I, the zero solution is the only solution and it is a sink (stable). Thus, no subharmonic solution exists for parameter values in this region. In region II, the zero solution is a saddle (unstable) and a nonzero solution in the form of a stable sink exists. In region III also the zero solution is stable, although there additionally exist two nonzero solutions of the amplitude equations. One of these subharmonic solutions of order one-half is a sink whereas the second solution is a saddle and unstable.

A typical frequency-response curve for a fixed excitation level is shown in **Figure 8**. The trivial solution corresponding to the solution with the period of excitation is unstable over the frequency interval $\sigma_1 < \sigma < \sigma_2$. There exist subharmonic solutions in the frequency interval $\sigma_1 < \sigma < \sigma_3$. While the subharmonic solutions are created from the zero solution at frequencies σ_1 and σ_2 via a pitchfork bifurcation, the frequency σ_3 corresponds to a turning point in the subharmonic response. In the interval $\sigma_2 < \sigma < \sigma_3$, the subharmonic solution with smaller amplitude is unstable. This figure again shows the existence of jump phenomenon and hysteresis in the response.

Superharmonic resonance of order two In this case, $2\Omega \approx \omega_n$, and one assumes that:

$$2\Omega = \omega_n + \varepsilon\sigma \quad [24]$$

where σ is the frequency mistuning from the exact superharmonic resonance condition. Then, the two-term approximation to the solution of eqn [5] is:

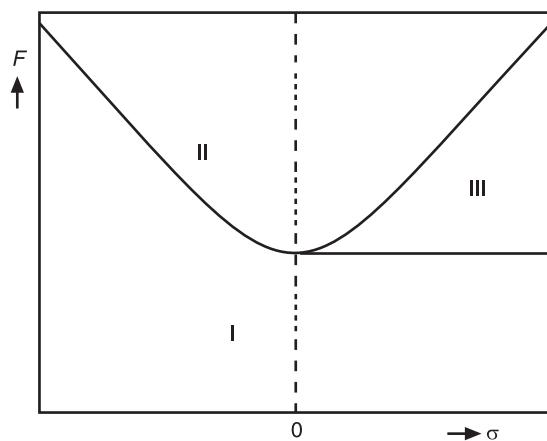

Figure 7 A typical bifurcation set in the (σ, F) plane for subharmonic response of order one-half for a single-degree-of-freedom system.

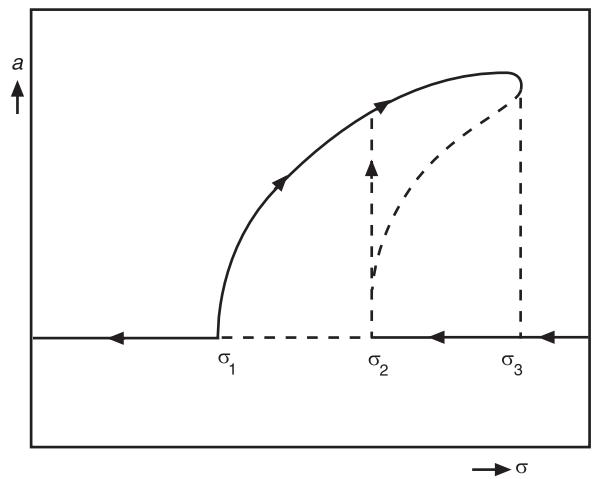

Figure 8 A representative frequency-amplitude response curve for subharmonic response of order one-half for a single-degree-of-freedom system.

$$\begin{aligned} x = & a \cos(\omega_n t + \beta) + \Lambda \cos \Omega t \\ & - \varepsilon [\alpha_1 \{(a^2 + \Lambda^2)/2\omega_n^2 \\ & - (a^2/6\omega_n^2) \cos(2\omega_n t + 2\beta) \\ & - (\Lambda a/\Omega(\Omega - 2\omega_n)) \cos((\omega_n - \Omega)t - \beta) \\ & - (\Lambda a/\Omega(\Omega + 2\omega_n)) \cos((\omega_n + \Omega)t + \beta)\} \\ & - (2\zeta\Omega\Lambda/(a^2 - \Omega^2)) \sin \Omega t] + \dots \end{aligned} \quad [25]$$

where the amplitude a and the phase $\beta = (\varepsilon\sigma t - \gamma + v)$, are defined by the solutions of the amplitude equations:

$$\begin{aligned} a' = & -(\zeta a + \alpha_1 \Lambda^2 \Gamma \sin \gamma / 4\omega_n) \\ a\gamma' = & a[\sigma - (\alpha_1 \Lambda^2 \Gamma / 4\omega_n) \cos \gamma - \varepsilon \{-\zeta^2 + (3\alpha_2/2 \\ & - 23\alpha_1^2/15\omega_n^2)\Lambda^2\} / 2\omega_n - \varepsilon \alpha_e a^2] \end{aligned} \quad [26]$$

Here, the constants v and Γ are defined by the relation $G e^{iv} = 1 - \varepsilon(\sigma + 13i\zeta/3)/2\omega_n$.

The steady-state solutions of eqns [26] define the superharmonic solutions of order two. Note that in this case zero is not a possible equilibrium solution. Then, depending upon the strength and frequency of the external excitation, and the system parameters, eqns [26] can have one or three equilibrium solutions. The stability of these solutions is governed by the eigenvalues of the linearized system corresponding to eqns [26]. A typical set of frequency-response curves for superharmonic response of order two are shown in **Figure 9**. These curves again show the usual regions of multiple solutions, and the associated jump

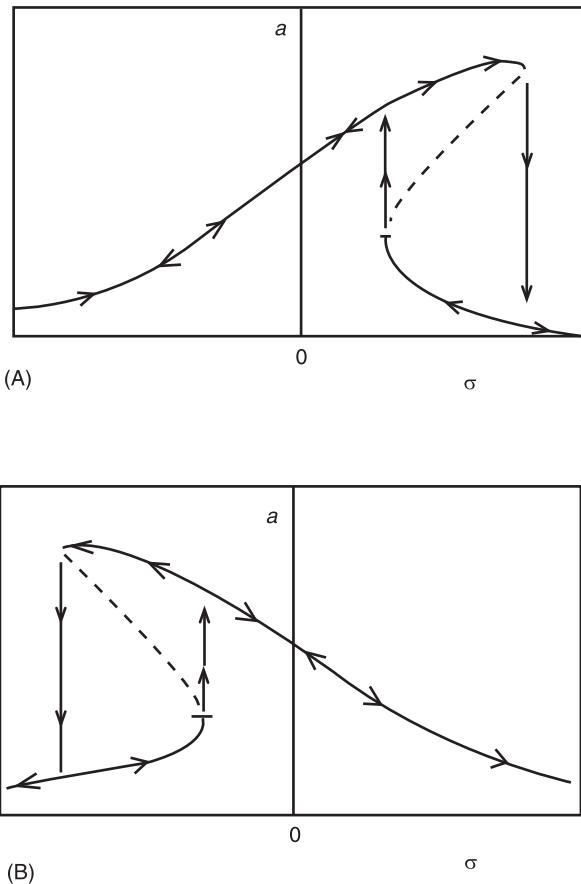

Figure 9 A representative frequency-amplitude response curve for superharmonic response of order two for a single degree-of-freedom system: (A) Hardening nonlinearity ($\alpha_e > 0$); (B) softening nonlinearity ($\alpha_e < 0$).

phenomenon and hysteresis. The response curves are bent forward or backward depending on the sign of the effective nonlinearity α_e .

Subharmonic resonance of order one-third When $\Omega \approx 3\omega_n$, elimination of secular terms in the solution of eqn [20] requires $D_1 A + \zeta A = 0$. Then, the solution for eqn [20] is:

$$\begin{aligned} x_1 = & i\zeta\Omega\Lambda e^{i\Omega T_0}/(\Omega^2 - \omega_n^2) \\ & + \alpha_1 [(A^2/3\omega_n^2)e^{2i\omega_n T_0} - (4A\bar{A} + \Lambda^2)/4\omega_n^2 \\ & + (\Lambda^2/4(4\Omega^2 - \omega_n^2))e^{2i\Omega T_0} \\ & + (\Lambda A/\Omega(\Omega + 2\omega_n))e^{i(\Omega + \omega_n)T_0} \\ & + (\Lambda\bar{A}/\Omega(\Omega - 2\omega_n))e^{i(\Omega - \omega_n)T_0} + \text{c.c.}] \end{aligned} \quad [27]$$

Substituting this solution into eqn [8c], using $\Omega = 3\omega_n + \varepsilon\sigma$, and eliminating terms that result in

secular terms, gives the amplitude equations for subharmonic oscillations of order one-third:

$$\begin{aligned} a' &= -\zeta a - \varepsilon(3\alpha_2/8\omega_n + \alpha_1^2/4\omega_n^3)\Lambda a^2 \sin \gamma \\ a\beta' &= \sigma a - \varepsilon[3\{-\zeta^2 + 3(\alpha_2/2 - \alpha_1^2/5\omega_n^2)\Lambda^2\}a/2\omega_n \\ &+ \alpha_e a^3 + (3\alpha_2/8\omega_n + \alpha_1^2/4\omega_n^3)\Lambda a^2 \cos \gamma] \end{aligned} \quad [28]$$

where $A = ae^{i\beta}/2$ and $\gamma = \sigma T_1 - 3\beta$. The two-term uniformly valid solution for the system response is now:

$$\begin{aligned} x &= a \cos (\omega_n t + \beta) + \Lambda \cos \Omega t \\ &- \varepsilon[\alpha_1 \{(a^2 + \Lambda^2)/2\omega_n^2 \\ &- (a^2/6\omega_n^2) \cos (2\omega_n t + 2\beta) \\ &- (\Lambda a/\Omega(\Omega - 2\omega_n)) \cos ((\omega_n - \Omega)t - \beta) \\ &- (\Lambda a/\Omega(\Omega + 2\omega_n)) \cos ((\omega_n + \Omega)t + \beta) \\ &+ (\Lambda^2/2(\omega_n^2 - 4\Omega^2)) \cos \Omega t\} \\ &- (2\zeta\Omega\Lambda/(\omega_n^2 - \Omega^2)) \sin \Omega t] + \dots \end{aligned} \quad [29]$$

As was the case with the subharmonic response of order one-half, the amplitude equations for subharmonic response of order one-third also have a zero solution ($a = 0$). This implies a periodic solution with the period of the excitation. A linearized stability analysis of eqns [28] for the zero solution reveals that the zero solution, or the periodic solution at the period of excitation, is stable for all parameter values. There also exist nonzero equilibrium solutions of eqns [28] when the system and excitation parameters satisfy certain conditions. From the form of the solution in eqn [29], it can be seen that the solution then has a period which is three times that of excitation, thus implying a subharmonic solution.

Superharmonic resonance of order three When $\Omega \approx \omega_n/3$, the analysis follows steps identical to those for the case of subharmonic resonance. Introducing the appropriate mistuning, $3\Omega = \omega_n + \varepsilon\sigma$, the two-term uniformly valid response of the system is again given by eqn [29], and the amplitude and phase of the superharmonic component of the response satisfy:

$$\begin{aligned} a' &= -\zeta a - \varepsilon\Gamma \sin \gamma \\ a\beta' &= \sigma a - \varepsilon[\{-\zeta^2 + (3\alpha_2/2 - 53\alpha_1^2/35\omega_n^2)\Lambda^2\}a/2\omega_n \\ &+ \alpha_e a^3 + \Gamma \cos \gamma] \end{aligned} \quad [30]$$

where $\Gamma = \{(\alpha_2 - 18\alpha_1^2/5\omega_n^2)\Lambda^3/8\omega_n\}$, and $\gamma = \sigma T_1 - \beta$. Solutions of these equations can be studied as a function of the system and excitation parameters.

This concludes the discussion of some of the important resonances that arise in harmonically excited single-degree-of-freedom nonlinear mechanical systems with quadratic and cubic stiffness, or position-dependent, nonlinearities. The nonlinearities can contribute significantly to the response of the system when the excitation frequency and the linear natural frequency of the system satisfy certain frequency relations. The most significant resonance is called the primary resonance, and it occurs when the excitation frequency is close to the system's linear natural frequency. Then, the excitation amplitude has to be $O(\varepsilon)$ and, depending on the sign of the effective stiffness, multiple periodic solutions only arise for excitation frequencies above or below the natural frequency. When the excitation frequency is nearly two or three times the natural frequency, periodic solutions at one-half or one-third of the excitation frequency can also exist in addition to the solutions at the frequency of excitation. These are the subharmonic solutions of appropriate order. When the excitation frequency is nearly one-half or one-third of the natural frequency, the periodic response at the excitation frequency also contains higher harmonics of the appropriate order, and these are the superharmonic resonances. In either of these cases, the excitation amplitude is $O(1)$ in ε .

Two-Degree-of-Freedom Systems (Quadratic Nonlinearities)

The general equations of motion for this class of system are:

$$\begin{aligned} \ddot{x}_1 + \omega_1^2 x_1 + \varepsilon \\ \times \left[2\zeta_1 \dot{x}_1 + \sum_{i=1}^2 \sum_{j=1}^2 \{a_{1ij}x_i x_j + b_{1ij}\dot{x}_i \dot{x}_j + c_{1ij}x_i \ddot{x}_j\} \right] \\ = F_1 \cos (\Omega t + \tau_1) \\ \ddot{x}_2 + \omega_2^2 x_2 + \varepsilon \\ \times \left[2\zeta_2 \dot{x}_2 + \sum_{i=1}^2 \sum_{j=1}^2 \{a_{2ij}x_i x_j + b_{2ij}\dot{x}_i \dot{x}_j + c_{2ij}x_i \ddot{x}_j\} \right] \\ = F_2 \cos (\Omega t + \tau_2) \end{aligned} \quad [31]$$

Free and forced responses for many physical systems, including ships, robots, elastic pendula, beams and

plates under static loadings, shallow arches, composite plates and shells, and free-surface oscillations in containers, have been described by these equations. For example, in the study of motions of a shallow arch, x_1 and x_2 represent the modal amplitudes of the lowest-frequency antisymmetric and symmetric modes, respectively. These modes and their associated linear frequencies vary as a function of the transverse load acting at the center of the arch. In the case of rigid-body motions of a ship, these coordinates represent the roll and pitch motions, respectively. In general, the pitch and roll motions are uncoupled for the linear model and the pitch frequency is higher than the frequency for roll motion. The nonlinearities couple these two motions, especially when the pitch frequency is nearly twice the roll frequency.

Periodic solutions of eqns [31] can be constructed using any number of techniques. Following the method of multiple time scales, the solution for each of the oscillators can be assumed to be of the form given in eqn [6]. Then, proceeding as for the single-degree-of-freedom system, a sequence of approximation equations similar to eqns [8] are obtained. At the zeroth-order, each oscillator has a solution in the form of eqn [9] where the complex amplitude A is determined at the next approximation by developing the appropriate solvability conditions. The solution (eqn [9]) is uniformly valid (there are no small divisor terms) unless either of the primary resonances arise, that is, Ω is near ω_1 or ω_2 . In that case, only weak excitations can be considered.

In the first-order approximation, even in the absence of any excitation, small divisor terms arise when $\omega_2 \approx 2\omega_1$. In the presence of an external excitation, nonuniformity in solution arises when $2\omega_2 \approx \Omega$ (subharmonic resonance of order one-half), $\omega_1 \approx 2\Omega$ (superharmonic resonance of order two), or $\omega_1 + \omega_2 \approx \Omega$ (combination resonance of additive type). Thus, depending on the frequency relation involving the linear natural frequencies ω_1 , ω_2 , and the excitation frequency Ω , various resonances arise for these systems.

There is an exchange of energy between the two modes of response only when the natural frequencies satisfy the relation $\omega_2 \approx 2\omega_1$. Thus, let $\omega_2 = 2\omega_1 + \varepsilon\sigma_1$, where σ_1 is called the internal mistuning. Now, the response depends on the strength of excitation. When the excitation frequency is near either of the natural frequencies, the excitation force has to be $O(\varepsilon)$ in order for the nonlinear terms to balance the excitation. In the case of sub- or superharmonic resonances, the excitation force can be $O(1)$ in ε . Only the primary resonance cases are presented here.

Primary Resonances

Let $F_i = \varepsilon \tilde{F}_i$, $i = 1, 2$. Then, the one-term uniformly valid solution of the system given in eqn [31] is:

$$x_i(t; \varepsilon) = a_i \cos (\omega_i t + \beta_i) + O(\varepsilon), \quad i = 1, 2, \dots \quad [32]$$

where the amplitude equations governing the evolution of the two amplitudes and phases, (a_i, β_i) , $i = 1, 2$, can be written in a unified way as:

$$\begin{aligned} a'_1 &= -\zeta_1 a_1 - \Pi_1 a_1 a_2 \sin \gamma_1 + \Gamma_1 \\ a_1 \beta'_1 &= \Pi_1 a_1 a_2 \cos \gamma_1 + \Gamma_2 \\ a'_2 &= -\zeta_2 a_2 + \Pi_2 a_1^2 \sin \gamma_1 + \Gamma_3 \\ a_2 \beta'_2 &= \Pi_2 a_1^2 \cos \gamma_1 + \Gamma_4 \end{aligned} \quad [33]$$

where:

$$\begin{aligned} \Pi_1 &= \left\{ (a_{112} + a_{121}) + (b_{112} + b_{121})\omega_1 \omega_2 - c_{121}\omega_1^2 \right. \\ &\quad \left. - c_{112}\omega_2^2 \right\} / 4\omega_1 \\ \Pi_2 &= \left\{ a_{211} - (b_{211} + c_{211})\omega_1^2 \right\} / 4\omega_1 \\ \gamma_1 &= \varepsilon \sigma_1 t + \beta_2 - 2\beta_1 \end{aligned} \quad [34]$$

The phase angle γ_2 and the excitation terms Γ_i , $i = 1 - 4$, depend on the primary resonance condi-

tion satisfied. These terms for the two cases of interest are given below. In the absence of an external excitation, the amplitudes a_1 and a_2 of the two linear modes are coupled by the nonlinear quadratic terms. Considering eqns [31] and (34), note that only a few specific nonlinear coefficients contribute to this modal interaction. Thus, for modal interaction and internal resonance to occur, non-vanishing of the coefficients Π_1 and Π_2 is required in addition to the frequency relation. Figure 10 depicts a representative set of time responses for the amplitude equations for the unforced system with zero damping. There is a clear interchange of energy between the two modes which depends also on the internal mistuning σ_1 . Thus, the undamped system (eqns [31]) performs amplitude-modulated motions with the modulations in the two modes being out of phase. Introduction of any dissipation results in decaying oscillations. In the presence of an external excitation, there are a large variety of steady-state solutions possible for eqns [33]. These then imply constant-amplitude periodic solutions, almost periodic motions as well as chaotically modulated motions for the original equations (eqns [31]).

Primary resonance of the first mode Here the phase angle γ_2 and the excitation terms Γ_i , $i = 1 - 4$, are defined by:

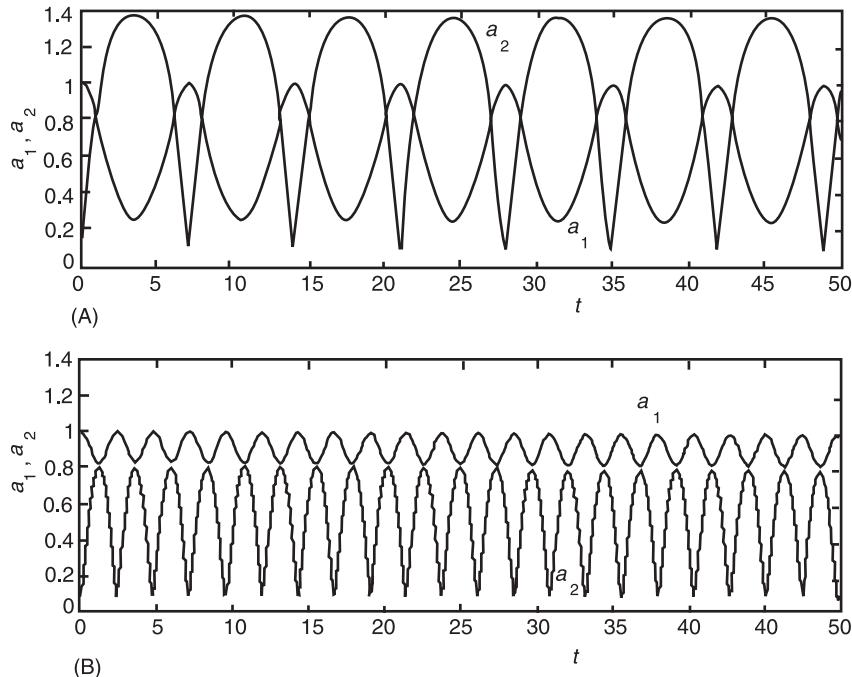

Figure 10 Free, undamped response of the amplitude equations for a two-degree-of-freedom system with quadratic nonlinearities and two-to-one internal resonance (eqns [33]): (A) Internal mistuning $\sigma_1 = 0$; (B) internal mistuning $\sigma_1 = 2.0$.

$$\begin{aligned}\gamma_2 &= \varepsilon\sigma_2 t - \beta_1 + \tau_1 \\ \Gamma_1 &= (\tilde{F}_1/2\omega_1) \sin \gamma_2, \quad \Gamma_2 = -(\tilde{F}_2/2\omega_1) \cos \gamma_2, \\ \Gamma_3 &= \Gamma_4 = 0\end{aligned}\quad [35]$$

Furthermore, $\Omega = \omega_1 + \varepsilon\sigma_2$, and σ_2 is called the external mistuning. It represents the deviation of the excitation frequency from the lower of the two natural frequencies. Thus, the first or the lower natural frequency mode, is directly excited and the higher-frequency mode only obtains energy due to the nonlinear modal interaction. Also note that both modes have nonzero amplitudes of oscillation in a steady state. The steady-state solutions of eqns [34] and [35], determined by the conditions $a'_i = 0, \dot{\gamma}_i = 0, i = 1, 2$, correspond to periodic solutions of the system given in eqn [31]. Representative sets of response curves (amplitudes of solutions) for the two modes at small damping level, as a function of the excitation frequency (or external mistuning) σ_2 , are shown in Figure 11. These curves show that the directly excited mode (a_1) has larger stable solutions except near exact resonance where the second mode extracts larger energy from the external excitation. The response curves also show the usual jump phenomenon, at least for sufficiently small damping parameters. Compared to the resonant responses in the case of a single-degree-of-freedom system, there arise additional instabilities in these response curves. They correspond to a Hopf bifurcation in the amplitude equations. Consequently, in the frequency interval near $\sigma_2 = 0$, a direct integration of eqns [33] shows limit cycle oscillations in amplitudes and

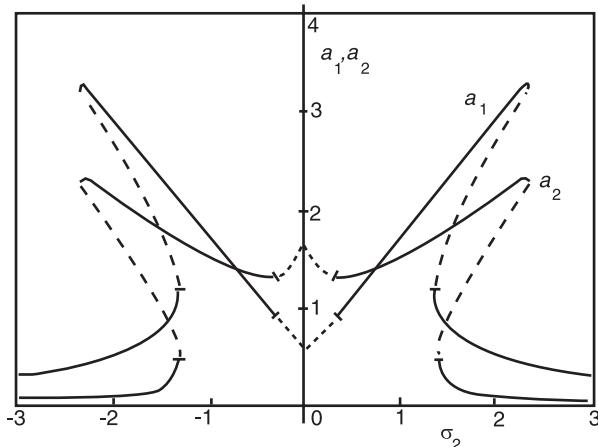

Figure 11 A representative set of frequency-response curves for a two degree-of-freedom system with quadratic nonlinearities, two-to-one internal resonance, and primary resonance of the first mode (eqns [33]).

phases. Thus, the coupled system given in eqns [31] executes amplitude-modulated periodic oscillations when it is excited near exact resonance and the internal mistuning is also small. These types of modulated responses have been verified in many experimental investigations. In fact, for suitable parameter combinations, eqns [33] have been shown to exhibit period-doubling bifurcations to chaotic solutions, thus implying amplitude-modulated chaos for the original oscillators.

Primary resonance of the second mode Now, the phase angle γ_2 and the excitation terms $\Gamma_i, i = 1-4$, are defined by:

$$\begin{aligned}\gamma_2 &= \varepsilon\sigma_2 t - \beta + \tau_2 \\ \Gamma_1 &= \Gamma_2 = 0, \quad \Gamma_3 = (\tilde{F}_2/2\omega_2) \sin \gamma_2, \\ \Gamma_4 &= -(\tilde{F}_2/2\omega_2) \cos \gamma_2\end{aligned}\quad [36]$$

Here, $\Omega = \omega_2 + \varepsilon\sigma_2$, and σ_2 is the external mistuning. Thus, the excitation frequency is close to the higher of the two natural frequencies. Interestingly, in this case, one steady-state solution of eqns [33] is with zero amplitude ($a_1 = 0, a_2 \neq 0$) for the first mode. Then, the response of the directly excited mode is like that of a linear oscillator near resonance. It is also possible to find steady-state solutions for which both $a_1 \neq 0, a_2 \neq 0$. In this coupled-mode solution, while the amplitude a_2 of the directly excited mode turns out to be independent of the excitation force, the amplitude of the first mode depends on it. This has been termed the saturation phenomenon, and has been suggested as a way to control passively the response amplitude of a resonantly excited system. In this sense, it is a nonlinear analog of the dynamic vibration absorber in linear vibration theory.

Representative sets of response curves depicting both the single-mode ($a_1 = 0, a_2 \neq 0$) and the coupled-mode ($a_1 \neq 0, a_2 \neq 0$) responses are shown in Figures 12 and 13. The single-mode solution, which is basically the linear solution, is unique. For the parameter values chosen, it loses stability by a pitchfork bifurcation to a coupled-mode equilibrium solution in some frequency interval around $\sigma_2 = 0$. For zero internal mistuning ($\sigma_1 = 0$) the coupled-mode solution branches are symmetrical around $\sigma_2 = 0$ and multiple solutions, leading to the jump phenomenon, can coexist. The amplitudes of the indirectly excited oscillator depend heavily on the damping in that mode. For very small damping in the indirectly excited oscillator ($\zeta_1 \approx 0$), the response of the directly excited oscillator (a_2) can be nearly completely suppressed. In the frequency interval

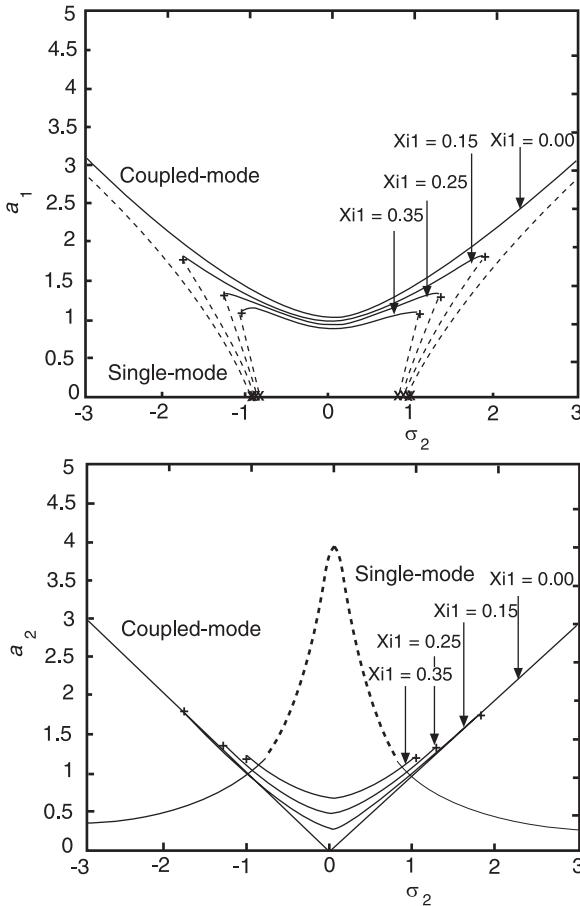

Figure 12 A representative set of frequency-response curves for a two degree-of-freedom system with quadratic nonlinearities, two-to-one internal resonance, and primary resonance of the second mode (eqns [33]); zero internal mistuning ($\sigma_1 = 0$).

where the single-mode solution is unstable, there is a unique and stable coupled-mode solution. Outside of this interval, however, multiple coupled-mode solutions arise. No Hopf bifurcation to limit cycles is possible here unless there exists a frequency mistuning between the two oscillators (Figure 13). For moderate values of internal mistuning σ_1 , the coupled-mode solution undergoes Hopf bifurcation to a limit cycle which then leads to chaotic solutions via a period-doubling sequence (Figure 14). For large internal mistuning σ_1 , $\sigma_1 \rightarrow \pm\infty$, the modal interaction, as expected, becomes weak and the response of the system tends toward the single-mode solution.

Two-Degree-of-Freedom Systems (Cubic Nonlinearities)

The general equations of motion for this class of structural and mechanical system are:

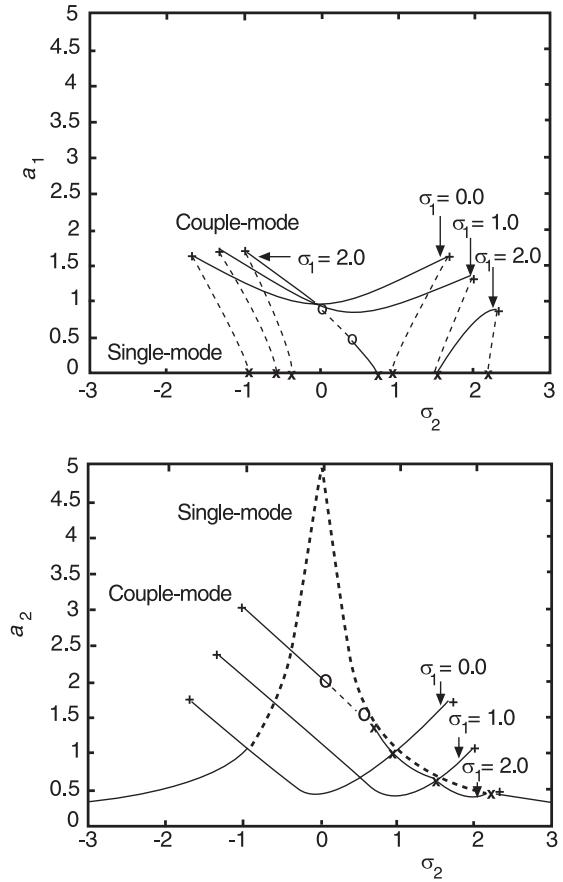

Figure 13 A representative set of frequency-response curves for a two degree-of-freedom system with quadratic nonlinearities, two-to-one internal resonance, and primary resonance of the second mode (eqns [33]); nonzero internal mistuning ($\sigma_1 \neq 0$).

$$\begin{aligned}
 & \ddot{x}_1 + \omega_1^2 x_1 \\
 & + \varepsilon \left[2\zeta_1 \dot{x}_1 + \sum_{i=1}^2 \sum_{j=1}^2 \sum_{k=1}^2 \{ a_{1ijk} x_i x_j x_k \right. \\
 & \left. + b_{1ijk} x_i \dot{x}_j \dot{x}_k + c_{1ijk} x_i x_j \ddot{x}_k \} \right] \\
 & = F_1 \cos (\Omega t) \\
 & \ddot{x}_2 + \omega_2^2 x_2 \\
 & + \varepsilon \left[2\zeta_2 \dot{x}_2 + \sum_{i=1}^2 \sum_{j=1}^2 \sum_{k=1}^2 \{ a_{2ijk} x_i x_j x_k \right. \\
 & \left. + b_{2ijk} x_i \dot{x}_j \dot{x}_k + c_{2ijk} x_i x_j \ddot{x}_k \} \right] \\
 & = F_2 \cos (\Omega t + \tau)
 \end{aligned} \tag{37}$$

Many physical systems, including robots, elastic pendula, beams and plates, composite plates and shells,

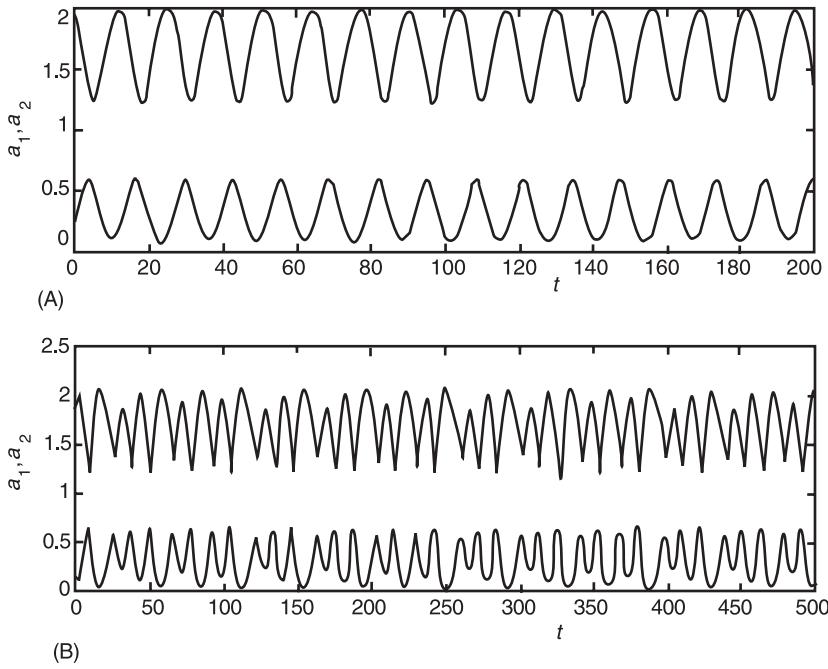

Figure 14 Typical oscillatory solutions of the amplitude equations (eqns [33]) for a two-degree-of-freedom system with quadratic nonlinearities, two-to-one internal resonance, and primary resonance of the second mode: (A) \$\sigma_2 = 0.49\$; (B) \$\sigma_2 = 0.48\$.

and free-surface oscillations in containers, have been described by these equations. Primary resonances arise in these systems when the external excitation frequency \$\Omega\$ is near either of the natural frequencies \$\omega_1\$ or \$\omega_2\$. Then, only weak excitations can be considered and the results here are limited to these cases. For this, let \$F_i = \varepsilon P_i\$, \$i = 1, 2\$. Two possible cases of internal resonance also arise, and the amplitude equations for the case of \$\omega_2 \approx \omega_1\$ are much more complex than the equations for the \$\omega_2 \approx 3\omega_1\$ case. In either case, the one-term approximate solution of the coupled system is:

$$x_n = \{A_n(T_1, T_2)e^{i\omega_n T_0} + \text{c.c.}\} + O(\varepsilon), \quad n = 1, 2 \quad [38]$$

In the case when \$\omega_2 \approx 3\omega_1\$, the complex amplitudes for the two oscillators satisfy:

$$\begin{aligned} A'_1 &= \left[\left\{ \sigma_1 A_1 - 2iv\zeta_1 A_1 - \Pi_1 A_1^2 \bar{A}_1 \right. \right. \\ &\quad \left. \left. - \Pi_3 A_1 A_2 \bar{A}_2 \right\} + \left\{ \Gamma_1 \delta_{1j} - \Pi_2 \bar{A}_1^2 A_2 \right\} \right] / iv \\ A'_2 &= \left[\left\{ \sigma_2 A_2 - 6iv\zeta_2 A_2 - \Pi_4 A_2^2 \bar{A}_2 \right. \right. \\ &\quad \left. \left. - \Pi_6 A_1 \bar{A}_1 A_2 \right\} + \left\{ \Gamma_1 \delta_{2j} - \Pi_5 A_1^3 \right\} \right] / 3iv \end{aligned} \quad [39]$$

where \$\varepsilon\sigma_1 = (v^2 - \omega_1^2)\$, and \$\varepsilon\sigma_2 = (9v^2 - \omega_2^2)\$ are the external mistunings, \$\delta_{ij}\$ is the Kronecker delta, \$\Pi_i\$, \$i = 1 - 6\$ are nonlinear coefficients dependent on the system nonlinearities, and \$\Gamma_i\$, \$i = 1, 2\$, are constants related to the excitation amplitudes \$F_1\$ and \$F_2\$, respectively. The index \$j = 1\$ when the first oscillator is in primary resonance, and \$j = 2\$ when the second oscillator is in primary resonance.

For the case when \$\omega_2 \approx \omega_1\$, the complex amplitudes of the one-term solution are governed by:

$$\begin{aligned} A'_1 &= \left[\left\{ \sigma_1 A_1 - 2iv\zeta_1 A_1 - \Pi_1 A_1^2 \bar{A}_1 - \Pi_3 A_1 A_2 \bar{A}_2 \right\} \right. \\ &\quad \left. + \left\{ \Gamma_1 - \Pi_2 A_1 \bar{A}_1 A_2 - \Pi_4 A_1^2 \bar{A}_2 - \Pi_5 \bar{A}_1 A_2^2 \right. \right. \\ &\quad \left. \left. - \Pi_6 A_2^2 \bar{A}_2 \right\} \right] / iv \\ A'_2 &= \left[\left\{ \sigma_2 A_2 - 2iv\zeta_2 A_2 - \Pi_7 A_2^2 \bar{A}_2 - \Pi_9 A_1 \bar{A}_1 A_2 \right\} \right. \\ &\quad \left. + \left\{ \Gamma_2 - \Pi_8 A_1^2 \bar{A}_1 - \Pi_{10} A_1^2 \bar{A}_2 - \Pi_{11} A_1 A_2 \bar{A}_2 \right. \right. \\ &\quad \left. \left. - \Pi_{12} \bar{A}_1 A_2^2 \right\} \right] / iv \end{aligned} \quad [40]$$

where $\varepsilon\sigma_1 = (v^2 - \omega_1^2)$, and $\varepsilon\sigma_2 = (v^2 - \omega_2^2)$ are the external mistunings, and $\Pi_i, i = 1 \dots 12$ are coefficients determined by the system nonlinearities. Note that the terms in the first sets of parentheses in eqns [39] and [40] are identical, and represent the amplitude equations in the absence of any internal or external resonance in the system.

The amplitude equations (eqns [39] and [40]) cover a large class of structural and mechanical systems and are yet to be studied in their greatest generality, even for steady-state constant solutions representing periodic motions of the original oscillators in eqns [37]. Such a study will allow for the classification of response curves for these systems based on the system nonlinearities. In many systems, the nonlinearities arise due to the scalar potential and kinetic energy functions. Then, quite a few of the nonlinear coefficients $\Pi_i, i = 1, 2 \dots 12$ are interdependent, thus reducing the independent nonlinear coefficients. Forms of the amplitude equations are further simplified when the system possesses certain inherent symmetries. For example, many physical systems are such that their equations of motion (eqn [37]) are invariant to the change of variables: $(x_1, x_2) \rightarrow (-x_1, x_2) \rightarrow (x_1, -x_2)$. This necessarily implies that $\Pi_2 = 0 = \Pi_5$ in eqns [39], and $\Pi_2 = 0 = \Pi_4 = \Pi_6 = \Pi_8 = \Pi_{11} = \Pi_{12}$ in eqns [40]. Physically, these are systems that possess reflection symmetry about two perpendicular axes. Examples include transverse motions of rectangular plates and nonplanar oscillations of beams with rectangular sections. Further restriction of invariance to $(x_1, x_2) \rightarrow (x_2, x_1)$ appears in the study of the response of square plates, beams with square section, orthogonal double pendula, etc. Still further simplifications result when one considers structural systems having cyclic or rotational symmetry, e.g., a stretched string, cylindrical rings and shells, circular plates, and antenna dishes.

As a final illustration of the complex dynamics arising due to the simultaneous presence of external and internal resonances, the frequency-response curves for an orthogonal double pendulum are now described. The double pendulum consists of two pendulums. The upper pendulum is attached to a point of suspension with a pin. The lower pendulum is attached with a pin at the mass point of the upper pendulum. The two pendulums have equal lengths and the particles have equal masses. The two individual pendulums oscillate in orthogonal planes that intersect along the vertical axis. The stable equilibrium position of the system corresponds to the configuration in which the two pendulums hang vertically downward. About this equilibrium position, one mode of vibration corresponds to the

upper pendulum oscillating with the bottom pendulum remaining vertical. In the second mode of vibration, the upper pendulum remains stationary (vertical) and the lower pendulum oscillates. These two modes of oscillation have nearly equal natural frequencies. This leads to a one-to-one internal resonance. The excitation is in primary resonance, and is in the form of a horizontal harmonic motion of the point of suspension in the plane containing the upper pendulum. Then, the first mode of vibration is directly excited. The second mode of response is coupled to the first one only through nonlinearities in the model that arise due to geometric as well as inertial interactions.

Figures 15 and 16 show the frequency-response curves for the double pendulum. While Figure 15 is for zero internal mistuning between the two linear modes of oscillation, Figure 16 gives results when the upper pendulum has a slightly longer length compared to the lower pendulum. There exist stable as

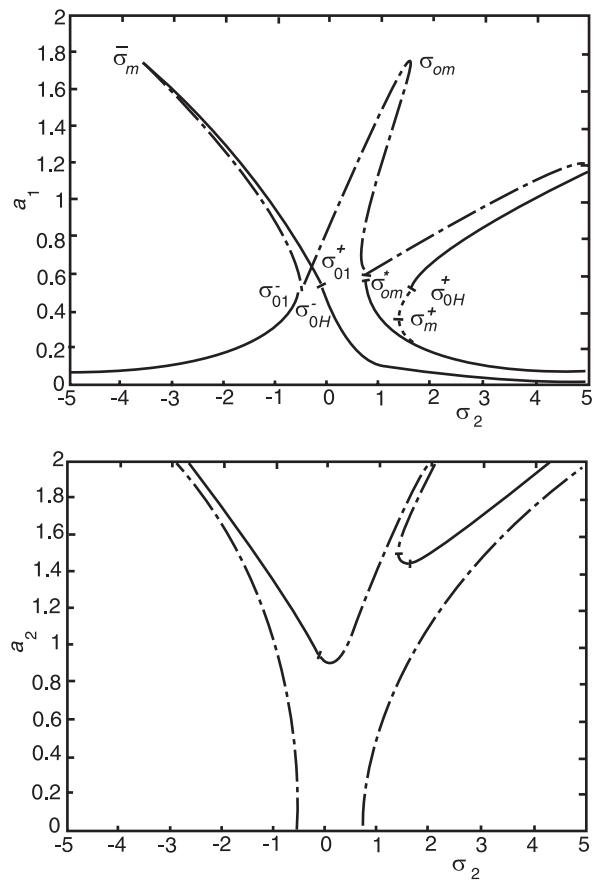

Figure 15 Frequency-response curves for an orthogonal double pendulum in primary resonance, with the two pendulums in one-to-one internal resonance; zero internal mistuning.

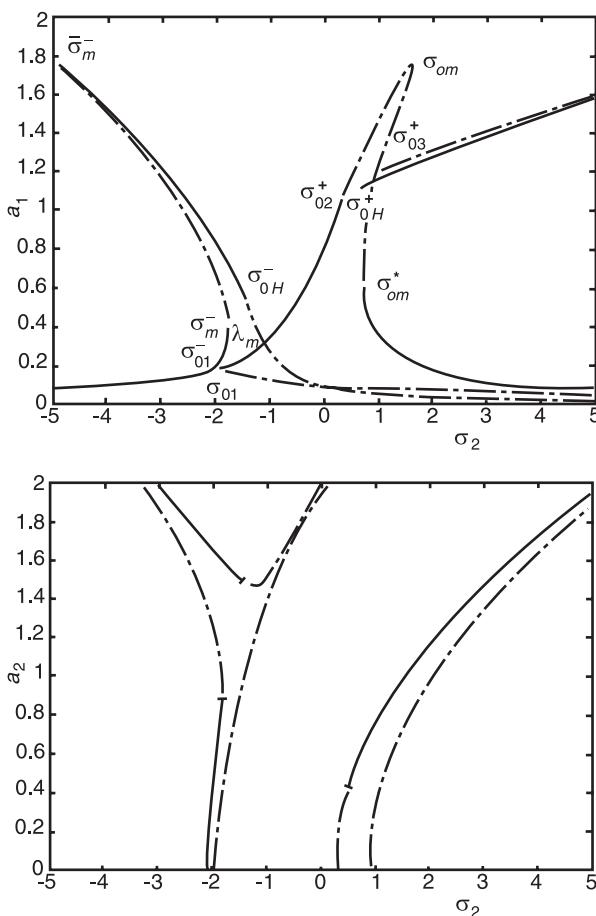

Figure 16 Frequency-response curves for an orthogonal double pendulum in primary resonance, with the two pendulums in one-to-one internal resonance; non-zero internal mistuning.

well as unstable solutions in the single-mode (lower pendulum stationary, $a_2 = 0$) with two turning points σ_{om} and σ_{om}^* . In the zero mistuning case (Figure 15), coupled-mode solutions (both pendulums oscillating, $a_1 \neq 0, a_2 \neq 0$) arise due to a pitchfork bifurcation at excitation frequencies σ_{01}^- and σ_{01}^+ . Both stable and unstable branches are also present in coupled-mode solutions indicating jumps from one branch to other as the frequency is monotonically and slowly varied. Hopf bifurcations to limit cycle oscillations, and possible transitions to chaotic solutions in coupled-mode solutions, arise at frequencies σ_{0H}^- and σ_{0H}^+ . The introduction of internal mistuning results in even more solution branches and additional bifurcations (Figure 16).

This discussion provides a glimpse into the rich variety of dynamical motions exhibited by nonlinear systems under resonant excitations. The last two decades have seen exciting developments whereby one can analytically study the origins of such complex dynamical behavior, and many of these motions have also been experimentally observed in simple structural systems.

NONLINEAR SYSTEMS, OVERVIEW

doi:10.1006/rwvb.2001.0036

Introduction

Nonlinear behavior is pervasive in mechanical systems. In fact, it is fair to state that linear behavior is just an idealization of the many nonlinear phenomena that influence dynamic response. It is equally fair and important to add that assuming linear behavior quite often leads to successful estimates of dynamic response. Moreover, the analytical methods made possible through linearization form the foundation for classical vibration analysis and companion experimental methods as well; refer, for example, to entries under **Modal analysis, experimental**. Thus, the central issue is not whether a phenomenon is nonlinear or not, but rather whether the nonlinearities ultimately influence the response in any significant manner. The objective of this article is to indicate the significant ways that nonlinearities manifest themselves, and then to identify and classify their sources in mechanical systems.

Significant Effects of Nonlinearities

To appreciate immediately the effect of nonlinearities, consider the possible responses that may be exhibited by the single-degree-of-freedom system illustrated in Figure 1A to sustained harmonic excitation. In this example, we shall assume that the nonlinearity derives solely from the nonlinear behavior of a spring, as might be realized by either material nonlinearities or geometric nonlinearities, as discussed in the following sections. In particular, the spring-restoring force, $F(x) = k_1x + k_3x^3$, is a nonlinear function of the stretch x , and the stiffness of this spring, $k(x) = dF/dx = k_1 + 3k_3x^2$, either monotonically decreases or increases with the stretch, depending on the sign of the ratio k_3/k_1 . A spring whose stiffness decreases with stretch is said to exhibit softening behavior, while one whose stiffness increases with stretch is said to exhibit hardening behavior (refer to Figure 1B and examples that follow). In either case, the nonlinearity can produce motions that are qualitatively distinct from those of the approximate linear system, that is, the system for which $k_3 = 0$. (This

example is classified as a damped, forced Duffing system, as discussed in the article **Analysis of nonlinear systems.**)

This fact is depicted in Figure 1C which shows the long-term response (the response after transients have decayed) of the approximate linear system and those possible for the nonlinear system subject to the same harmonic excitation. For the linear system, harmonic input generates a harmonic response with the very same frequency as the input. The amplitude and phase of this harmonic response are controlled by nearness to resonance, that is, how close the excitation frequency Ω is to the natural frequency $\omega_n = \sqrt{k_1/m}$ as discussed in the entry for **Resonance and antiresonance**. By contrast, the response of the nonlinear system can be periodic (harmonic as an example) or aperiodic. Among possible periodic responses are the primary resonant response (a modification of the sole resonant response of the linear system), and secondary resonant responses, including subharmonic and superharmonic resonant responses, as described in article **Resonance and antiresonance**. The secondary resonant responses include response frequencies that are related to the excitation frequency by $(p/q)\Omega$, where p and q are positive integers. Among possible aperiodic responses are quasiperiodic responses (motions with periodically modulated amplitude and/or phase) and chaotic responses, as described in the article **Chaos**. In addition, multiple responses of the nonlinear system may coexist; that is, multiple solutions exist (in general) to the governing equation of motion. By contrast, solution uniqueness is guaranteed for the approximate linear system. Thus, even the prototypical single-degree-of-freedom nonlinear system illustrated here may exhibit significantly different responses than its linear counterpart. These differences become even greater with the inclusion of additional degrees-of-freedom; for example, witness the role of internal resonances as described in article **Resonance and antiresonance**. For more detailed discussions of nonlinear vibrations, see Further Reading.

With this as background, let's now proceed to classify the major types of nonlinearities and their sources in mechanical systems.

Sources of Nonlinearities

Nonlinearities arise from virtually all forces that govern the motion of mechanical systems. They may

manifest themselves in the forces contributing to system stiffness, damping, and inertia. To appreciate the many ways in which nonlinearities arise, consider a general continuum illustrated in Figure 2.

Let (x_1, x_2, x_3) be the components of a Cartesian triad and (u_1, u_2, u_3) be the associated components of the three-dimensional displacement field of the continuum from some reference configuration. The body occupies the three-dimensional domain D bounded by the surface B . The motion of the body, as described by the displacement components, is determined by the three momentum equations:

$$\tau_{ij,j} + f_i = \rho \ddot{u}_i \quad \text{in } D \quad [1a]$$

and the boundary conditions:

$$\tau_{ij} n_j = T_i \text{ on } B_1 \quad [1b]$$

$$u_i = U_i \text{ on } B_2 \quad [1c]$$

where the index $i = 1, 2, 3$, $(\cdot)_{,j}$ denotes partial differentiation with respect to the independent spatial variable x_j , \ddot{u}_i denotes total differentiation with respect to time (twice), and summation of repeated

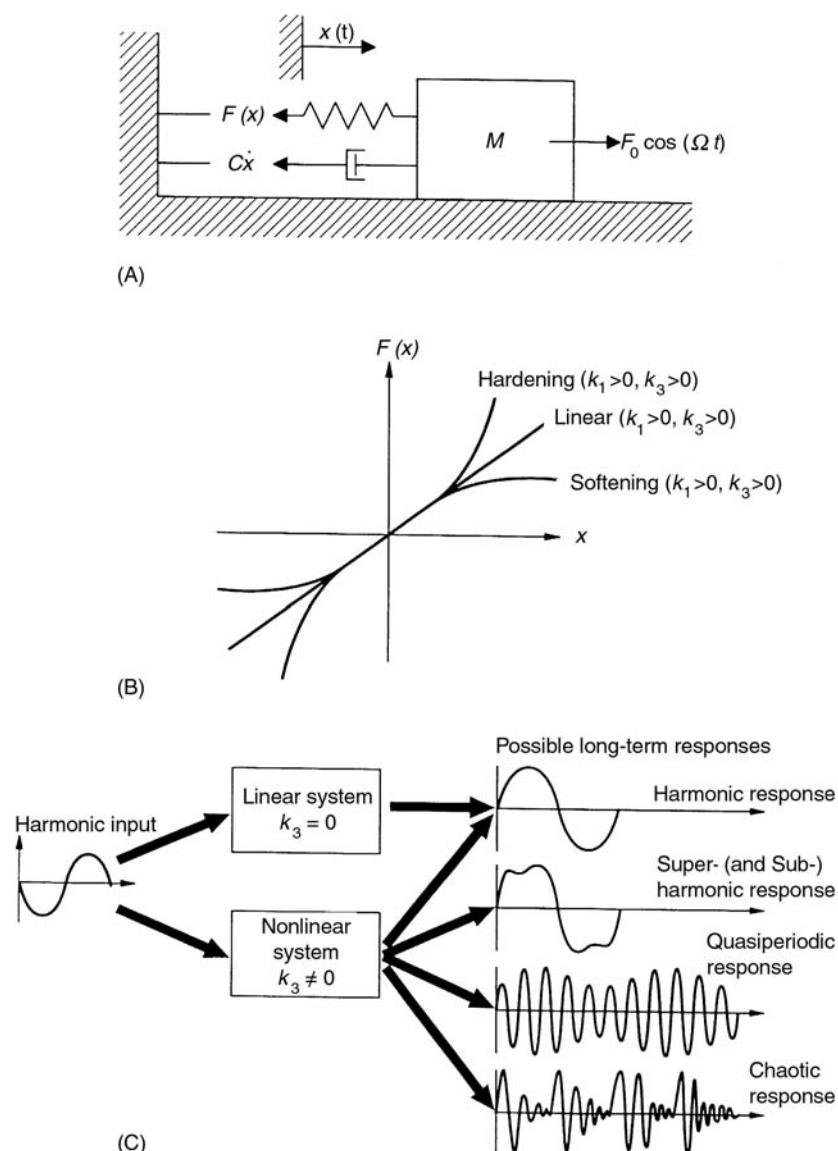

Figure 1 (A) Nonlinear single-degree-of-freedom system subject to harmonic excitation. (B) Nonlinearity derives from nonlinear elastic element that may exhibit hardening or softening behavior. (C) A comparison of possible responses of linear and nonlinear single-degree-of-freedom systems to harmonic excitation.

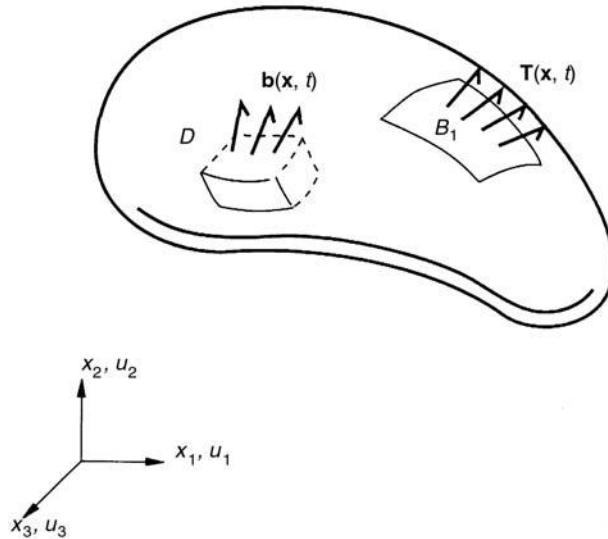

Figure 2 General continuum subject to applied body forces $\mathbf{b}(\mathbf{x}, t)$ and surface tractions $\mathbf{T}(\mathbf{x}, t)$.

indices is implied. Here, τ_{ij} is the (Cauchy) stress tensor, f_i are components of applied body forces, ρ is the material density, n_j are components of the unit normal vector (outward) to the boundary B_1 on which tractions with components T_i are applied, and U_i denotes prescribed displacements on the remainder of the boundary B_2 . This general formulation, which applies to any continuum (e.g., solids and fluids), includes all common structural elements (shells, plates, beams, etc.) as special cases and serves as a means to introduce major classes of nonlinearities.

Consider first nonlinearities introduced through the stress tensor τ_{ij} . These nonlinearities are referred to either as material nonlinearities or as geometric nonlinearities, depending upon how they arise in τ_{ij} . Material nonlinearities arise from nonlinear material laws (constitutive equations) that relate the stress tensor to the strain tensor (or derivatives thereof). By contrast, geometric nonlinearities arise from nonlinear strain-displacement relations. Thus, a linearly elastic material may exhibit nonlinear response when (finite) strain measures are used that capture the effect of geometrically large deformations. Several examples of material and geometric nonlinearities follow below. The body forces (f_i) become a source of nonlinearity whenever they are a nonlinear function of the displacement field (or derivatives thereof). Examples may include magnetic and electrostatic forces and fluid/structure interaction forces (when treated as body forces). The inertia term on the right-hand side of eqn [1a] may also introduce nonlinearities as seen in fluid mechanics (Navier-Stokes equation) where an Eulerian description of fluid motion is employed. Continuing to eqn [1b], note that the tractions T_i applied on the traction boundary

may also be nonlinearly related to the displacement field (and derivatives thereof), with common examples being fluid/structure interaction forces (when treated as surface tractions), surface friction, and impact. The displacement boundary eqn [1c] may also introduce nonlinearities as, for instance, in the case of clearance problems where traction boundary conditions are suddenly replaced by displacement boundary conditions. Finally, the domain D may depend on the displacement field and thereby capture the nonlinearities that arise, for example, in fluid/structure interaction problems with free surfaces or some contact problems with deformable bodies.

Classes of Nonlinearities

Many classifications of nonlinearities are possible, with one being based upon how they enter the equations of motion, as described above. An alternative classification may be based on the mathematical forms these nonlinearities take, including analytic forms (e.g., most geometric and material nonlinearities) versus nonanalytic (nondifferentiable) forms (e.g., dry friction and impact nonlinearities). Within this article, we will describe nonlinearities associated with four major sources for mechanical systems including: (1) geometrically large motion, (2) nonlinear material behavior, (3) fluid/structure interaction, and (4) friction and impact. Each of the four major categories of nonlinearities is reviewed below.

Geometrically Large Motion

Geometrically large motions may introduce nonlinearities through inertia, damping, and stiffness terms. For the general continuum described above, geometric nonlinearities enter through the nonlinear strain-displacement relations associated with finite strain measures. For instance, consider the prototypical example of a flexible beam undergoing deformation in the plane, as depicted in Figure 3. Let x_1 denote the independent spatial variable along the undeformed neutral axis of the beam and let u_1 and u_2 denote the longitudinal and transverse components of the displacement field of the neutral axis. Using Kirchhoff assumptions for beam deformation, the strain of a beam element becomes:

$$\varepsilon(\mathbf{x}_1, \mathbf{x}_2, t) = \varepsilon_0(\mathbf{x}_1, t) - x_2 \kappa(\mathbf{x}_1, t) \quad [2a]$$

where:

$$\varepsilon_0(\mathbf{x}, t) = u_{1,1} + \frac{1}{2} (u_{1,1}^2 + u_{2,1}^2) \quad [2b]$$

represents the strain of the neutral axis and $-x_2 \kappa(\mathbf{x}_1, t)$ represents the additional strain at the level x_2 from the neutral axis due to the curvature

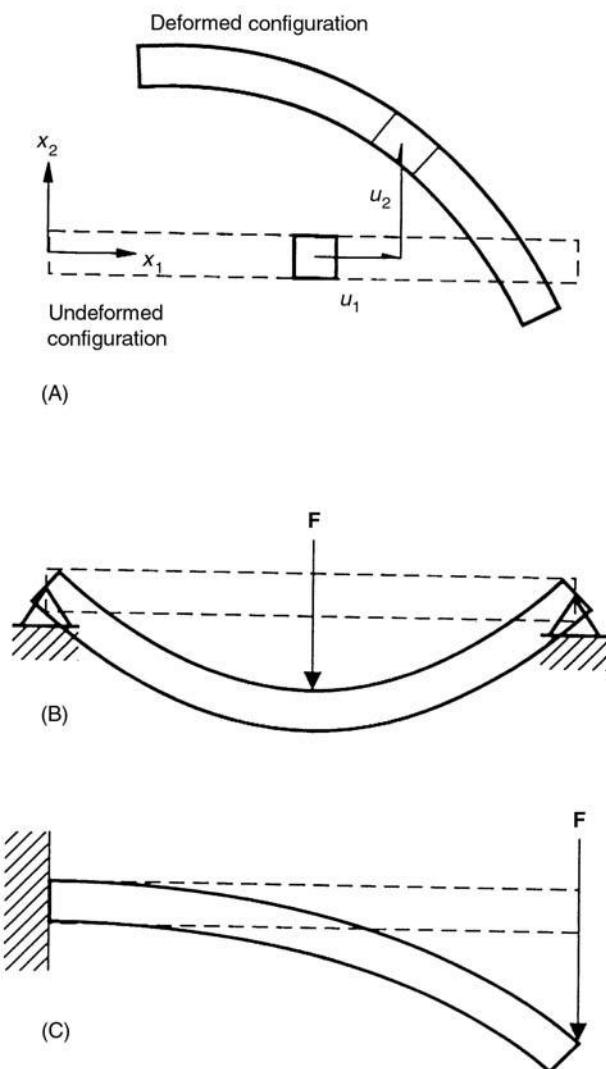

Figure 3 (A) Geometrically large planar motion of a beam as measured by the displacements $u_1(x_1, t)$ and $u_2(x_1, t)$ of the neutral axis. (B) Simply supported beam for which the dominant nonlinearity derives from the stretching of the neutral axis. (C) Cantilevered beam for which the dominant nonlinearity derives from large rotations of the beam cross-sections.

$\kappa(x_1, t)$ of the neutral axis. The curvature of the neutral axis is given by:

$$\kappa(x_1, t) = \frac{u_{2,11}}{\left(1 + u_{2,1}^2\right)^{3/2}} \quad [2c]$$

Inspection of the strain-displacement relation, eqn [2a] with eqn [2b] and eqn [2c], reveals two sources of geometric nonlinearity for the beam. The first of these is the nonlinear strain-displacement relationship [2b] that describes the stretching of the beam neutral axis, and the second is the nonlinear curvature-displacement relationship [2c] describing

large rotation of the beam cross-section. Either or both of these nonlinear mechanisms may arise in a particular application. For instance, in the case of the simply supported beam shown in Figure 3B, the neutral axis must stretch as the beam deflects and the dominant nonlinear mechanism in this case is associated with neutral axis stretching (eqn [2b]). By contrast, large rotation (eqn [2c]) represents the dominant nonlinear mechanism for the cantilevered beam of Figure 3C. Here, the beam centerline may not stretch appreciably, but the cross-sections may rotate through moderate to large angles. This effect is captured in the classical problem of the elastica; see Further Reading.

The discussion above for beams forms a special case of the general topic of the theory of rods (see Further Reading). Qualitatively similar geometrical nonlinearities arise in other structural elements, including cables, membranes, plates, and shells. For instance, von Ka'rm'an plate theory captures the nonlinearities produced by the stretching of the neutral plane of the plate in analogy to the effect modeled for the beam by eqn [2b] above. It should also be noted that the geometric nonlinearities of structural elements can exhibit hardening or softening effects or both. Consider for instance the geometric nonlinearities produced by the stretching of the centerline of a sagged flexible cable, as shown in Figure 4A. Note that the strain of the centerline will initially decrease (i.e., tension will decrease) if a load F is directed along the normal (i.e., towards the center of curvature). Thus the cable can exhibit softening behavior. By contrast, hardening behavior is immediately observed if the direction of the load is reversed (applied away from the center of curvature). Thus, the overall force-deflection behavior of the cable is asymmetric (describable by both even and odd functions of deflection), as illustrated in Figure 4B. This structural asymmetry is generic to all structural elements that are precurved (e.g., arches and shells).

Nonlinear Material Behavior

As discussed above, material nonlinearities may arise in eqn [1a] and eqn [1b] through the nonlinear dependence of the stress on the strain (and/or strain rate) measure. Common examples of materials that obey nonlinear material (constitutive) laws include ductile metals that yield, elastomeric materials (e.g., most rubbers), viscoelastic materials (e.g., rubbery compounds and polymers), biomaterials (membranes, skin, collagen fibers, muscle tissue), and various 'new' materials, including rheological fluids, shape memory alloys, etc. For the purpose of this overview, we shall consider two broad classes of

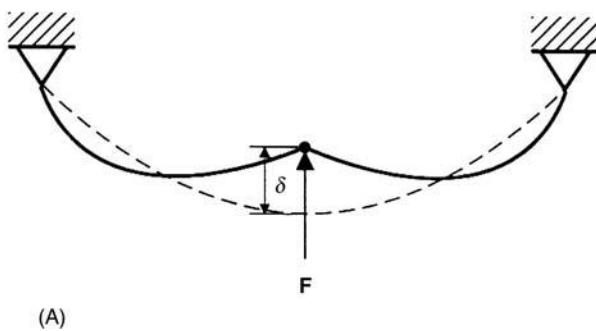

Figure 4 (A) Sagged cable subject to a central load. (B) Asymmetric force-deflection curve.

nonlinear material behavior by distinguishing materials that are dissipative from those that are not.

The nondissipative materials are nonlinearly elastic and may exhibit hardening characteristics, softening characteristics or a combination of both. As a simple example, consider the scalar constitutive law:

$$\tau = f(\varepsilon) \quad [3a]$$

which might be expanded in a Taylor series in the strain measure ε (about a stress-free state):

$$\tau = f'(0)\varepsilon + \frac{1}{2}f''(0)\varepsilon^2 + \frac{1}{6}f'''(0)\varepsilon^3 + \dots \quad [3b]$$

in which $(\cdot)'$ denotes differentiation with respect to ε . In the expansion (eqn [3b]), the quantity $f'(0) = E$ would be identified as Young's modulus. Many nonlinearly elastic materials are 'symmetric' in their material response in that the stress changes sign when the strain changes sign (but remains the same magnitude). For these materials, eqn [3a] and eqn [3b] are odd functions of the strain (hence the coefficient $f''(0)$ would vanish in eqn [3b]). The constitutive law (eqn

[3a]) or (eqn [3b]) for a typical elastomeric material might appear as shown in Figure 5A and exhibit an initial softening behavior for small to moderate strains followed by hardening behavior for larger strains.

Nonlinear material laws for dissipative materials include those materials exhibiting viscoelastic effects (dissipation produced by strain-rate dependency) as well as plastic effects (dissipation produced by material hysteresis). For instance, a general (scalar) model for a nonlinear viscoelastic material could be written:

$$\tau(\varepsilon, \dot{\varepsilon}) = f(\varepsilon, \dot{\varepsilon})\varepsilon + g(\varepsilon, \dot{\varepsilon})\dot{\varepsilon} \quad [4]$$

in which the 'elastic' contribution f and the 'visco' contribution g could depend explicitly on the strain, strain rate, or both. Alternative (integral) material laws for viscoelastic materials have also been proposed that capture material memory effects. Materials exhibiting elastic-plastic behavior develop dissipation through the hysteresis loop associated

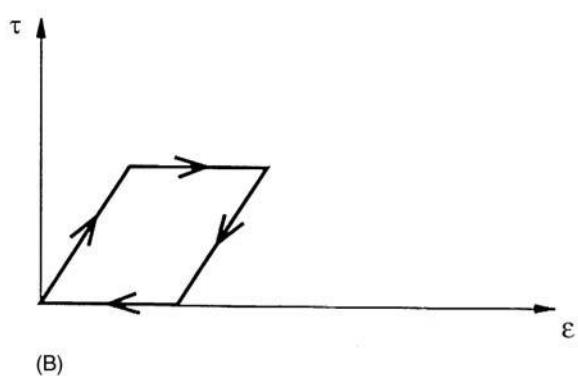

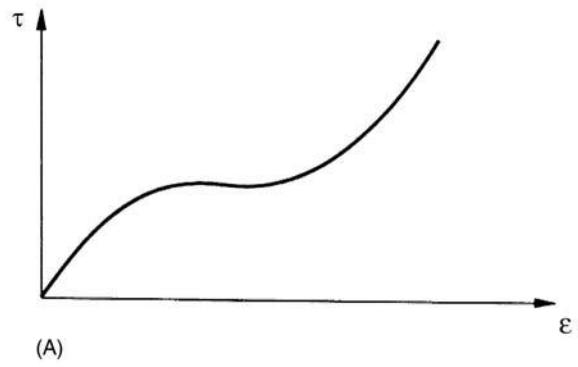

Figure 5 (A) Nonlinear stress-strain relationship for an elastomeric material, (B) nonlinear stress-strain relationship for an ideal elastic-plastic material.

with cyclical loading and unloading. For instance, consider the material law for an ideal elastic/plastic solid, as depicted in **Figure 5B**. Starting from the undeformed state, the material exhibits linearly elastic behavior up to the yield point, beyond which it exhibits ideal plastic behavior. Upon unloading, the behavior is first elastic then plastic, leading to the illustrated hysteresis loop.

Fluid/Structure Interaction

Fluids surrounding a structure exert pressure (modeled either as body forces or tractions, following the discussion above) that ultimately influence the inertia and/or damping of the structure. A survey of this topic can be found under the entry **Fluid/structure interaction**. Here, we shall focus on two common types of fluid/structure interactions that are governed by nonlinearities (recognizing that other nonlinear interactions also exist). The first example will focus on the Morison relation that accounts for the added mass and nonlinear drag imparted to a structure in a surrounding fluid (e.g., water). The second example will focus on a nonlinear wake oscillator model proposed to describe the phenomenon of vortex-induced vibrations of structures.

Consider first a body moving with some speed \dot{x} in an otherwise quiescent fluid. The surrounding fluid provides both a source of added mass to the body as well as drag. These features are captured in the classical Morison relation (scalar form):

$$F_f = C_a \rho_f V \ddot{x} + \frac{1}{2} C_d \rho_f A |\dot{x}| \dot{x} \quad [5]$$

in which the force due to the fluid F_f captures the effects of added fluid mass (first term) and fluid drag (second term). Here, ρ_f is the fluid density, V is the volume of the body, A is the projected area of the body in the plane orthogonal to the relative motion, C_a is the added mass coefficient, and C_d is the drag coefficient. These coefficients are often determined by experiments. In employing eqn [5], it is tacitly assumed that the Reynolds number is high enough such that the drag force is proportional to the square of the relative velocity. For low Reynolds numbers in the Stokes flow regime, the drag is adequately represented as being proportional to the relative speed, rendering the drag force linear. See Further Reading for further information on this model.

The drag force modeled by the Morison relation above is strictly dissipative. However, under certain flow conditions, a slender bluff body can actually extract energy from the flow and achieve sustained vibrations. The mechanisms responsible for this behavior trace to the fluid vortices shed from the

surface of the bluff body and the resulting motion is often referred to as vortex-induced vibration. Consider, for instance, the vortex-induced vibrations of the subsurface instrumentation array depicted in **Figure 6**.

While no one model for vortex-induced vibration is used exclusively, a class of nonlinear models described as wake oscillator models has received considerable attention. These phenomenological models introduce a single oscillator equation to describe the fluctuating lift forces (lift coefficient) caused by vortex shedding and invariably include several empirical coefficients that must be fit to experimental data to produce estimates of vortex-induced vibration. The wake oscillator is then coupled to a model of the structure (typically, a single-degree-of-freedom model) in forming the two equations of coupled fluid/structure interaction. For instance, let $x(t)$ denote the modal coordinate for a vibration mode of a slender structure having natural frequency ω_n and damping ratio ζ . Let q denote the excitation to this mode produced by vortices shed with Strouhal frequency ω_s (a frequency that depends on the flow velocity, the diameter of the structure, and the Strouhal number). A typical model proposed for the coupling of the vibration response $x(t)$ and the fluid lift coefficient $q(t)$ is:

$$\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2 x = \mu\omega_s^2 q \quad [6a]$$

$$\ddot{q} - \omega_s G(C_{Lo}^2 - 4q^2)\dot{q} + \omega_s^2 q = \omega_s F \dot{x} \quad [6b]$$

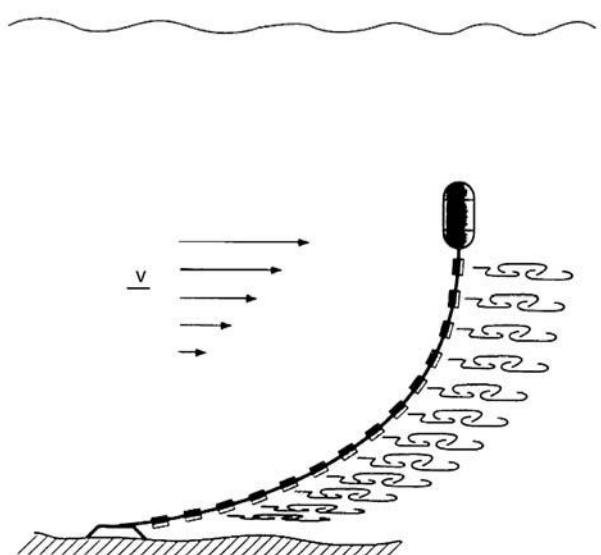

Figure 6 Fluid vortices shed may resonantly drive sustained structural vibrations as, for example, in this subsurface instrumentation array.

in which μ is a mass ratio parameter and G , C_{Lo}^2 , and F are three empirically determined coefficients. While the ‘structure equation’ (eqn [6a]) is assumed linear, the ‘fluid equation’ (eqn [6b]) is of the form of a van der Pol equation with both the sign and magnitude of the damping determined by the magnitude of q . Inspection of eqn [6b] reveals that the damping is negative (energy increases) when q is small and becomes positive (energy decreases) when q is large. Thus, there is an intermediate value of q that leads to a self-sustained oscillation (a limit cycle) that drives a sustained vortex-induced vibration, as measured by x . This self-sustained vibration is governed by the coupling of eqns [6a] and [6b] and the strength of this coupling is determined by the resonance condition $\omega_s \approx \omega_n$. Further information on vortex-induced vibrations can be found in Further Reading.

Friction and Impact

Most of the nonlinear models discussed above are analytic (differentiable) and thus are amenable for analysis using asymptotic methods, as described in the articles **Nonlinear systems analysis** and **Perturbation techniques for nonlinear systems** under the entry Nonlinear Vibrations. Exceptions to this are the ideal elastic-plastic material law (see above) and the nonlinear drag model (see above) that are described by nonsmooth functions. The same is true of commonly used nonlinear models for friction and impact, as will be discussed here. In addition, the nonlinearities associated with friction and impact have little to do with large-amplitude motion as they are frequently exercised even for the relatively small-scale motions of mechanical assemblies. Friction and impact are also the underlying causes of squeak-and-rattle problems that remain a concern in many applications.

The study of friction has a long history, with contributions from prominent scientists including Coulomb, who proposed the classical laws for dry friction still commonly used in models of mechanical systems; refer to articles **Frictional damping** and **Friction-induced vibrations**. As an example, consider the Coulomb friction law illustrated in Figure 7 that describes the friction force developed between two surfaces as a function of the relative (sliding) velocity. For vanishing sliding velocity, the friction force that develops is that required to maintain equilibrium and is limited by a maximum value as determined by a coefficient of static friction μ_s . Upon sliding, the friction force has a constant magnitude, as determined by a coefficient of dynamic friction μ_d . While this description is attractive because it is simple, it brings with it difficulties in analysis. This friction model

renders the acceleration discontinuous in time as the friction force is a discontinuous function of the sliding velocity. Numerical and analytical methods frequently have difficulties in resolving this discontinuity.

An important nonlinear effect produced by dry friction is friction-induced vibration; refer to **Friction-induced vibrations**. These vibrations are often small-amplitude, high-frequency oscillations that produce audible tones. Friction-induced vibrations have been observed in many systems, with classic examples being the sustained vibration of the violin string due to friction from the bow and the sustained tone produced by circulating a wet finger around the perimeter of a wine glass. Other examples include the squeal of disk brakes, the screeching of railway wheels guided by rails, and the squeak of a wiper blade on a drying windshield.

Most assemblies containing moving mechanical parts have unavoidable clearances and/or backlash. Like the ideal model for friction above, ideal models representing systems with clearances and backlash are nonsmooth and may also involve impacts. Examples of mechanical systems modeled in this manner include mating gears, seating valves, seating chains, and impacting heat exchanger tubes, print hammers, pile-drivers, impulsive drills, jack-hammers, and the like.

For instance, consider a classical model for backlash represented by the system of Figure 8A. Here, a body (e.g., a particle) is free to move within a ‘dead zone’ of length d prior to contacting elastic stops. The motion of the body could be induced in many ways, one of which is through prescribing the base motion $y(t)$, as in Figure 8A. The simplest force/displacement model for this process would appear as a piecewise

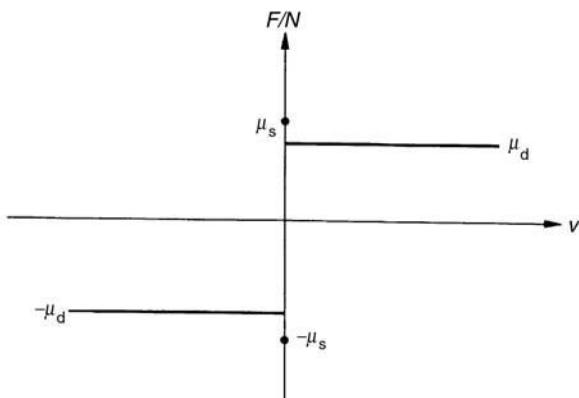

Figure 7 Classical Coulomb friction law. F and N are friction and normal forces acting between two surfaces, with v being the relative (sliding) velocity.

linear model, as illustrated in Figure 8B. Piecewise nonlinearities represent an important class of non-smooth nonlinearities and are frequently used as approximations for systems with clearances and backlash. A variation on this theme is an impact oscillator which can be obtained from the above example as the limiting case of infinite (contact) stop stiffness, as depicted in Figure 8C. The resulting motion-limiting rigid stops now form sites where impacts occur as the body rattles about in between. The simplest model for this process would be to represent the contact forces as impulses that produce discontinuities in the particle's velocity. These discontinuous changes in velocity might be modeled by introducing a coefficient of restitution for the impact process. Further discussion and examples of the nonlinearities generated by impact and clearances can be found in Further Reading.

Nomenclature

A	area
B	boundary
C_a	added mass coefficient
C_d	drag coefficient
D	three-dimensional domain
E	Young's modulus
p, q	positive integers
V	volume
ε	strain measure
μ	mass ratio parameter
ρ	density
τ_{ij}	stress tensor
Ω	excitation frequency

NONLINEAR SYSTEMS ANALYSIS

A Bajaj, Purdue University, West Lafayette, IN, USA

doi:10.1006/rwvb.2001.0037

Nonlinear models arise for most real systems and their presence in one form or another is generally the rule. The source of nonlinearity in structural and mechanical systems may be geometric, inertial, or material in nature. In mechanical systems interacting with surroundings, forces can arise due to the interacting media (dry friction, fluid-structure interactions, impacts) or fields (magneto-elastic, acousto-elastic). The resulting nonlinear models exhibit a rich variety of phenomena of interest to scientists and engineers. Some of the well-known phenomena are: static and dynamic instabilities and buckling in structures; jump phenomenon, and sub- and super-harmonic resonances in plates and shells; flutter in wind-loaded buildings and structures; parametric instabilities in systems with pulsating loads; rattle and squeak in automotive systems; and ship capsize under wave excitation.

The equations governing the nonlinear response are usually ordinary or partial differential equations that depend on external excitations and/or parameters. Their solution can be sought with different viewpoints guided by the applications in mind. As an example, one may be interested in knowing if the system has only one equilibrium point and that it is globally stable, that is, regardless of the size of a disturbance the system returns to the equilibrium position. On the other hand, one may seek to know whether a system has some periodic solution, and if yes, how many of them exist. Thus, there arise questions of existence, uniqueness, and stability of different type of solutions a system may possess. Seeking solutions to these questions brings into play many different branches of mathematical and numerical analysis. The scope of this article is limited to the most commonly used techniques in the analysis of nonlinear vibratory systems.

Few solutions to dynamical systems, other than equilibrium points, can be obtained analytically in closed form. Thus, the investigator has to resort to analytical approximation methods or to numerical computations and simulations. In the 19th and the early part of the 20th century, the emphasis was on analytic solutions of specific nonlinear differential equations. Both convergent and asymptotic expan-

sion techniques were developed that relied on the existence of a (small) parameter or parameters in the equations of motion. Knowing the solutions at one parameter value, techniques were developed that allowed for the prediction of behavior at neighboring parameter values. The class of solutions studied was limited to periodic solutions in periodically excited systems, and limit cycles in self-excited or autonomous systems. These techniques, where possible, were also extended to almost periodic solutions.

In recent years, motivated by the exciting developments in geometric theory of dynamical systems, the emphasis in applied dynamical systems literature has shifted to the more geometric approaches to study of solutions. These provide a global understanding of the behavior of the system in the parameter as well as phase space. The basic point of this qualitative approach is that low-order dynamical models can provide paradigms of global behavior, and these low-order models reside at the core of larger dimensional systems. There exist analytical techniques that allow for a systematic reduction of the system dimension to the bare minimum. When not possible analytically, the response of low-order models can be studied numerically. This approach has resulted in uncovering and understanding of various types of bifurcations, qualitative changes in system response as a system parameter is varied, as well as complex dynamical behaviors, including temporal and spatial chaos.

The advent of analog computers in the middle of the 20th century was critical to the early studies in complex dynamical behavior. It allowed for the exploration of responses that could not be investigated analytically. The digital computer accelerated this process of exploration and is now playing an integral part in the development of techniques for system analysis, specially for systems that are high dimensional, and those exhibiting complex behavior.

This article is focused on techniques commonly used in the analysis of various nonlinear vibratory systems. The starting point is the study of equilibria and their stability. Most of the analytical techniques for the study of resonance phenomena are based on constructing asymptotic or perturbation expansions for periodic and almost periodic solutions. The essence of these perturbation and asymptotic methods is described next. This is followed by a discussion of the techniques used in the geometric approach of applied dynamical systems theory, and some

of the essential results useful in the study of local bifurcations.

Equilibria and Stability

The simplest continuous-time, autonomous dynamical models of vibratory systems are of the form:

$$\dot{x} = f(x, p) \quad [1]$$

where $x \in \mathbb{R}^n$ is an n -dimensional real vector and $p \in \mathbb{R}^m$ is an m -dimensional vector of control parameters. An equilibrium point, critical point, or singular point is defined to be a point (x_e, p_0) at which the vector field vanishes, that is, $f(x_e, p_0) = 0$. The origin of eqn [1] can be translated to the equilibrium point (x_e, p_0) to give the new system:

$$\dot{y} = Ay + g(y, \hat{p}) \quad [2]$$

where $y = x - x_e$, $\hat{p} = p - p_0$, $A = (\partial f / \partial x)|_{(x_e, p_0)}$, and $g(y, \hat{p}) \equiv f(x_e + y, p_0 + \hat{p}) - Ay$. The linearized approximation to the system (2) is given by:

$$\dot{z} = Az \quad [3]$$

Classification of Equilibrium Points

When all the eigenvalues of the constant matrix A have nonzero real parts, the corresponding equilibrium point (x_e, p_0) is called a hyperbolic equilibrium point. Otherwise, it is called a nonhyperbolic equilibrium point.

There are three types of equilibria: sinks, sources, and saddles. If all the eigenvalues of the matrix A have negative real parts, the solution $z(t, z_0)$ for any given initial condition z_0 decays to zero exponentially in time. Thus, the equilibrium $z = 0$, called a sink, is asymptotically stable. On the other hand, if all the eigenvalues of the matrix A have positive real parts, the solution $z(t, z_0)$ for any given initial condition z_0 grows unbounded in time, and the equilibrium $z = 0$ is called a source. A source is an unstable equilibrium. Finally, if some of the eigenvalues have positive real parts, and the rest of the eigenvalues have negative real parts, the equilibrium is unstable and is called a saddle. If all the eigenvalues of the matrix are on the imaginary axis, and at least one pair is pure imaginary and nonzero, the equilibrium is called a center. In physical systems, the equilibria as well as their stability depend on parameters. Thus, as a parameter is varied, an equilibrium may lose its stability as it changes from a sink to a center or just stable, and then to a saddle. This situation is what usually leads to

a local bifurcation: creation of additional equilibria, exchange of stability in coexisting equilibria, and creation of limit cycles or periodic solutions.

The connection between the stability of an equilibrium point for the linearized approximation [3] and the nonlinear system [2] is provided by the Hartman-Grobman theorem, which implies that the equilibrium point $y = 0$ for the nonlinear system [2] is asymptotically stable if $\text{Re}(\lambda_i) < 0$ for all eigenvalues of the matrix A . The origin is unstable if $\text{Re}(\lambda_i) > 0$ for one or more of the eigenvalues of A . If some eigenvalues are with $\text{Re}(\lambda_i) = 0$ and the remaining eigenvalues are in the left-half of the complex plane, no conclusion can be drawn based on the linearized system. These are called the critical cases of stability. In these cases, nonlinear terms $g(y, \hat{p})$ are essential for determining the behavior of the system. Phase portraits (a typical set of trajectories) for linearized systems with various types of equilibria in two-dimensional systems are shown in Figure 1. A few representative phase portraits for three-dimensional systems are given in Figure 2.

Stable, Unstable, and Center Eigenspaces

Suppose that the matrix A has n_s eigenvalues with negative real parts, n_c eigenvalues with zero real parts, and n_u eigenvalues with positive real parts. Then, as is well known, there exists a change of coordinates that transforms system [3] into:

$$\dot{u}_s = B_s u_s, \quad \dot{u}_c = B_c u_c, \quad \dot{u}_u = B_u u_u \quad [4]$$

Furthermore, the state space of the system [3] is decomposed into a direct sum of the invariant linear spaces E^S , E^C , and E^U -corresponding to the eigenvalues with negative real parts, zero real parts, and positive real parts, respectively. These are the stable, center, and unstable eigenspaces of the linear system. They are characterized for system [4] by the conditions:

$$\begin{aligned} E^S &= \{(u_s, u_c, u_u) | u_c = 0, u_u = 0\} \\ E^C &= \{(u_s, u_c, u_u) | u_s = 0, u_u = 0\} \\ E^U &= \{(u_s, u_c, u_u) | u_s = 0, u_c = 0\} \end{aligned} \quad [5]$$

There exists a similar decomposition of the phase space for the nonlinear system [2] in the neighborhood of the equilibrium point $y = 0$.

Local Invariant Manifolds

The stable manifold of an equilibrium point of system [2] (denoted by W^S) is the set of all initial conditions such that any solution initiated at these points asymp-

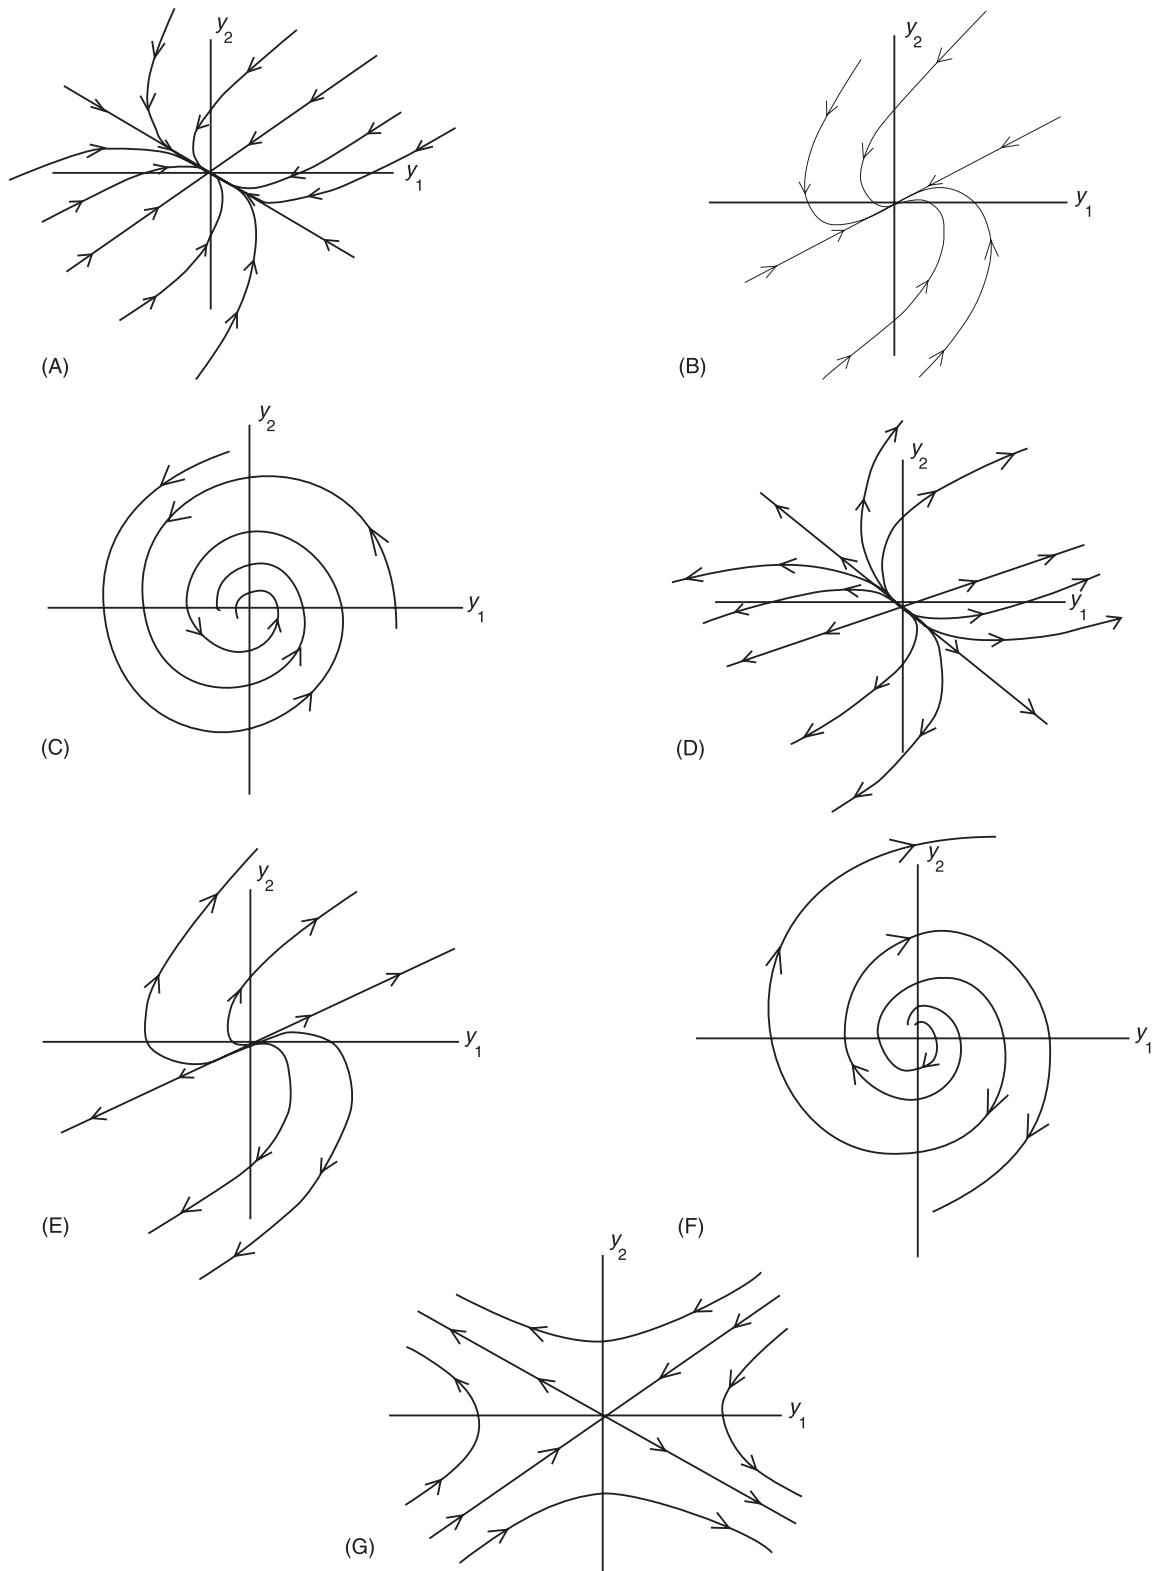

Figure 1 Various types of equilibria in two-dimensional systems: (A) sink or stable node; (B) sink or improper stable node; (C) sink or stable spiral or stable focus; (D) source or an unstable node; (E) source or an unstable improper node; (F) source or an unstable focus; (G) saddle point.

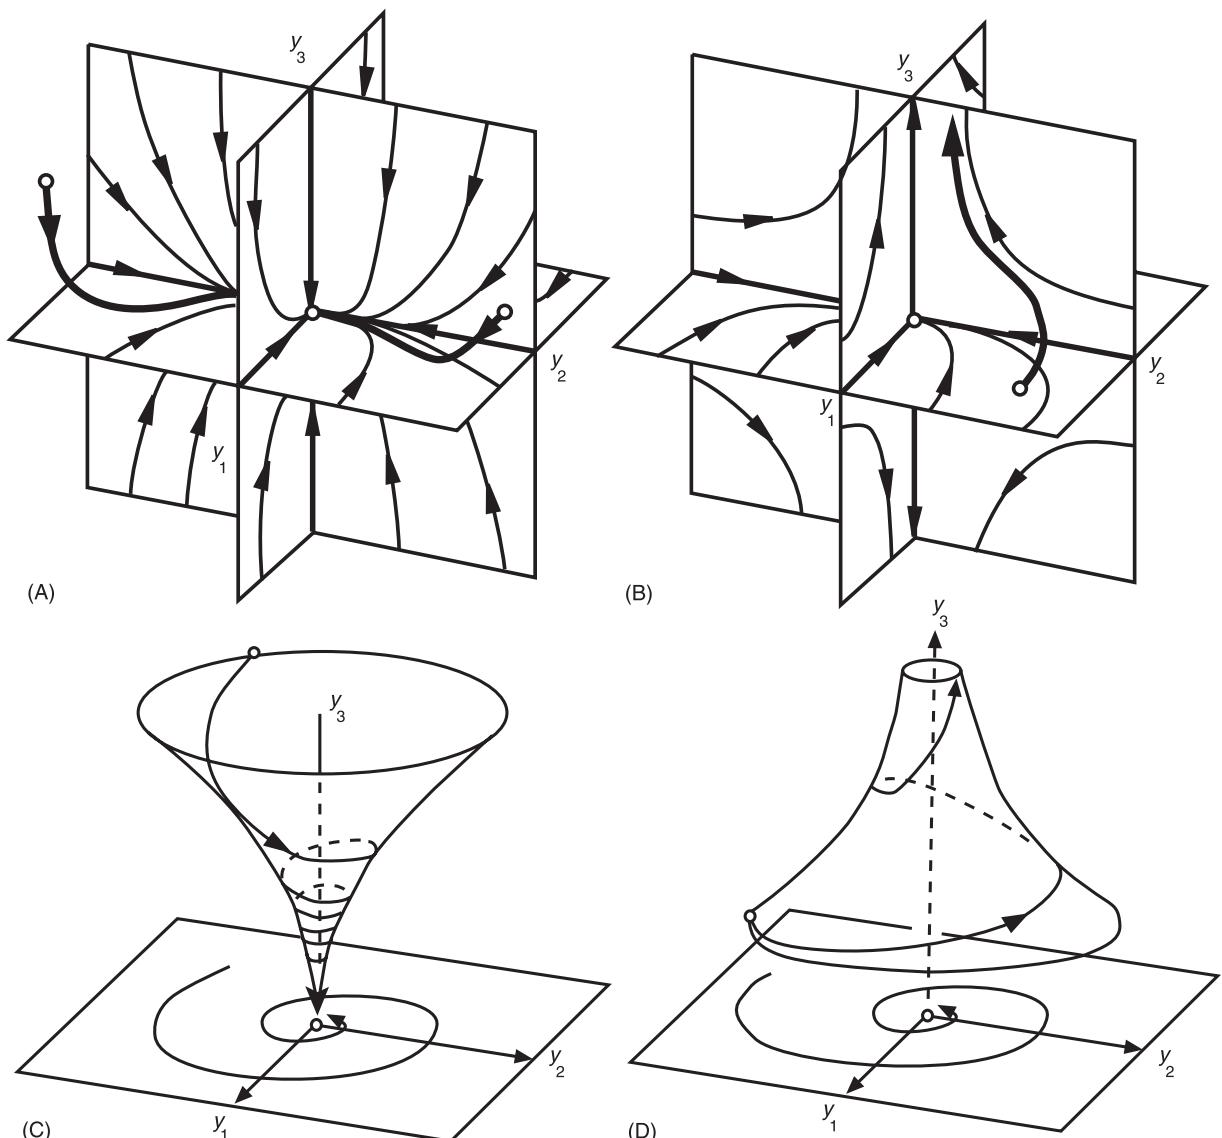

Figure 2 Examples of various types of equilibria in three-dimensional systems: (A) stable node: all eigenvalues are real and negative; (B) unstable saddle node: all eigenvalues are real, one is positive and the other two are negative; (C) stable focus: one eigenvalue is real and the other two are a complex pair, all being with negative real parts; (D) unstable saddle focus: one real positive eigenvalue and a complex pair with negative real parts.

totically approaches the equilibrium point as $t \rightarrow \infty$. Similarly, the unstable manifold of an equilibrium (denoted as W^U) is the set of all initial conditions such that solutions initiated at these points asymptotically approach the equilibrium as $t \rightarrow -\infty$. Linear eigenspaces are trivial examples of invariant manifolds for the linear system.

With these definitions in place, one can state the important stable manifold theorem: suppose that the equilibrium point $y = 0$ of [2] is a hyperbolic point and E^S and E^U are the stable and unstable manifolds of the linear system [3]. Then, there exist

local stable and unstable manifolds $W_{loc}^S(0)$ and $W_{loc}^U(0)$ of the same dimension as E^S and E^U respectively (Figure 3). These manifolds are (respectively) tangent to E^S and E^U at the origin and are as smooth as the original function $g(y, \dot{y})$. This result provides, in the case of hyperbolic equilibrium points, a close relationship between the phase portraits of the linearized system and the original nonlinear system near the equilibrium point. The difference arises when there are eigenvalues with zero real parts, and the center eigenspace E^C comes into picture. This is treated in the section on geometric theory and bifurcation analysis.

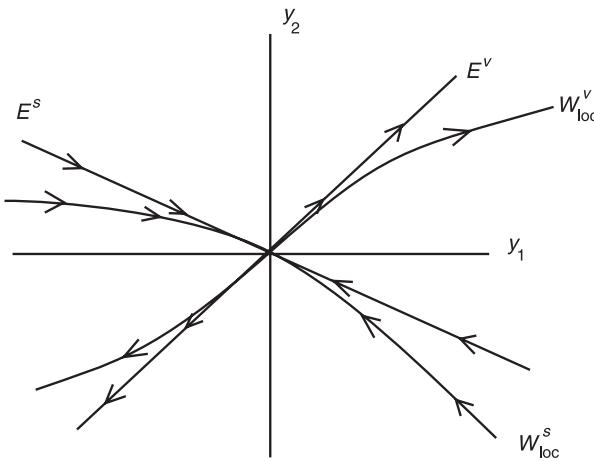

Figure 3 Local stable and unstable manifolds and linear eigenspaces near the origin.

When the eigenbasis for the linear system [3] is used to represent the nonlinear system [2], the nonlinear system takes the form:

$$\begin{aligned}\dot{u}_s &= B_s u_s + h_s(u_s, u_c, u_u) \\ \dot{u}_c &= B_c u_c + h_c(u_s, u_c, u_u) \\ \dot{u}_u &= B_u u_u + h_u(u_s, u_c, u_u)\end{aligned}\quad [6]$$

Though linearly uncoupled, the coordinates in these equations are coupled in the nonlinear terms. Also, note that $(u_s, u_c, u_u) = (0, 0, 0)$ is an equilibrium solution. Then, the stable manifold theorem guarantees the existence of local stable and unstable invariant manifolds when $n_c = 0$, that is, when there are no center coordinates. If $u_u = H_u(u_s)$ defines the graph of the local stable manifold, it must satisfy $H_u(0) = 0, DH_u(0) = 0$, that is, the graph must pass through the equilibrium point and must be tangent to the stable eigenspace E^s . Similarly, if $u_s = H_s(u_u)$ defines the graph of the local unstable manifold, it must satisfy $H_s(0) = 0, DH_s(0) = 0$, that is, it also must pass through the equilibrium point and must be tangent to the unstable eigenspace E^u . Using the fact that $u_u = H_u(u_s)$ is an invariant for the solutions of system [6], one can easily show that the function $u_u = H_u(u_s)$ must satisfy the quasilinear partial differential equation:

$$\begin{aligned}DH_u(u_s)[B_s u_s + h_s(u_s, H_u(u_s))] \\ = B_u H_u(u_s) + h_u(u_s, H_u(u_s))\end{aligned}\quad [7]$$

In addition, the function $u_u = H_u(u_s)$ must satisfy the conditions specified at the origin. This is called the

manifold condition. A similar equation must be satisfied by the graph of the unstable manifold $u_s = H_s(u_u)$. These equations can be used to construct approximations to the stable and unstable invariant manifolds.

Remarks

1. The most familiar examples of invariant manifolds are the normal modes of vibration for a linear undamped vibratory system. These characterize the free vibration response and provide a linear decomposition of the configuration space into invariant subspaces. When a system is given initial conditions consistent with a normal mode, the response of the system is a harmonic motion with the corresponding natural frequency characterizing the temporal component of the solution. In a normal mode, all components of the system vibrate in unison with a fixed-amplitude relationship among them.
2. There also exist counterparts to normal modes for nonlinear vibratory systems. The concept of a nonlinear normal mode was initially defined for conservative systems completely characterized by a potential function. Two types of nonlinear normal modes are known to exist. Similar nonlinear normal modes are modes in which the various generalized coordinates of the system vibrate with a fixed (constant) relationship among them. Nonsimilar nonlinear normal modes are the modes in which the various generalized coordinates maintain a fixed relationship on a configuration manifold.
3. Motivated by the geometric viewpoint described above, the concept of a nonlinear normal mode has also been extended to general nonlinear vibratory systems. Furthermore, techniques based on the manifold conditions have been developed to find their approximations.
4. For dynamic systems with periodic excitation, the equations of motions are of the form $\dot{x} = f(x, t, p)$, where f is 2π -periodic in t . Let there exist a 2π -periodic solution $\hat{x}(t, p)$, $\hat{x}(t + 2\pi, p) = \hat{x}(t, p)$. Then, the variational system around this solution can be written as $\dot{y} = \mathbf{A}(t, p)y + g(y, t, p)$, where the matrix $\mathbf{A}(t, p)$ and the function $g(y, t, p)$ are 2π -periodic in t . The origin $y = 0$ is now an equilibrium solution and its stability can be studied by using the nonlinear variational equation, or the linearized system $\dot{z} = \mathbf{A}(t, p)z$. The stability of the linearized system is determined by the characteristic or Floquet multipliers. Then, there is a close parallel between the concepts of stability, eigen-

spaces, and invariant manifolds for the constant coefficient systems and those for the time-periodic systems.

5. The first-order models of the type of eqn [1] arise in many nonlinear structural vibratory systems with finite degrees of freedom. They also arise as reduced-order models, obtained by an assumed-mode or Galerkin projection, for continuous structural systems having infinite-dimensional phase space. Examples include beams and columns with axial as well as thermal loads, arches with transverse loads, axially loaded plate and shell structures, wind and fluid-loaded transmission lines (cables), rotating shafts and disks, and tubes in axial or cross-flow in heat exchangers. The physical parameters of interest then turn out to be the axial and transverse loads or the fluid flow rates. So long as these parameters are constant, the models are autonomous, and one can discuss the stability of equilibrium configurations. When the parameters in the system are such that an equilibrium loses stability, phenomena like buckling and flutter arise, and local bifurcation theory, discussed later, can be used to understand the behavior of the structure close to criticality.

Perturbation and Asymptotic Techniques

There are many perturbation and asymptotic techniques available in the literature, the most prominent of them being the method of Poincaré–Lindstedt, the method of averaging, and the method of multiple time scales. Each of these techniques has associated theoretical underpinnings, and many variants on practical implementation. In this article, only the first two techniques are discussed.

Method of Poincaré

Consider the dynamic system:

$$\dot{x} = f(t, x, \varepsilon) \quad [8]$$

where f is 2π -periodic in t , ε is a small parameter, $0 \leq \varepsilon \ll 1$, and f is smooth as a function of its arguments. Let $\phi(t, \xi, t_0, \varepsilon)$ define a solution of eqn [8] with initial condition ξ , that is $\phi(t_0, \xi, t_0, \varepsilon) = \xi$. Then, a necessary and sufficient condition for $\phi(t, \xi, t_0, \varepsilon)$ to be a 2π -periodic solution is that:

$$\phi(t_0 + 2\pi, \xi, t_0, \varepsilon) = \xi \quad [9]$$

The method of Poincaré for finding 2π -periodic solutions is centered around the expression [9], and the simplest analytical result can be stated in the following form.

Let $\phi(t, \xi, t_0, \varepsilon)$ with $\phi(t_0, \xi, t_0, \varepsilon) = \xi$ be a solution of eqn [8], and let $\phi(t, \xi_0, t_0, 0)$ be a 2π -periodic solution of the reduced equation $\dot{x} = f(t, x, 0)$. Let the variational equation:

$$\dot{y} = \frac{\partial f}{\partial x}(t, \phi(t, \xi_0, t_0, 0), 0)y \quad [10]$$

corresponding to the solution $\phi(t, \xi_0, t_0, 0)$ have no characteristic multiplier $+1$. Then, there exist a constant ε^* , a function $\xi = \hat{\xi}(\varepsilon)$ with $0 \leq \varepsilon \leq \varepsilon^*$ and $\xi_0 = \hat{\xi}(0)$ such that $\phi(t, \xi, t_0, \varepsilon)$ is a 2π -periodic solution for all ε , $0 \leq \varepsilon \leq \varepsilon^*$, and this solution is unique, that is, if $\xi_1 \neq \hat{\xi}(\varepsilon)$, then $\phi(t, \xi_1, t_0, \varepsilon)$ is not a 2π -periodic solution. Furthermore, if the function $f(t, x, \varepsilon)$ is analytic in ε , so is the solution $\phi(t, \xi, t_0, \varepsilon)$.

As an illustration, consider the weakly nonlinear oscillator:

$$\ddot{y} + \Omega^2 y = F(t) + \varepsilon f(t, y, \dot{y}, \varepsilon) \quad [11]$$

where $F(t)$ and $f(t, y, \dot{y}, \varepsilon)$ are 2π -periodic in t and f is analytic in ε . This system in vector form, with $y_1 = y$, $y_2 = \dot{y}$, is:

$$\begin{aligned} \dot{y}_1 &= y_2 \\ \dot{y}_2 &= -\Omega^2 y_1 + F(t) + \varepsilon f(t, y_1, y_2, \varepsilon) \end{aligned} \quad [12]$$

The associated reduced system, for $\varepsilon = 0$, is:

$$\begin{aligned} \dot{y}_1 &= y_2 \\ \dot{y}_2 &= -\Omega^2 y_1 + F(t) \end{aligned} \quad [13]$$

Clearly, if $\Omega^2 \neq k^2$, with k an integer, the reduced system has a unique 2π -periodic solution $\psi(t)$. In case the function $F(t)$ is expressed in Fourier series as:

$$F(t) = a_0 + \sum_{n=1}^{\infty} \{a_n \cos nt + b_n \sin nt\} \quad [14]$$

the solution of the reduced system [13] is:

$$\begin{aligned}\psi(t) &= \begin{Bmatrix} a_0/\Omega^2 \\ 0 \end{Bmatrix} + \sum_{n=1}^{\infty} \frac{1}{(\Omega^2 - n^2)} \\ &\times \left[\begin{Bmatrix} a_n \\ nb_n \end{Bmatrix} \cos nt + \begin{Bmatrix} b_n \\ -na_n \end{Bmatrix} \sin nt \right]\end{aligned}\quad [15]$$

Now, the variational equation for system [12], with $\varepsilon = 0$, is:

$$\dot{z}_1 = z_2, \quad \dot{z}_2 = -\Omega^2 z_1 \quad [16]$$

The principal matrix solution for system [16] is given by:

$$X(t, 0) = \begin{bmatrix} \cos \Omega t & \sin \Omega t / \Omega \\ -\Omega \sin \Omega t & \cos \Omega t \end{bmatrix} \quad [17]$$

The corresponding characteristic multipliers satisfy the characteristic equation $\det(X(2\pi 0) - \lambda I) = 0$, or $\lambda^2 - (2 \cos 2\pi\Omega)\lambda + 1 = 0$. None of the roots of this equation equals $+1$ so long as $2 \cos 2\pi\Omega \neq 2$, or $\Omega \neq k$, where k is an integer. This implies that so long as $\Omega \neq k$, the system (12) has a unique 2π -periodic solution $y = y(t, \varepsilon)$. Furthermore, this solution is analytic in ε . Thus, the solution can be expanded in a convergent power series:

$$y(t, \varepsilon) = \sum_{n=0}^{\infty} \varepsilon^n y_n(t) \quad [18]$$

where each function $y_n(t)$ is 2π -periodic in t . This series converges for each ε , $0 \leq \varepsilon \leq \varepsilon^*$, where ε^* is the radius of convergence.

Now, examine the case when the condition $\Omega \neq k$ is violated. Then, consider the system:

$$\ddot{y} + n^2 y = \varepsilon f(t, y, \dot{y}, \varepsilon) \quad [19]$$

where the function f is as defined above. The variational equation:

$$\ddot{z} + n^2 z = 0 \quad [20]$$

has 2π -periodic solutions. This implies that one of the corresponding characteristic multipliers is $+1$ and the

condition of the above result is violated. This difficulty can be circumvented by a reformulation of the problem as an integral equation. Let $\phi(t, \xi, \varepsilon)$ be the solution vector for the system expressed in first-order form. Then, using the impulse response function for system [19] with $\varepsilon = 0$, and treating the nonlinearity as a nonhomogeneous term, the solution for the vector form of the system can be written as:

$$\begin{aligned}\phi_1(t, \xi, \varepsilon) &= \xi_1 \cos nt + \xi_2 \sin nt \\ &+ \frac{\varepsilon}{n} \int_0^t f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \sin n(t-s) ds \\ \phi_2(t, \xi, \varepsilon) &= -n\xi_1 \sin nt + n\xi_2 \cos nt \\ &+ \varepsilon \int_0^t f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \cos n(t-s) ds\end{aligned}\quad [21]$$

Now, the periodicity condition for the existence of a 2π -periodic solution requires that:

$$\begin{aligned}F_1(\xi, \varepsilon) &\equiv \phi_1(2\pi, \xi, \varepsilon) - \xi_1 = 0 \\ F_2(\xi, \varepsilon) &\equiv \phi_2(2\pi, \xi, \varepsilon) - \xi_2 = 0\end{aligned}\quad [22]$$

Using eqn [21], the condition [22] gives:

$$\begin{aligned}F_1(\xi, \varepsilon) &= \xi_1 (\cos 2\pi n - 1) + \xi_2 \sin 2\pi n \\ &+ \frac{\varepsilon}{n} \int_0^{2\pi} f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \\ &\times \sin n(2\pi - s) ds = 0 \\ F_2(\xi, \varepsilon) &= -n\xi_1 \sin 2\pi n + n\xi_2 (\cos 2\pi n - 1) \\ &+ \varepsilon \int_0^{2\pi} f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \\ &\times \cos n(2\pi - s) ds = 0\end{aligned}\quad [23]$$

Note that the development so far has not depended on n being an integer. Suppose that n is not an integer. Also, note that $\xi_1 = \xi_2 = 0$, $\varepsilon = 0$, is a solution of eqn [23], and the Jacobian matrix:

$$\begin{bmatrix} \frac{\partial F_1}{\partial \xi_1} & \frac{\partial F_1}{\partial \xi_2} \\ \frac{\partial F_2}{\partial \xi_1} & \frac{\partial F_2}{\partial \xi_2} \end{bmatrix} \quad [24]$$

evaluated at the solution $\xi_1 = \xi_2 = 0$, $\varepsilon = 0$, is non-singular. Thus, the implicit function theorem implies that there exists an ε^* , $\varepsilon^* > 0$, and a function $\hat{\xi}(\varepsilon)$, $0 \leq \varepsilon \leq \varepsilon^*$, with $\hat{\xi}(0) = 0$, such that:

$$\begin{aligned} & \left\{ \begin{array}{l} \phi_1(t, \xi_0, 0) \\ \phi_2(t, \xi_0, 0) \end{array} \right\} \\ &= \left\{ \begin{array}{l} \xi_{10} \\ n\xi_{20} \end{array} \right\} \cos nt + \left\{ \begin{array}{l} \xi_{20} \\ -n\xi_{10} \end{array} \right\} \sin nt \equiv \left\{ \begin{array}{l} \phi_{10} \\ \phi_{20} \end{array} \right\} \end{aligned} \quad [28]$$

$$\begin{aligned} F_1\left(\hat{\xi}(\varepsilon), \varepsilon\right) &\equiv \phi_1\left(2\pi, \hat{\xi}(\varepsilon), \varepsilon\right) - \hat{\xi}_1(\varepsilon) = 0 \\ F_2\left(\hat{\xi}(\varepsilon), \varepsilon\right) &\equiv \phi_2\left(2\pi, \hat{\xi}(\varepsilon), \varepsilon\right) - \hat{\xi}_2(\varepsilon) = 0 \end{aligned} \quad [25]$$

The corresponding 2π -periodic solution of eqn [19] is given by $\phi(t, \hat{\xi}(\varepsilon), \varepsilon)$ such that $|\phi(t, \hat{\xi}(\varepsilon), \varepsilon)| \rightarrow 0$ as $\varepsilon \rightarrow 0$. This case is also called the nonresonant case.

The situation with n an integer is called the resonant case. Then, the first two terms on the right-hand side in eqn [23] vanish to give:

$$\begin{aligned} F_1(\xi, \varepsilon) &= \frac{\varepsilon}{n} \int_0^{2\pi} f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \sin ns \, ds = 0 \\ F_2(\xi, \varepsilon) &= -\varepsilon \int_0^{2\pi} f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \cos ns \, ds = 0 \end{aligned} \quad [26]$$

One can show that the implicit function theorem does not apply here and no conclusions can be made regarding the existence of a 2π -periodic solution.

The difficulty encountered can be overcome by defining new functions $G_i(\xi, \varepsilon) \equiv \varepsilon^{-1}F_i(\xi, \varepsilon)$, $i = 1, 2$. Then:

$$\begin{aligned} G_1(\xi, \varepsilon) &= \frac{1}{n} \int_0^{2\pi} f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \sin ns \, ds = 0 \\ G_2(\xi, \varepsilon) &= - \int_0^{2\pi} f(s, \phi_1(s, \xi, \varepsilon), \phi_2(s, \xi, \varepsilon), \varepsilon) \cos ns \, ds = 0 \end{aligned} \quad [27]$$

and the goal is to find functions $\hat{\xi}_1(\varepsilon)$ and $\hat{\xi}_2(\varepsilon)$ that satisfy eqn [27]. When $\varepsilon = 0$, the solution $\phi(t, \xi, \varepsilon)$ is given by:

where ξ_{10} , ξ_{20} are arbitrary. The corresponding eqn [27] reduces, for $\varepsilon = 0$, to:

$$\begin{aligned} G_1(\xi_0, 0) &= \frac{1}{n} \int_0^{2\pi} f(s, \phi_{10}, \phi_{20}, 0) \sin ns \, ds = 0 \\ G_2(\xi_0, 0) &= - \int_0^{2\pi} f(s, \phi_{10}, \phi_{20}, 0) \cos ns \, ds = 0 \end{aligned} \quad [29]$$

Given the form of solutions in [28], eqn [29] reduces to a system of nonlinear equations in the amplitudes ξ_{10} and ξ_{20} . Now, suppose that eqn [29] is satisfied by a vector ξ_0 , and the associated Jacobian matrix is nonsingular. Then, from the implicit function theorem, there exists a constant $\varepsilon^* > 0$, and a function $\xi = \hat{\xi}(\varepsilon)$ for $0 \leq \varepsilon \leq \varepsilon^*$ with $\hat{\xi}(0) = \xi_0$, such that $G_i(\hat{\xi}(\varepsilon), \varepsilon) = \varepsilon^{-1}F_i(\hat{\xi}(\varepsilon), \varepsilon) = 0$, $i = 1, 2$. Thus, in the resonant case, the system (19) has a 2π -periodic solution $\phi(t, \hat{\xi}(\varepsilon), \varepsilon)$. In the limit, as $\varepsilon \rightarrow 0$, the 2π -periodic solution is approximated by the solution given in eqn [28].

Remarks

1. In general, the method of Poincaré can be used to prove the existence of $(2\pi m/n)$ -periodic solutions to systems with 2π -periodic excitations, thus generating sub-, super-, and ultraharmonic responses. For systems with analytic nonlinearities, the solutions are analytic in the parameter ε . Thus, if one uses the power series expansion in eqn [18] as a representation of the solution, the terms in the solution can be obtained by successively solving an infinite set of linear nonhomogeneous equations. The fact that the series is uniformly convergent implies that, for a given $\varepsilon_0 \leq \varepsilon \leq \varepsilon^*$, the partial sum of a finite number of terms converges to the true solution as more and more terms are included. Before the advent of symbolic algebra techniques for digital computers, only a small number of terms in the series could be computed and, thus, the question of convergence of the series was not considered in most applications.

2. For a solution to be periodic, each term in the expansion [18] must be periodic. In the resonant case, when one uses the straightforward expansion, secular terms in the form of polynomials in time arise in the solution at each order of approximation. Poincaré–Lindstedt technique is one of the techniques used to remove this nonuniformity in the expansion. Thus, each successive term in the power series is obtained as a periodic function with bounded amplitude.
3. The analysis approach, described above for the nonautonomous case, can also be used to find limit cycle solutions in self-excited systems. In these systems, the period or frequency of oscillation is an additional unknown. The phase of the solution is, however, arbitrary and the process of finding limit cycles is modified by choosing one of the initial conditions to be zero. There also exist methods by which the range of small parameter ε for which the solution is convergent can be increased.
4. It is important to note that if many different periodic solutions are found to coexist for a system, the stability of each of the solutions has to be studied separately. This requires the use of linearized stability analysis using Floquet theory, as already discussed.

Method of Averaging

The method of averaging is concerned with dynamic systems of the form:

$$\dot{y} = \mathbf{A}y + \varepsilon g(y, t) + \varepsilon^2 h(y, t, \varepsilon), \quad y \in \mathbb{R}^n \quad [30]$$

where \mathbf{A} is a constant real matrix with pure imaginary eigenvalues, $g(y, t)$ and $h(y, t, \varepsilon)$ are sufficiently smooth in y and 2π -periodic functions of time, and ε is a small parameter. Using the solution $y = e^{\mathbf{A}t}z$ for the system with $\varepsilon = 0$ as a transformation, the system [30] is transformed to:

$$\begin{aligned} \dot{z} &= \varepsilon e^{-\mathbf{A}t}g(e^{\mathbf{A}t}z, t) + \varepsilon^2 e^{-\mathbf{A}t}h(e^{\mathbf{A}t}z, t, \varepsilon) \\ &\equiv \varepsilon \hat{g}(z, t) + \varepsilon^2 \hat{h}(z, t, \varepsilon), \quad z \in \mathbb{R}^n \end{aligned} \quad [31]$$

where $\hat{g}(z, t)$ and $\hat{h}(z, t, \varepsilon)$ are 2π -periodic functions of time. System [31] is called the system in standard form in the method of averaging.

The idea behind the method of averaging is to seek a near-identity transformation

$$z = u + \varepsilon w(u, t) \quad [32]$$

where $w(u, t)$ is some yet-to-be determined 2π -periodic function in time, such that the transformed

system in u is simpler in some sense than the system [31]. Now, let the function $\hat{g}(z, t)$ be decomposed into its mean and oscillating parts:

$$\begin{aligned} \hat{g}(z, t) &= \bar{\hat{g}}(z) + \tilde{\hat{g}}(z, t) \\ \bar{\hat{g}}(z) &= \frac{1}{2\pi} \int_0^{2\pi} \hat{g}(z, t) dt \\ \tilde{\hat{g}}(z, t) &= \hat{g}(z, t) - \frac{1}{2\pi} \int_0^{2\pi} \hat{g}(z, t) dt \end{aligned} \quad [33]$$

Then, it can be shown that with the transformation [32], the system [31] is transformed to:

$$\dot{u} = \varepsilon \left[\bar{\hat{g}}(u) + \tilde{\hat{g}}(u, t) - \frac{\partial w}{\partial t} \right] + \varepsilon^2 b_1(u, t, \varepsilon) \quad [34]$$

where:

$$\begin{aligned} b_1(u, t, \varepsilon) &\equiv D_u \bar{\hat{g}}(u)w + D_u \tilde{\hat{g}}(u, t)w + \hat{h}(u, t, 0) \\ &\quad - D_u w \bar{\hat{g}}(u) - D_u w \tilde{\hat{g}}(u, t) \\ &\quad + D_u w \frac{\partial w}{\partial t} + O(\varepsilon) \end{aligned}$$

Now, let $w(u, t)$ be the 2π -periodic function that solves $\partial w / \partial t = \tilde{\hat{g}}(u, t)$. Then, eqn [34] reduces to:

$$\dot{u} = \varepsilon \bar{\hat{g}}(u) + \varepsilon^2 b_1(u, t, \varepsilon) \quad [35]$$

This system [35] is completely equivalent to eqn [31] and, hence, to the system [30]. Dropping the second-order term in eqn [35], we get the averaged system for first-order averaging:

$$\dot{u} = \varepsilon \bar{\hat{g}}(u) \quad [36]$$

There are many types of theorems in averaging theory. They relate steady-state as well as transient solutions of the averaged system [36] to those of the original system [35]. Here, some of the basic results for steady-state solutions are reviewed:

1. Let the averaged system [36] have a hyperbolic equilibrium solution u_0 . Then, for each ε , $0 < \varepsilon < \varepsilon^*$, and some $0 < \varepsilon^* \ll 1$, there exists a 2π -periodic solution $\hat{u}(t, \varepsilon)$ of [35] that lies near u_0 and $\|\hat{u}(t, \varepsilon) - u_0\| \rightarrow 0$ as $\varepsilon \rightarrow 0$. The stability of the solution $\hat{u}(t, \varepsilon)$ is the same as that of the constant solution u_0 with respect to the averaged system [36].

2. Let the averaged system possess a limit cycle solution $u^*(\theta)$, where $u^*(\theta)$ is 2π -periodic in θ with $\theta \equiv \varepsilon \Omega t$ for some $\Omega > 0$. Then, if the limit cycle is hyperbolic, that is, all but one of the associated Floquet multipliers are away from the unit circle, for each ε , $0 < \varepsilon < \varepsilon^*$, and some $0 < \varepsilon^* \ll 1$, the solution of [35] is of the form $\hat{u}(\theta, t, \varepsilon)$. This solution lies on an integral manifold, which is a 2π -periodic surface in θ and 2π -periodic in t , lies close to the cylinder generated by the solution $u^*(\theta)$, and coincides with it as $\varepsilon \rightarrow 0$. The stability of the integral manifold is the same as that of the limit cycle for the averaged system.

As an illustration, consider the system:

$$\begin{aligned} z'' + z = \varepsilon [\cos \tau e_1 - \beta z'' - \alpha z' - 2|z|^2 z], \\ z \in \mathbb{R}^2, \quad e_1 = \begin{pmatrix} 1 & 0 \end{pmatrix}^T \end{aligned} \quad [37]$$

These equations represent a two-degree-of-freedom system whose two coordinates are coupled by cubic nonlinearities. The first oscillator (z_1 coordinate) is excited by a 2π -periodic excitation. Also, the two oscillators have identical linear natural frequencies equal to 1. The parameters α and β , respectively, represent the modal damping and the linear frequency mistuning for each of the oscillators.

Since eqn [37] represents a two-degree-of-freedom system, the existence of its 2π -periodic solutions can be addressed by generalizing the method of Poincaré (as presented above), or by using the method of averaging. If the method of Poincaré is followed, it can be shown that the result is the following set of nonlinear equations:

$$G_1(\xi, \varepsilon) = G_2(\xi, \varepsilon) = G_3(\xi, \varepsilon) = G_4(\xi, \varepsilon) = 0 \quad [38]$$

where $\xi \in \mathbb{R}^4$. In the limit of $\varepsilon \rightarrow 0$, eqn [38] can be reduced to the form:

$$\begin{aligned} G_1(\xi_0, 0) &= -\alpha\xi_{10} - (\beta - 1.5E)\xi_{20} + M\xi_{30} = 0 \\ G_2(\xi_0, 0) &= -\alpha\xi_{20} - (\beta - 1.5E)\xi_{10} + M\xi_{40} + 1 = 0 \\ G_3(\xi_0, 0) &= -\alpha\xi_{30} - (\beta - 1.5E)\xi_{40} - M\xi_{10} = 0 \\ G_4(\xi_0, 0) &= -\alpha\xi_{40} - (\beta - 1.5E)\xi_{30} - M\xi_{20} = 0 \end{aligned} \quad [39]$$

where $E = \xi_{10}^2 + \xi_{20}^2 + \xi_{30}^2 + \xi_{40}^2$ and $M = \xi_{10}\xi_{40} - \xi_{20}\xi_{30}$. Eqn [39] is a system of four simultaneous cubic equations in the constant vector $\xi_0 \in \mathbb{R}^4$, and depends on the parameters α and β . If a solution can be found for these equations and the associated 4×4

Jacobian matrix is nonsingular, the Poincaré theory guarantees the existence of a constant vector

$\hat{\xi}(\varepsilon) \in \mathbb{R}^4$ which is a solution of eqn [38]. There is then the corresponding 2π -periodic solution of the excited coupled oscillators in eqn [37] which, in the limit of $\varepsilon \rightarrow 0$, is given by:

$$\begin{aligned} \left\{ \begin{array}{l} \phi_1(\tau, \xi_0, 0) \\ \phi_2(\tau, \xi_0, 0) \\ \phi_3(\tau, \xi_0, 0) \\ \phi_4(\tau, \xi_0, 0) \end{array} \right\} &= \begin{Bmatrix} z_1 \\ z'_1 \\ z_2 \\ z'_2 \end{Bmatrix} = \begin{Bmatrix} \xi_{10} \\ \xi_{20} \\ 0 \\ 0 \end{Bmatrix} \cos \tau \\ &+ \begin{Bmatrix} \xi_{20} \\ -\xi_{10} \\ 0 \\ 0 \end{Bmatrix} \sin \tau + \begin{Bmatrix} 0 \\ 0 \\ \xi_{30} \\ \xi_{40} \end{Bmatrix} \cos \tau + \begin{Bmatrix} 0 \\ 0 \\ \xi_{40} \\ -\xi_{30} \end{Bmatrix} \sin \tau \end{aligned} \quad [40]$$

In general, since eqn [39] is nonlinear and depends on the parameters α and β , they may have more than one real solution for a given parameter set. This would then imply the existence of that many periodic solutions of the oscillators. Furthermore, the number of these solutions may change as the parameters are varied, and this would imply bifurcations in the dynamics of the system.

If the method of averaging is used to find approximate solutions of the coupled oscillators, interestingly, the averaged equations turn out to be:

$$\begin{aligned} \dot{\xi}_1 &= G_1(\xi, 0), \quad \dot{\xi}_2 = G_2(\xi, 0), \quad \dot{\xi}_3 = G_3(\xi, 0), \\ \dot{\xi}_4 &= G_4(\xi, 0) \end{aligned} \quad [41]$$

Then, constant solutions of [41] and their stability, determined by a linearized analysis, are related to the periodic solutions of the oscillators. Since these equations depend on the parameters α and β , bifurcations from the equilibrium solutions may arise in the form of additional equilibrium solutions. Furthermore, the nonlinear autonomous system [41] can also possess periodic solutions. Some of these periodic solutions may arise as a result of loss of stability of equilibria, and subsequent bifurcations. The periodic solutions of eqn [41] are related to the invariant manifold of solutions of the oscillators. In physical terms, these invariant manifolds really correspond to amplitude and phase-modulated oscillatory motions of the oscillators. Extensions of theorems in averaging, as well as the method of Poincaré can be used to determine explicitly the periodic solutions of the averaged equations.

The methods presented above have been used extensively to study the nonlinear vibratory response

of harmonically and parametrically excited multi-degree-of-freedom as well as continuous structural systems. The systems investigated have included resonant response of beams, columns, plates, and shells with different boundary conditions. Primary, subharmonic as well as superharmonic responses have been considered. It has been seen that complex amplitude and phase-modulated motions are possible for the structural systems when the excitation frequency satisfies some resonance condition with natural frequencies of more than one degree of freedom. Examples of such situations include internal and combination resonances. Limit cycle or periodic oscillations have also been studied for systems with self-excitation. A very familiar example of such a situation is panel flutter.

Dimension Reduction and Local Bifurcations

To understand the behavior of solutions in the vicinity of an equilibrium point, one needs to study the variational system and its linearization, as discussed in the section on Equilibria and stability, above. When an equilibrium is nonhyperbolic, the behavior in its vicinity is essentially determined by the nonlinear terms. To understand this, consider the system:

$$\dot{u}_s = B_s u_s + h_s(u_s, u_c) \quad \dot{u}_c = B_c u_c + h_c(u_s, u_c) \quad [42]$$

that has n_s stable eigenvalues and n_c eigenvalues with zero real parts. Then, in the vicinity of the equilibrium point, the behavior can be studied by a reduced dimensional system with dimension n_c . This result is a consequence of the center manifold theorem.

An invariant manifold of the system (42) is called a center manifold if it can locally be represented as:

$$\begin{aligned} W^c(0) &= \left\{ (u_s, u_c) \mid u_s = H(u_c), \|u_c\| < \delta, H(0) \right. \\ &\quad \left. = 0, DH(0) = 0 \right\} \end{aligned} \quad [43]$$

for δ sufficiently small. The conditions on $H(u_c)$ at $u_c = 0$ imply that the manifold is tangent to the center eigenspace E^C at the equilibrium point.

Center Manifold Theory

There are three important results in the theory.

1. The first result states that there exists a center manifold for the system [42]. The dynamics of the

system on the center manifold is, for sufficiently small v , given by the n_c -dimensional system:

$$\dot{v} = B_c v + h_c(H(v), v), \quad v \in \mathbb{R}^{n_c} \quad [44]$$

2. The second result states that the stability characteristics of the zero solution $(u_s, u_c) = (0, 0)$ of the system [42] are the same as those of the zero solution $v = 0$ for the system [44]. In addition, if the zero solution of [44] is stable, the solutions of [42] and [44] for small initial conditions are related, as $t \rightarrow \infty$, by:

$$\begin{aligned} u_s(t) &= H(v(t)) + O(e^{-\gamma t}) \\ u_c(t) &= v(t) + O(e^{-\gamma t}) \end{aligned} \quad [45]$$

3. The graph of the center manifold $u_s = H(u_c)$ is defined by the manifold condition:

$$\begin{aligned} DH(u_c)[B_c u_c + h_c(H(u_c), u_c)] \\ - B_s H(u_c) - h_s(H(u_c), u_c) = 0 \end{aligned} \quad [46]$$

The solution of this equation can be obtained up to any desired accuracy as an expansion in u_c .

When the system depends on parameters, the center manifold for the parameter-dependent system can be computed using the suspension trick where the parameters are also made state variables. Having reduced the dimension of the dynamic system to the essential minimum, further simplifications in eqn [44] can be achieved by the normal form theory.

Normal Form Theory

This generalizes the theory of normal forms for linear systems to nonlinear systems near equilibrium, and other steady-state solutions. In the case of linear systems, it is well known that there exists a linear transformation that reduces the system matrix to the Jordan canonical form (the normal form). It is the simplest form of the system matrix. The method of normal form provides a way of finding a coordinate system in which the nonlinear terms also take the simplest form. The method is local in that the form is valid in the neighborhood of a steady-state solution. Even though the transformation is nonlinear, the method relies on solving a sequence of linear problems in the appropriately defined space of polynomials.

The starting point is the nonlinear system on the center manifold (eqns [44]). Let the matrix B_c be in its simplest form and let the system be written as:

$$\begin{aligned}\dot{v} &= \mathbf{B}_c v + F(v) = \mathbf{B}_c v + F_2(v) + F_3(v) + F_4(v) \\ &\quad + \dots F_{r-1}(v) + O(\|v\|^r), \quad v \in \mathbb{R}^n\end{aligned}\quad [47]$$

where $F_i(v)$ represents the order i terms in the Taylor series expansion of $F(v)$. Now, consider the coordinate transformation:

$$v = x + X_2(x) \quad [48]$$

where $X_2(x)$ is second-order in x , and is unspecified at this stage. Substituting the near-identity transformation (48) into eqn [47] and simplifying gives:

$$\begin{aligned}\dot{x} &= \mathbf{B}_c x + \mathbf{B}_c X_2(x) - D X_2(x) \mathbf{B}_c x + F_2(x) \\ &\quad + \tilde{F}_3(x) + \dots \tilde{F}_{r-1}(x) + O(\|x\|^r)\end{aligned}\quad [49]$$

Note here that the original nonlinear terms of order higher than two have been modified. In terms of order two, additional terms due to the nonlinear coordinate transformation $X_2(x)$ have appeared. Since the linear term is already the simplest, one can try to choose the function $X_2(x)$ such that the second-order terms are also the simplest possible. Thus, one needs to find solution $X_2(x)$ of the equation:

$$L_{\mathbf{B}_c}(X_2(x)) \equiv D X_2(x) \mathbf{B}_c x - \mathbf{B}_c X_2(x) = F_2(x) \quad [50]$$

This is a linear equation with proper interpretation in the space of vector-valued monomials of degree 2. If this space is denoted by H_2 , $L_{\mathbf{B}_c}(\cdot) \equiv D X_2(x) \mathbf{B}_c x - \mathbf{B}_c X_2(x)$ is a mapping from H_2 to H_2 , and H_2 can be decomposed as a direct sum $H_2 = L_{\mathbf{B}_c}(H_2) \oplus G_2$ where G_2 is space complementary to $L_{\mathbf{B}_c}(H_2)$. From standard linear algebra, if $F_2(x)$ is in the range of $L_{\mathbf{B}_c}(\cdot)$, eqn [50] can be solved uniquely for $X_2(x)$ for every given $F_2(x)$. Then, all terms of second order are eliminated from eqn [48] and one can go on to eliminating third-order terms. Thus, the only terms that cannot be eliminated are those in the complement G_2 . Interestingly, the linear operator $L_{\mathbf{B}_c}(\cdot)$ is essentially determined by the matrix \mathbf{B}_c . Thus, the nonlinear terms that cannot be removed are determined by the eigenvalues of the linearized approximation. Let $F_2^r(x) \in G_2$ be the terms that cannot be eliminated. Then, eqn [47] simplifies to:

$$\dot{x} = \mathbf{B}_c x + F_2^r(x) + \tilde{F}_3(x) + \dots \tilde{F}_{r-1}(x) + O(\|x\|^r) \quad [51]$$

This process can be continued until terms up to the desired order are simplified. Note that, as with the center manifold theory, normal form theory can also be modified to be applicable to systems with parameters.

Local Bifurcations

The simplest critical case of stability for an equilibrium point (when linearized analysis is not sufficient) arises when $n_c = 1$, that is, when an equilibrium point of a system dependent on a parameter loses stability with one eigenvalue leaving the left half of the complex plane. At the critical parameter value, the center eigenspace is one-dimensional, and a center manifold reduction results in a scalar nonlinear equation dependent on the parameter. Similarly, if the linearized system has a pure imaginary pair of eigenvalues at the critical parameter value, the center manifold is two-dimensional. Having reduced the system to the center manifold, normal form theory can be used to simplify the nonlinear terms. These simplified equations can then be used to investigate the solutions as a function of the system parameters.

The normal form equations in the various low-dimensional cases for systems with one and two parameters, and the bifurcation diagrams associated with steady-state solutions are summarized here.

Single zero eigenvalue

1. The system on the center manifold simplifies to:

$$\dot{x} = \mathbf{B}_c(p)x + F(x, p) = cpx - ax^2 + O(|x|^3, |p^2x|) \quad [52]$$

Here c and a are model constants, and p is the variation of the parameter from its critical value. The steady-state solutions of eqn [52] are depicted in Figure 4A, called a bifurcation diagram. In this specific case, the bifurcation is called a transcritical bifurcation. Note that there is an exchange in stability at the critical parameter value.

2. Suppose that the simplest system, on the center manifold, is of the form:

$$\dot{x} = \mathbf{B}_c(p)x + F(x, p) = cpx - ax^3 + O(|x|^4, |p^2x|) \quad [53]$$

The corresponding steady-state solutions up to this order are shown in the bifurcation diagram (Figure 4B). This type of bifurcation is called a pitchfork bifurcation.

3. Let the system on the center manifold be defined by:

$$\dot{x} = \mathbf{B}_c(p)x + F(x, p) = cp - ax^2 + O(|x|^3, |p|^2) \quad [54]$$

The associated bifurcation diagram is shown in Figure 4C. This type of bifurcation is called a saddle node bifurcation.

Pure imaginary pair of eigenvalues In this case, the center manifold is two-dimensional. The system on the center manifold can be simplified using the normal form theory for systems with parameters. The final system in normal form is given by:

$$\begin{aligned} \dot{x}_1 &= \alpha(p)x_1 - \omega(p)x_2 \\ &\quad + \left\{ a(p)x_1 - b(p)x_2 \right\}(x_1^2 + x_2^2) + O(|x_1|^5, |x_2|^5) \\ \dot{x}_2 &= \omega(p)x_1 + \alpha(p)x_2 \\ &\quad + \left\{ b(p)x_1 + a(p)x_2 \right\}(x_1^2 + x_2^2) + O(|x_1|^5, |x_2|^5) \end{aligned} \quad [55]$$

Here, $\alpha(0) = 0$, $(d\alpha/dp)(0) > 0$ and $\omega(0) \neq 0$. Also, let $a(0) \neq 0$. This implies that, at $p = 0$, the linear system is critical and the imaginary part of the critical eigenvalues is $\omega(0)$. The steady-state solutions of this system, near $(0,0)$, can be obtained using any of the methods for finding periodic solutions. These include the method of Poincaré and the method of averaging, already discussed in this article. In polar coordinates, with $x_1 = r \cos \theta$, $x_2 = r \sin \theta$, eqn [55] takes the form:

$$\begin{aligned} \dot{r} &= \alpha'(0)pr + a(0)r^3 + O(p^2r, pr^3, r^5) \\ \dot{\theta} &= \omega(0) + \omega'(0)p + b(0)r^2 + O(p^2, pr^2, r^4) \end{aligned} \quad [56]$$

The final result is the Hopf bifurcation theorem which states that there exists a periodic orbit with approximate amplitude $r = \sqrt{-p\alpha'(0)/\alpha(0)}$, and frequency

$$\Omega = \omega(0) + \left\{ \omega'(0) - \frac{b(0)\alpha'(0)}{a(0)} \right\} p$$

The periodic solution is supercritical (exists for $p > 0$) and asymptotically stable for $a(0) < 0$. It is unstable for $a(0) > 0$. These results are depicted in Figure 5.

Note that the above result regarding the existence of a bifurcating limit cycle can also be obtained using

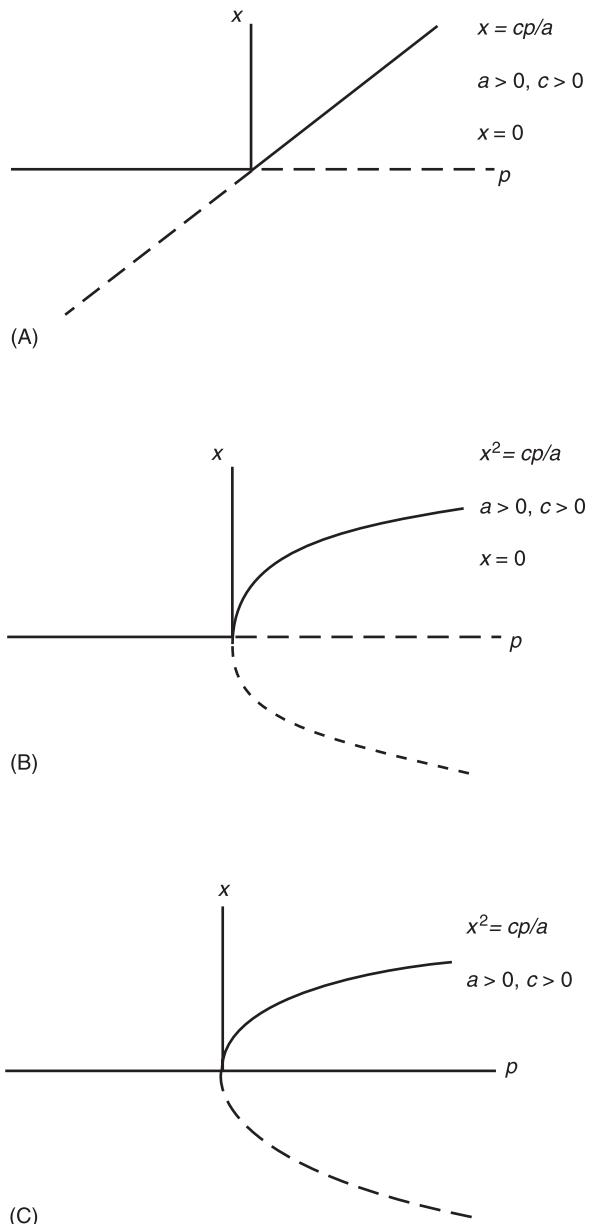

Figure 4 Local bifurcations in one-parameter systems for one zero eigenvalue; (A) transcritical bifurcation; (B) pitchfork bifurcation; (C) saddle node bifurcation.

the other methods discussed. While the method of Poincaré gives the existence of a periodic solution, its stability has to be determined separately using the Floquet theory. The method of averaging, like the method of Poincaré requires the explicit introduction of a small parameter. It does, however, relate the stability of the limit cycle to the stability of the corresponding equilibrium point of the averaged equations. This makes it easier to get the complete picture, though the method is cumbersome when higher-order terms are required in the analysis. The results obtained via the use of the normal form theory

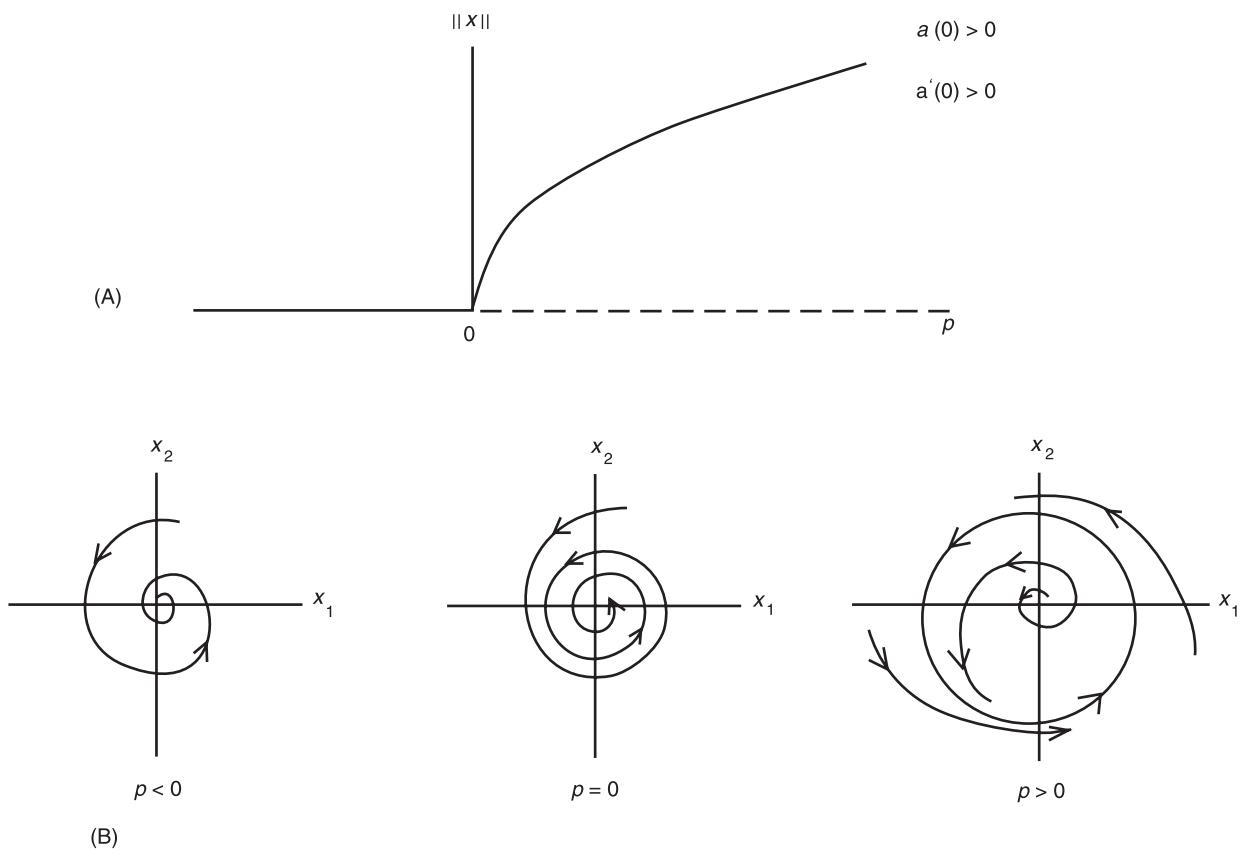

Figure 5 Hopf bifurcation to limit cycle oscillations in one-parameter system: (A) bifurcation diagram for the supercritical case; (B) phase plane for various parameter values.

do not require the explicit introduction of a small parameter, and the process is the most straightforward when even as well as odd terms are present in the original differential equations.

The results presented above are just the simplest of those available in the literature. The reader can find extensive treatments on analysis techniques and the predicted results in the literature.

Introduction

The finite element (FE) method is currently used as an extremely valuable tool of analysis in many fields of engineering and science. Since 1960, several research teams have developed analysis software based on this method, software which has continuously grown over the years leading to powerful packages that are in use today in industry and research. However, computers and software technology have changed a lot since the days when these programs were conceived, and today provide new techniques for managing information. Also, new faster computers open the way for the solution to more complex problems, requiring in turn modern information-handling techniques. Consequently, developers are experiencing increasing difficulty, with very high costs of maintenance in keeping their software up to date. Yet, they are facing a growing demand for user-friendliness in the form of graphics, menus, and boxes.

New software technologies try to remedy the deficiencies encountered with conventional programming. In particular, 'object-oriented programming' (OOP) is currently seen as the most promising way of devising a new application.

Software Design Considerations

Research in FE software design is the result of two main observations. The first concerns the growing needs of modeling complex interaction phenomena between different physical fields. The second con-

cerns the evolution of new computer technology which invites developers to reconsider the design of their current tools of analysis, for example, by using new language features or by proposing adapted algorithms to distribute tasks between computers connected in parallel.

The last two decades have been marked by growing computer power, allowing us to consider modeling more and more complex phenomena. Both from the point of view of model size and of the interaction between different models, management of information is always more complicated and has become a crucial issue. Achieving a correct implementation is at least as important as developing a sound basis for the formulation of the method.

Objectives

Scientific applications have usually been associated with intensive arithmetic computing and small volume of data management. However, current FE programming in a user-friendly environment requires large volumes of a variety of data:

1. to and from memory (between different zones of the program)
2. to other process or computers
3. to secondary storage (results, DB)
4. to graphic devices (display of results)

Experience with existing programs shows that large parts of the program are spent on data handling with a small amount of arithmetic (input and preprocessing, output, intermediate processing, even computation of finite element matrices), while only a small part of the program is dedicated to intensive arithmetic (algebraic linear systems solver).

Quality

Quality standards in industrial codes can be specified as follows:

- Accuracy: does the code give correct answers to correct specifications?
- Robustness: how does the code react to different conditions from those specified?
- Portability: can the code be easily implemented on different computers?
- Efficiency: is it efficient from the point of view of CPU time consumption, main and secondary storage demands, I/Os, etc.?
- Extensibility: can the code be adapted simply to follow an evolution of specifications?
- Reusability: is it possible to use parts of the code (modules) to solve a different problem?

Accuracy and robustness in a 10-year project is not so easy to assume as in a 100-line program. Besides accuracy, efficiency and extensibility priorities must also be considered as the main criteria for code design. Whenever these two features coexist, the numerical efficiency aspect must be considered first in the context of dynamics analysis. Maintainability and portability are also important issues that have to be considered.

Human Aspects

Numerous people are generally involved in the development of a large FE software. They can be grouped as follows, from the point of view of their interests and skills:

1. The final users of the code, who are interested in getting an answer to the physical problem in hand;
2. The numerical analysts, who propose new finite element methods and algorithms;
3. The programmers, seen as users of classes and methods implemented by other programmers;
4. The programmers of new classes and methods to be used by people of the previous group.

A single person may belong to more than one group. In fact, the group to which a person belongs is often determined by the task being performed at a given moment. All the groups must be taken into consideration from the very beginning of the design of a new FE program. The main concerns about software quality differ for each task, and may be described as in Table 1.

Object-Oriented Programming

Object-oriented methods have existed since 1960, but structured and procedural programming methods imposed themselves as being more adapted to the architecture of the new computer tool (see Figure 1). This was a first evolution despite the linear chaotic way of using computer technology. Today there is a

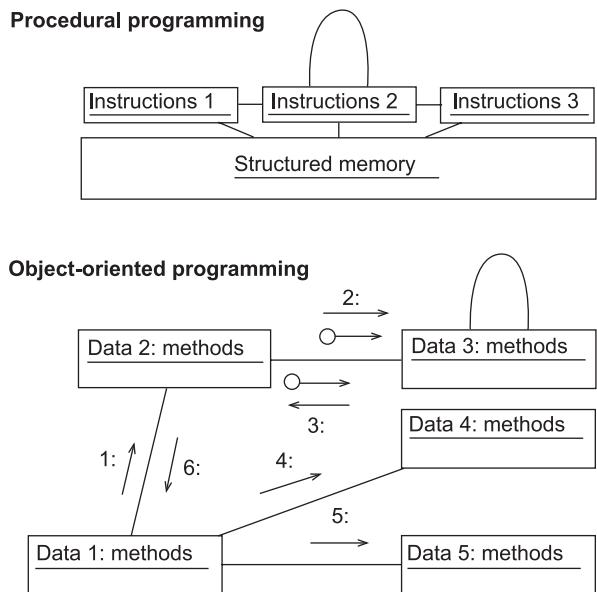

Figure 1 Procedural versus object-oriented (interaction diagram).

tendency to invert this trend and to design software independently from the architecture of the hardware. This announces the age of maturity of the computer which is (finally) in sympathy with the human way of thinking (Table 2).

A New Philosophy

The object-oriented philosophy comes from the idea that tools (methods) must be associated with the information (data) they manage. In order to do that, some new concepts have been introduced.

Classes A class defines an abstract data type. It may represent, for example, a family of objects in the real world. Classes are identified during the analysis phase of application development. A class incorporates the definition of the structure as well as the operations on the abstract data type. For example, Element would be defined as a class in a finite element method application. Typically, data that the system analyst would define relating to the class Element may include such items as localization, connected nodes, number of degrees-of-freedom, etc. Elements belonging to the collection of objects described by the class are called ‘instances’ of the class.

Subclasses and inheritance A subclass is subordinated to a class and has all the same elements of the class which it has inherited. Therefore, the term ‘inheritance’ indicates an ‘is a ...’ relationship between two classes. A subclass is usually of a special type and has additional data elements relating to it. For example, an Isoparametric_Element is an Element for which both positions and displacements are interpolated from nodal values.

Encapsulation In an object-oriented application, all data, functions, and services offered by a class (or subclass) are packaged together. This (independent) self-containment of classes and their functions and services (i.e., members) is called ‘encapsulation’. This full modularity both greatly enhances the introduction of changes during the development phase as well as the performance of ongoing maintenance. In addition, as we will see below, encapsulation makes possible the unique ‘polymorphic’ capability of object-oriented applications.

Polymorphism A given function or service may be made to respond differently when performed on objects from different classes. For example, a single request to fill_stiffness will automatically be computed differently for a bar than for a quad4 element. This is due to the fact that different calculation methods are encapsulated within subclasses bar and quad4. This unique capability of object-oriented applications to interpret the same request differently depending on the object being processed is known as polymorphism. Some languages allow polymorphism

capability to be implemented either at compilation time or at running time (dynamically).

The two latter concepts may be used to get a complete data abstraction, implying for example that we can ask the elementary stiffness to a list of Element objects without knowing exactly what element types form each item in the list.

Analysis and Methodology

An essential factor of success in a large project is the employment of powerful analysis tools. As the complexity of systems increases, the analysis becomes even more important. Object-oriented philosophy has brought new techniques in modeling and analysis first proposed in 1991 by P. Coad and E. Yourdon (OOD) or J. Rumbaugh (OMT), then G. Booch in 1994 or with OOSE (object oriented systems engineering, Oden University). These analysis methodologies were proposed to help in the design of the architecture of an object-oriented project. Today, there is a tendency to use unified modeling language (UML) for modeling applications which fuses the concept of previously mentioned ones into a standardized modeling language, and design patterns (proposed by E. Gamma) to follow standard patterns for developing object-oriented abstractions. In design patterns, the idea is to use solutions that have been developed and evolved over time, and capture them in a succinct and easily applied form. They are broadly categorized into patterns for creational, structural, and behavioral purposes on classes or objects.

The models contain diagrams which provide a means of visualizing and manipulating the models’ components and their properties. Diagrams are used to illustrate multiple views of a model and the components they represent. Several kinds of diagram can be used:

- The description of logical package uses ‘class’, ‘object’, and ‘interaction diagrams’.
- The description of component package uses ‘component diagrams’.
- The description of classes may use ‘state diagrams’.
- The model uses the diagrams for its top-level components, its ‘deployment diagram’, and the diagrams contained by its logical packages and component packages. These top-level components can be classes, modules, processors, devices, and connections.

A class diagram This is a picture providing generic descriptions of possible systems. Class diagrams and object diagrams are alternate representations of object models. These representations show the typical distinction between data (◊) and methods (◊), and

their attributes; public, private, protected or used for internal implementation (◆◆◆◆◆). Figure 2 shows an example of an implementation model for classes involved in the assembling process of the FE matrices. The class dynamic analysis contains matrix objects M, K, eigenmodes, a vect of eigenvalues and two methods for assembling and solving the analysis. It uses a localization manager and numerical grid(s). Matrix objects are virtual, i.e., they are independent of any storage scheme, full matrix, sparse, skyline, or even frontal matrix. The virtual matrix ‘mother’ class constrains its children to implement solve and product methods and imposes a unique interface.

A state transition diagram This is used to show the state space of a given class, the event that causes a transition from one state to another, and the actions that result from a state change. Each state diagram is usually associated with one class of objects. A frequent state mechanism is implemented on matrices to manage behavior, depending on whether it is factorized or not. Another example concerns the instruction phase state of a problem (domain). It can be distinguished from its computational state, and this requires a list of degrees-of-freedom. This is represented in Figure 3.

Sequence diagrams and collaboration diagrams Sequence diagrams and collaboration diagrams are alternative representations of an interaction. A sequence diagram traces the execution of an interaction in time. For the FE method, one could model the elementary assembling sequence as shown in Figure 4. The object that has been asked to build the generalized global system will first perform equation ordering using a bandwidth optimization scheme. Then, it will ask the numerical grid object to loop over each element object to get its global localization, elementary matrices, and vectors and add its values to the global system. Then it will call a solver corresponding to the case under study. If a solver is called for time-dependent problems, one can see a similar sequence differing only by an update message sent to elements.

A deployment diagram This shows processors, devices, and connections. Each model contains a single deployment diagram which shows the connections between its processors and devices, and the allocation of its processes to processors. An example of a module which could have the ability to distribute tasks on several CPUs through a graphic workstation may have a deployment diagram as shown in Figure 5. The master process is controlled by mouse and

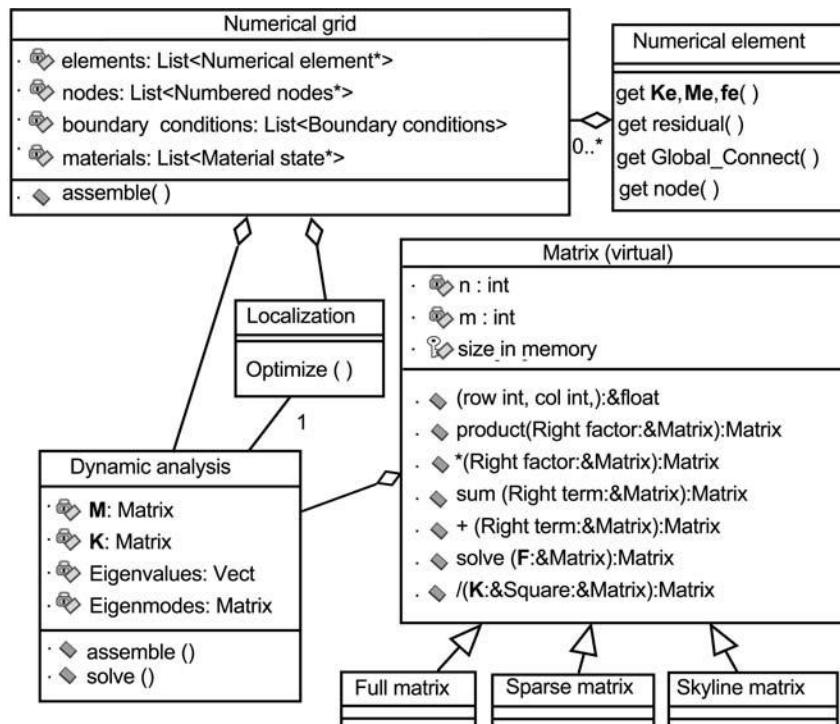

Figure 2 Class diagram for assembling process.

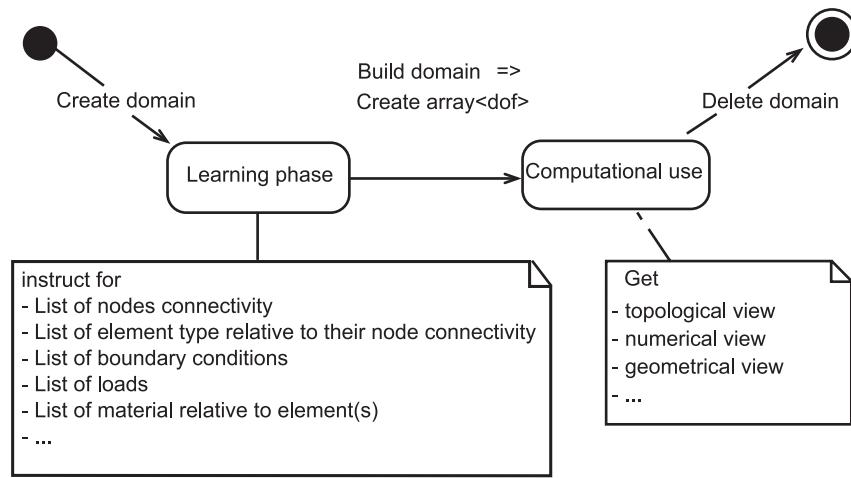

Figure 3 Domain state diagram.

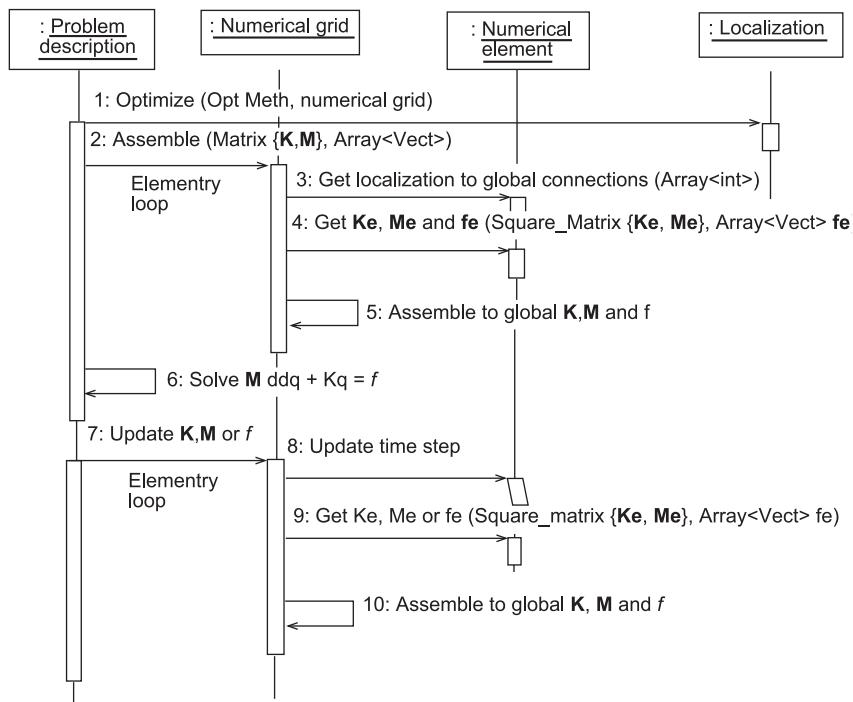

Figure 4 Sequence diagram of the assembling process.

keyboard devices. It will take benefits of other distributed memory and CPUs through a network device. A preemptive process dialogs with the master process to send graphical window output to the screen device, both accessing database on disk.

Component diagrams

These describe physical elements and their relations in the realization environment. They translate realization choices. In Figure 6, for example, the main

process controls two tasks: communication and visualization. The first uses the OOMPI package incorporating the MPI and TCP/IP protocols. The second is split into two options depending on the nature of the visualization: 2D or 3D, each option using different graphics libraries.

The Language

Discussions on the different languages which currently propose object-oriented philosophy (OOPL)

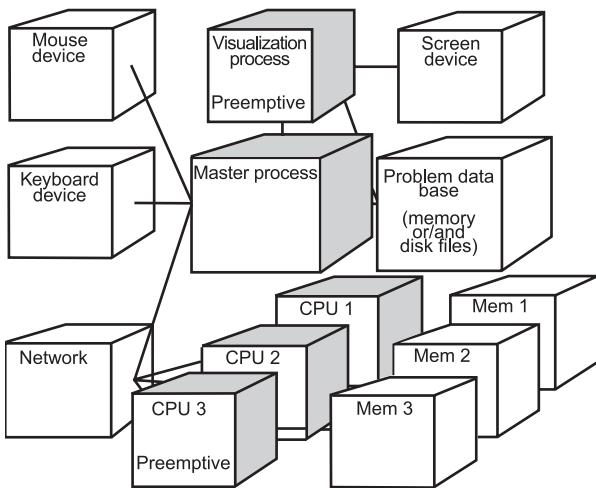

Figure 5 Example of a deployment diagram.

have been made by J. Rumbaugh and P. Coad and E. Yourdon. J. Barton gave a point of view on scientific applications. Among the many existing object-oriented languages, C++ developed by B. Stroustrup, is preferred for reasons of portability and efficiency, and because of the large number of tools available (graphical interface libraries, network tools, etc.). It revealed itself to be a language which imposes such a discipline on the programmer that it allows a single person to maintain an important code.

Several researchers, like G.W. Zeglinski and R.P.S. Han, have worked on the application of object-oriented programming techniques to the FE method in recent years. T. Zimmermann et al. used the

Smalltalk programming language. Although it is considered as a pure object-oriented language, it is not used for real numerical applications for efficiency reasons. Other researchers, like B.W.R. Forde et al. and R.I. Macjkie, have presented object-oriented implementations of the FE method using object-oriented extensions of Pascal or Ada. The new standard Fortran 90 includes features which can be considered as object-oriented extensions, making this option appealing for those who are strongly involved in Fortran programming. However, it has many limitations: for instance, it does not support inheritance or dynamic polymorphism.

It is generally agreed that the C++ language – an extension to C – remains the most widespread object-oriented language for numerical computations. The success of the C++ language made usual standard C libraries to be reviewed, adapted to object-oriented philosophy, and extended with new standard tools.

Several applications of FE programming using C++ have been reported in references. In particular, A. Cardona and I. Klapka incorporated an object-oriented command line interpreter (OoFeLie) which gives the end-user direct access to the object-oriented internal architecture.

Numerical Efficiency

From a numerical efficiency point of view, it is important to understand that in C++ most of the object-oriented concepts do not extend beyond the compilation step. Only the polymorphism concept needs dynamic (during execution) binding. Historically, first versions of C++ compilers were simply translators to C, theoretically limiting efficiency to

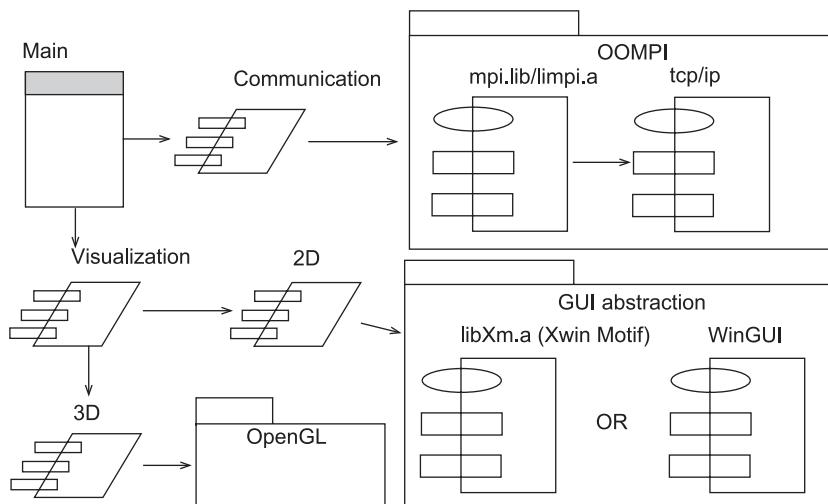

Figure 6 Component diagram.

that of C. In fact, as announced by the creator of the language, C++ is designed to be an improved C, supporting data abstraction and object-oriented philosophy. This means more concepts to be understood by the programmer and, thus, more sources of mistakes. We should bear in mind that the object-oriented philosophy must be considered as a tool, and not as a systematic obligation which could lead to make an object with each ‘bit’ of information.

Most of the criticisms of C++ efficiency are not valid. Practice has taught that inefficient implementation of C++ programs is the consequence of a poor understanding of the language. For example, when implementing a vector class one may be tempted to overload operator [i] so as to test if index i is inside the vector range. It may be a useful feature in some cases, but one should not expect to get Blas performance if using this operator in a vector product. It must be borne in mind that abstraction often comes with a loss of performance. Stepanov calls it the abstraction penalty and proposed a test to quantify it.

For efficiency reasons, good practice consists of limiting the nonanticipation principle proposed by Dubois-Pelerin to objects directly accessed by the end-user, or to high-level methods. This principle tries to extend the data abstraction concept to a state abstraction concept, which implies verifying the state of each data entity before using it. This idea may result in the implementation of many costly tests which may be considered unacceptable at execution time if performed with often-called functions or operators (operator [], for example). This choice seems to contradict the object-oriented philosophy. However, using analysis techniques such as state diagrams, one can acquire a good knowledge about the state of the object before using it, which makes some tests unnecessary or useful only during the debugging phase of development.

Finally, the user of classes has an unavoidable responsibility; for instance, many algorithms do not need zero initialization of matrices. This is why most matrix class implementations do not initialize matrix values by default, leaving the choice to the user (e.g., Lapack++).

In terms of pure computational efficiency, J.J. Dongarra and R. Pozo obtained with the Lapack++ library (a C++ extension of the Fortran Lapack library for numerical linear algebra) exactly the same performance as with Fortran. However, the C++ implementation provided scalability, portability, flexibility, and ease of use features which were not so easy to obtain for large codes implemented in For-

tran. Other researchers reported better performance than using Fortran in some cases (T. Veldhuizen, Blitz++ Consortium).

To get these results, frequent use was made of the template mechanism which allows one to define concepts (methods, algorithms) independently of the type of object being used. The main difference with the virtual inheritance mechanism consists in the fact that the connection between data and methods is made by the compiler. This implies that the compiler receives enough information to produce optimized code. This technique not only increases legibility without losing efficiency, but also allows methods to be reused without considering how data structures are implemented. The template concept is preferred to the class inheritance mechanism when implementing static polymorphism.

Numerical Solution of a Continuum Mechanics Problem

The process of solving a continuum mechanics problem customarily involves a discretization step followed by a step of finding the solution to an algebraic (discrete) problem.

Discretization allows the behavior of the continuum (e.g., space, time) to be described in terms of the behavior computed at selected points (we then talk of values computed at the degrees-of-freedom of the model). The original problem is transformed into a discrete algebraic one which can be effectively formulated and solved numerically. The components of this algebraic problem express values computed at the degrees of freedom of our model. Several kinds of algebraic problems have to be solved, depending on the problem to analyze. For instance, the continuum mechanics problem in linear statics is expressed by a boundary value problem which is transformed after discretization into a system of linear algebraic equations. When dealing with linear vibration analysis, we have to solve a linear eigenvalue problem. In nonlinear statics the problem to be solved is a system of nonlinear algebraic equations.

These algebraic problems share several characteristics unique to FE analysis. The number of equations and unknowns can be very large (e.g., it is not uncommon to talk of more than 500 000 unknowns in linear statics industrial applications). Also, the degree of coupling between unknowns is moderate to low, so that appropriate schemes to handle sparse coefficient matrices should be employed to reach maximum computational efficiency. Several strategies, specialized to FE applications, exist: e.g., the

skyline, frontal, multifrontal solution schemes. Systems of nonlinear equations range from mildly nonlinear, for which it is fairly easy to find a solution, to very ill-conditioned. There exists a large number of algorithms to solve nonlinear systems of equations in FE applications, each being adapted to a particular kind of problem. In order to get a solution to a practical industrial problem, the analyst should have a variety of algorithms at hand, and should be able to switch from one to another even while advancing along the solution path.

What has been said for systems of nonlinear equations in the preceding paragraph also applies to methods for extracting linear eigenvalues, integrating systems of ordinary differential equations, and so forth. Many specialized algorithms exist and new ones are continuously being proposed which take into account the peculiarities of these systems and of new hardware technology. Finally, it must be mentioned that, in many cases, the problem to be solved consists of a sequence (or even nesting) of algebraic problems of the kind described in the previous paragraphs. Examples of these situations can be found, for instance, in optimization, stability analysis of nonlinear structures, and dynamic stability analysis of mechanisms and structures.

Dynamic Systems

The FE method is an analysis tool for many different problems of continuum mechanics, most widely used for structural analysis. The method essentially consists of discretizing the continuum and transforming the system of partial differential equations into an algebraic problem.

Most dynamic systems can be stated directly from Hamilton's principle. Assuming the dynamic system has n state variables \mathbf{q}_i and $\dot{\mathbf{q}}_i$ and m constraint equations, then the solution for a dynamic problem is a stationary value of:

$$\begin{cases} \delta \int_{t_1}^{t_2} (E^T - E^V - \frac{1}{2} k \phi^T \phi - \lambda^T \phi) dt = 0 \\ \delta \mathbf{q}(t_1) = \delta \mathbf{q}(t_2) = 0 \end{cases}$$

where:

- E^T = kinetic energy of the system
- E^V = potential energy stored within the system
- ϕ = a set of constraint functions
- k = value of the penalty amplification factor
- λ = vector of Lagrange multipliers associated with the constraint functions
- \mathbf{q} = vector of state variables

Assuming that the kinetic energy, potential energy, and constraint equation depend on a vector of state variables \mathbf{q} and their time derivatives $\dot{\mathbf{q}}$, the corresponding Lagrange equation takes the form:

$$\begin{cases} \left(\frac{d}{dt} (\nabla_{\dot{\mathbf{q}}} (E^T - E^V)) - \nabla_{\mathbf{q}} (E^T - E^V) \right)^T \\ + (\nabla_{\mathbf{q}} \phi)^T (k \phi + \lambda) = 0 \quad \phi = 0 \end{cases}$$

The number of equations is equal to the number of state variables plus the number of constraint functions. The first block of equations being linear in $\dot{\mathbf{q}}$, the system of equations can be rewritten as:

$$\begin{cases} M \ddot{\mathbf{q}} + \mathbf{f}(\mathbf{q}, \dot{\mathbf{q}}, t) = 0 \\ \phi(\mathbf{q}, \dot{\mathbf{q}}, t) = 0 \end{cases}$$

where:

$$M_{ij}(\mathbf{q}, \dot{\mathbf{q}}, t) = \frac{\partial(E^T - E^V)}{\partial \dot{\mathbf{q}}_i \partial \dot{\mathbf{q}}_j}$$

and \mathbf{f} include the contributions of the constraint equations.

Dynamic systems can be decomposed in components, where each component has its own kinetic energy, potential energy, dissipation rate, and/or constraints. The kinetic energy, potential energy, dissipation rate, and constraints of the complete system are obtained by summing up the corresponding values of its components. Coupling between the different components is characterized by the fact that they share state variables and constraint equations. This observation holds for systems composed of rigid bodies as well as for those resulting from the discretization of a continuum mechanics problem.

Basic Example of a Class Hierarchy

Programs applied to numerical simulation contain at least three packages: a utility package which contains vectors, lists, etc.; a mathematical/numerical package which implements different storage methods and algebra algorithms; and a physical package which instructs the numerical problem with material behavior resulting from physical models, and their integration schemes.

Tools classes The main needs are containers (tools to manage collections of user objects), memory management tools, iterators, algorithms, diagnostics, strings, and I/O tools. The standard template library (STL) proposes standard extension tools added to the C++ language itself.

Mathematical classes

Storage level Different kinds of matrix storage can be implemented with the objective of an independent-type interface. For example, a Skyline class inheriting from a *Moth_mat* class may be created to manage skyline array memory organization. See Figure 7.

Low-level computation methods In the context of the FE method, operations such as, matrix vector product, static Schur condensation and direct solver are identified as the basic matrix methods required by most algorithms. These methods can be added to the interface of the mother matrix class as member functions to allow nondependent use of children matrices in algorithms.

High-level computation methods These classes serve as ‘black boxes’ defining robust user interfaces to solution methods taking into account particular aspects such as, e.g., memory management, parallelism. Basic ones are:

1. *StatSyst*: base class for linear systems solvers
 - (a) Direct solvers
 - (b) Iterative solvers (implementations of GMRES, BiCg, BiCgStab, CGS, CG from SIAM Templates book)
2. *DynamSyst*: base class for all eigenvalue and eigenvector calculations
 - (a) Jacobi: Jacobi method for symmetric (eventually banded) matrices

- (b) qr: QR method for banded matrices
- (c) SVD: singular value decomposition implementation
- (d) Lanczos: Lanczos algorithm with single iteration vector and restart, or block Lanczos algorithm

3. Opti: optimization functions

Physical classes The class model approximates as closely as possible the theoretical consideration on the numerical approximation of dynamical systems. A dynamic system is composed of components (elements), each of which sums its contribution to a global residual vector. An analysis class groups all components within a global dynamical system and applies Newton iterations and/or line search algorithms to annihilate the residual vector at each timestep.

The interface design to element objects must be based on the data structure needed to answer questions asked by the solvers or the results manager.

The set of physical classes is used to describe the problem under analysis and the system state. Some of the usual physical classes are:

1. *Point_state*: virtual generic class which manages physical information at a point
2. *Node_state*: virtual class, inheriting from *Point_State*, providing standard interface to access state variables at a node, including:
 - (a) *Position*: coordinates of a point in Cartesian space

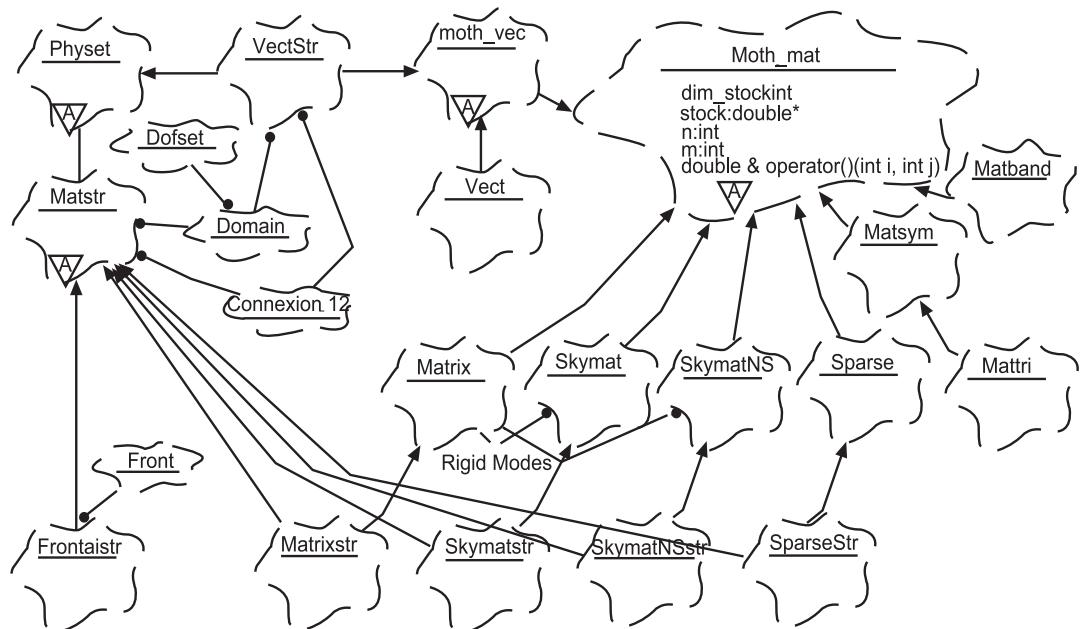

Figure 7 Hierarchy of matrix classes example in G. Booch inheritance diagram notation.

- (b) Displacement: displacement at a point
- (c) Force: data and methods to handle loads
- (d) Temperature: temperature at a point

Also, time derivatives of the above are accessed through `Point_State` interface. They can be managed through STL container `List<Type>` to declare, for example, the set of Displacement as `List<Displacement>`.

- `Material`: master class for description of materials of various kinds.
- `Propelem`: master class for description of element properties
- `Fixation`: master class for information concerning boundary conditions of the model.
- `Element`: virtual master class of the FE library. It provides methods to access their attributes, and to compute the different FE arrays and tables (e.g., `fill_stiffness()`, `fill_mass()`, etc.).

Some of them, in nonlinear hypothesis, should use:

- `Gauss_point_state`, inheriting both from `Point_State` and `Material`, to get access to material state story information
- `Skymat_str`, inheriting from `Skymat`, adds to the matrix features the ability to manage connectivity between elements

After having the different corresponding objects and having defined the problem, the resolution scheme will first fill a `Skymat_str` Mass matrix. The matrix object will ask the `List<Element>` to fill elementary matrices `Matsym` and assemble them using connectivity given by the current `Element`. The same is done for internal and external force vectors. The difference between the two vectors is applied as a parameter of the `Skymat_str::Mass` of the solver member function. The result is stored in a `List<Displacement>`.

OPTIMAL FILTERS

S J Elliott, University of Southampton,
Southampton, UK

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0068

Optimal filters are used to extract signals from noise and in the calculation of the optimal performance of active vibration control systems. Filters are defined to be optimal when they give the best possible performance under a given set of circumstances. The best possible performance is generally defined in terms of minimizing a least-square or H_2 cost function, since this has a physical interpretation in terms of minimizing the power of an error signal, and also leads to a linear set of equations to be solved for the optimal filter if it has a digital finite impulse response (FIR) form. It is also possible to design a filter which minimizes the maximum value of the error at any frequency, which is called minimax optimization in the signal-processing literature and H_∞ minimization in the control literature. Alternatively, the optimum parameter values could be calculated for each example of a random set of data, so the parameters are themselves random variables, and maximum *a posteriori* (MAP) or maximum likelihood (ML) estimates can then be defined.

Time Domain Formulation

We will specifically concentrate here on the optimal digital FIR filter which minimizes the mean-square (H_2) error in the prototypical electrical noise cancellation problem shown in Figure 1. In this figure the error signal, $e(n)$, is given by the difference between a desired signal, $d(n)$, and the reference signal, $x(n)$, filtered by an FIR filter with coefficients w_i , so that:

$$e(n) = d(n) - \sum_{i=0}^{I-1} w_i x(n-i) \quad [1]$$

The summation over $w_i x(n-i)$ in eqn [1] can be conveniently represented as a vector inner product, such that:

$$e(n) = d(n) - \mathbf{w}^T \mathbf{x}(n) = d(n) - \mathbf{x}^T(n) \mathbf{w} \quad [2a, b]$$

where:

$$\mathbf{w} = [w_0 w_1 \dots w_{I-1}]^T \quad [3]$$

and:

$$\mathbf{x}(n) = [x(n) x(n-1) \dots x(n-I+1)]^T \quad [4]$$

The objective is to find the value of each of the filter coefficients $w_0 \dots w_{I-1}$ which minimizes the quadratic cost function given by:

$$J = E[e^2(n)] \quad [5]$$

where E denotes the expectation operator. If $\mathbf{x}(n)$ were not stationary, then J , and the optimal filter coefficients, would be functions of time. We assume here that all the signals are stationary and ergodic so that the expectation is time-invariant, and can be calculated by averaging over time. The cost function given by eqn [5] is thus equal to the mean-square value of the error signal. This restricted use of the expectation operator will be assumed throughout this article.

Using eqns [2a] and [2b], the cost function can be written as:

$$J = \mathbf{w}^T \mathbf{A} \mathbf{w} + 2\mathbf{w}^T \mathbf{b} + c \quad [6]$$

where:

$$\mathbf{A} = E[\mathbf{x}(n)\mathbf{x}^T(n)] \quad [7]$$

$$\mathbf{b} = E[\mathbf{x}(n)d(n)] \quad [8]$$

$$c = E[d^2(n)] \quad [9]$$

In a quadratic equation having the general form of eqn [6], the matrix \mathbf{A} is known as the Hessian matrix, and in this case its elements are equal to the values of the autocorrelation function of the reference signal:

$$\mathbf{A} = \begin{bmatrix} R_{xx}(0) & R_{xx}(1) & \dots & R_{xx}(I-1) \\ R_{xx}(1) & R_{xx}(0) & & \\ \vdots & \ddots & & \ddots \\ R_{xx}(I-1) & & & R_{xx}(0) \end{bmatrix} \quad [10]$$

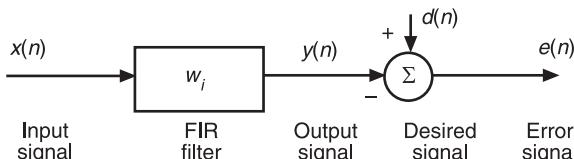

Figure 1 Model problem for the derivation of optimal FIR filter.

where $R_{xx}(m)$ is the symmetric autocorrelation function of $x(n)$, defined as:

$$R_{xx}(m) = E[x(n)x(n+m)] = R_{xx}(-m) \quad [11]$$

in which E denotes the expectation value. Notice that the matrix \mathbf{A} in eqn [10] has equal elements along each of the diagonals, i.e., it is Toeplitz.

The vector \mathbf{b} has elements which are equal to the values of the cross-correlation function between the reference signal and the desired signals so that:

$$\mathbf{b} = [R_{xd}(0) R_{xd}(1) \cdots R_{xd}(I-1)]^T \quad [12]$$

where:

$$R_{xd}(m) = E[x(n)d(n+m)] = E[x(n-m)d(n)] \quad [13]$$

and c is a scalar constant equal to the mean-square value of the desired signal.

When written in the form of eqn [6], it is clear that the mean-square error is a quadratic function of each of the FIR filter coefficients. This quadratic function always has a minimum rather than a maximum, since J must become large and positive if any one filter coefficient takes large positive or negative values. This minimum is only unique, however, if the matrix \mathbf{A} in eqn [6] is positive definite. In the case being considered here, \mathbf{A} is given by eqn [7] and can either be positive definite (in which case it is also nonsingular) or positive semidefinite (in which case it is singular) depending on the spectral properties of the reference signal and the number of coefficients in the FIR filter. If there are at least half as many spectral components as filter coefficients, the reference signal is said to be persistently exciting or spectrally rich, which insures that the autocorrelation matrix given by eqn [7] is positive definite and so eqn [6] has a unique minimum. The cost function when plotted against any two coefficients will thus define a bowl-shaped performance surface or error surface, as shown in Figure 2.

The Wiener Filter

The value of the coefficients of the FIR filter which reduce the mean-squared error to a minimum can be found by differentiating the cost function with respect to each coefficient and setting all of the resulting derivatives to zero. It is convenient to express this differentiation using vector notation, and so we define the vector of derivatives to be:

$$\frac{\partial J}{\partial \mathbf{w}} = \left[\frac{\partial J}{\partial w_0} \frac{\partial J}{\partial w_1} \cdots \frac{\partial J}{\partial w_{I-1}} \right]^T \quad [14]$$

Using the definition of J in eqn [6] and the properties of vectors of derivatives, eqn [14] can be expressed as:

$$\frac{\partial J}{\partial \mathbf{w}} = 2[\mathbf{Aw} - \mathbf{b}] \quad [15]$$

Assuming $x(n)$ is persistently exciting, so that \mathbf{A} is not singular, the vector of optimal filter coefficients can be obtained by setting each element of [15] to zero, to give:

$$\mathbf{w}_{\text{opt}} = \mathbf{A}^{-1}\mathbf{b} \quad [16]$$

The filter which has these optimal coefficients is often called the Wiener filter after the pioneering work of Wiener in the 1940s, although the explicit solution to the discrete-time form of the problem is due to Levinson. Levinson also put forward an efficient method for solving eqn [17] which exploits the Toeplitz nature of the matrix \mathbf{A} , and this method is widely used in speech coding. Levinson modestly

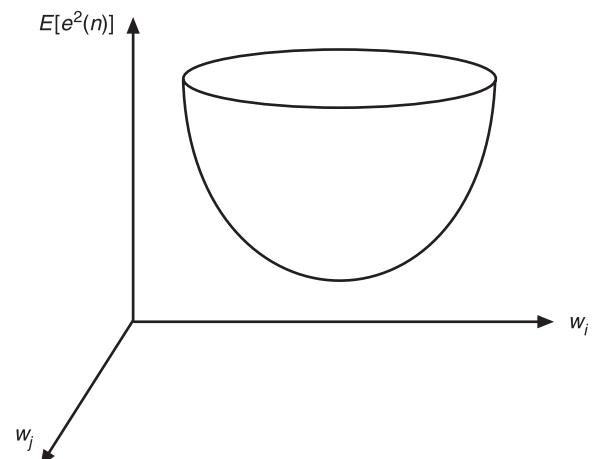

Figure 2 The quadratic error surface formed by plotting the mean square error in Figure 1 against any two coefficients of the FIR filter.

prefaces his paper by stating that: ‘A few months after Wiener’s work appeared, the author, in order to facilitate computational procedure, worked out an approximate, and one might say, mathematically trivial procedure’. In fact, the discrete form of Wiener’s formulation leads to an elegant matrix formulation which is very well suited to efficient numerical solution.

Using the definition of \mathbf{A} and \mathbf{b} in terms of the auto-and cross-correlation functions, eqn [15], for the optimal filter, can also be written as a summation of the form:

$$\sum_{i=0}^{I-1} w_i(\text{opt}) R_{xx}(k-i) R_{xd}(k) = 0 \quad \text{for } 0 < k < I-1 \quad [17]$$

This set of equations is known as the normal equations and represents a discrete form of the Wiener-Hopf equation.

The vector of cross-correlations between the I past values of the reference signal and the error signal can be written, using eqn [2b], as:

$$E[\mathbf{x}(n)e(n)] = E[\mathbf{x}(n)(d(n) - \mathbf{x}^T(n)\mathbf{w})] = \mathbf{b} - \mathbf{Aw} \quad [18]$$

It is clear that all the elements of this vector are zero when the FIR filter is adjusted to minimize the mean-square error, as in eqn [17]. In minimizing the mean-square error, the Wiener filter thus also sets to zero the cross-correlations between the reference signal and the residual error signal over the length of the filter, which is a statement of the principle of orthogonality.

The values of the auto- and cross-correlation functions required to define the elements of \mathbf{A} and \mathbf{b} in eqns [7] and [8] can often be most easily estimated from measured data using the power spectral density of $x(n)$ and the cross-spectral density between $x(n)$ and $d(n)$, since the correlation function and spectral density are Fourier transform pairs. From these average properties of the reference and desired signal, the coefficients of the Wiener filter can be calculated using eqns [10], [11], and [17]. The minimum value of the mean-square error can also be obtained directly by substituting eqn [17] into eqn [6] to give:

$$J(\min) = c - \mathbf{b}^T \mathbf{A}^{-1} \mathbf{b} \quad [19]$$

The residual mean-square error can thus be calculated directly from the statistical properties of the reference and desired signals. This can be very useful

in the early stages of a design, to help understand the trade-off between performance and filter length, for example.

Unconstrained Wiener Filter

Returning to the expression for the normal equations, eqn [17], we find that we can obtain a particularly simple expression for the frequency response of the optimal filter if we relax the assumptions that the filter must be causal and of finite length. Under these conditions the normal equations can be written as:

$$\sum_{i=-\infty}^{\infty} w_i(\text{opt}) R_{xx}(k-i) = R_{xd}(k) \quad \text{for } -\infty < k < \infty \quad [20]$$

Taking the z transform of eqn [20] allows us to express the Wiener filter in this completely unconstrained case, which is sometimes referred to as the unconstrained or two-sided Wiener filter, as:

$$W_{\text{opt}}(z) = \frac{S_{xd}(z)}{S_{xx}(z)} \quad [21]$$

where $S_{xd}(z)$ and $S_{xx}(z)$ are the double-sided z transforms of $R_{xd}(m)$ and $R_{xx}(m)$, which can also be written as:

$$S_{xx}(z) = E[X(z^{-1})X(z)] \quad [22]$$

and:

$$S_{xd}(z) = E[X(z^{-1})D(z)] \quad [23]$$

where E denotes the expectation operator, and $X(z)$ and $D(z)$ are the z transforms of $x(n)$ and $d(n)$. In principle, the expectation operator is taken over an ensemble of signals but in practice can be taken over a series of data lengths of finite duration if the signals are stationary and ergodic. The Fourier rather than the z transform could also be taken on measured data to give estimates of the power spectral density $S_{xx}(e^{j\omega T})$ and cross-spectral density $S_{xd}(e^{j\omega T})$, in which case the Fourier transform of the optimal filter becomes:

$$W_{\text{opt}}(e^{j\omega T}) = \frac{S_{xd}(e^{j\omega T})}{S_{xx}(e^{j\omega T})} \quad [24]$$

Causally Constrained Wiener Filter

It is easy to compute the frequency response of the optimal filter given by eqn [24], but its use could be misleading because it is not constrained to be causal, and so might be impossible to realize in a real-time system. It is also possible to calculate the frequency response of the optimum filter when it is constrained to be causal but not constrained to be of finite duration. In practice this gives an equivalent result to solving the normal equations for an FIR filter with very many coefficients and then taking the Fourier transform of the resulting impulse response. The method of deriving such a filter in the frequency domain, which is outlined below, was originally due to Bode and Shannon.

The Wiener-Hopf equation for the optimal filter when it is constrained to be causal, but not constrained to be of finite length, can be written from eqn [17] as:

$$\sum_{i=0}^{\infty} w_i(\text{opt}) R_{xx}(k-i) = R_{xd}(k) \quad \text{for } -\infty < k < \infty \quad [25]$$

We now assume the very special condition that the reference signal, $x(n)$, is given by a sequence, $v(n)$, which is completely uncorrelated from sample to sample, i.e., white noise, and also has zero mean and unit variance, so that $R_{xx}(m) = R_{vv}(m) = \delta(m)$, which equals 1 if $m = 0$ and which otherwise equals zero. Under these conditions eqn [25] has the form:

$$\sum_{i=0}^{\infty} w_i(\text{opt} : v) \delta(k-i) = R_{vd}(k) \quad \text{for } -\infty < k < \infty \quad [26]$$

and because of the sifting property of $\delta(m)$, eqn [26] is equivalent to:

$$w_k(\text{opt} : v) = R_{vd}(k) \quad \text{for } 0 < k < \infty \quad [27]$$

Thus, if the reference signal is white noise, the impulse response of the optimal causal filter is equal to the causal part of the cross-correlation function between the reference and desired signal. The z transform of the optimal filter under these conditions can be written as:

$$W_{\text{opt}:v}(z) = \{S_{vd}(z)\}_+ \quad [28]$$

where $S_{vd}(z)$ is the z transform of the cross-correlation between $v(n)$ and $d(n)$ and $\{\cdot\}_+$ denotes the fact that

the z transform of the causal part of the quantity inside the brackets has been taken, so that:

$$\{S_{vd}(z)\}_+ = Z[R_{vd}(m)U(m)] \quad [29]$$

where Z denotes z transformation and $U(m)$ is the discrete step function which is equal to 1 for $m > 0$ and is equal to zero for $m < 0$.

In the more general case, the reference signal is not a white-noise sequence. The problem can still be reduced to that of a white-noise reference, however, by prewhitening the reference signal. Specifically, we assume that the reference signal was originally generated by passing a zero mean white-noise signal, $v(n)$, which has a variance of unity, so that its power spectral density is also unity, through a minimum-phase shaping filter, with frequency response $F(e^{j\omega T})$. If the double-sided z transform of the auto-correlation function $R_{xx}(m)$, which can be written as $S_{xx}(z)$, is rational, i.e., it has a number of well-defined poles and zeros, then $S_{xx}(z)$ can be expressed in the form:

$$S_{xx}(z) = F^+(z)F^-(z) \quad [30]$$

where $F^+(z)$ contains the poles and zeros of $S_{xx}(z)$ inside the unit circle and thus has an entirely causal and minimum phase impulse response, and $F^-(z)$ contains the poles and zeros of $S_{xx}(z)$ outside the unit circle, and thus has a noncausal impulse response. $F^+(z)$ and $F^-(z)$ are called the spectral factors of $S_{xx}(z)$.

Notice that because $R_{xx}(m)$ is symmetrical and so $S_{xx}(z) = S_{xx}(z^{-1})$, then:

$$F^-(z) = F^+(z^{-1}) \quad [31]$$

$F^-(z)$ can thus be interpreted as having the same form of impulse response as $F^+(z)$, but reversed in time. Since we are assuming that $x(n)$ is generated by passing $v(n)$ through the shaping filter $F(e^{j\omega T})$, then in the frequency domain the power spectral density must be equal to:

$$S_{xx}(e^{j\omega T}) = F(e^{j\omega T})F^*(e^{j\omega T})S_{vv}(e^{j\omega T}) \quad [32]$$

where $*$ denotes complex conjugation. But $S_{vv}(e^{j\omega T})$ is equal to unity by definition and setting $z = e^{j\omega T}$ in eqn [30] and comparing this with eqn [32], we can see that the frequency response of the shaping filter and its conjugate are equal to:

$$F(e^{j\omega T}) = F^+(e^{j\omega T}), \quad F^*(e^{j\omega T}) = F^-(e^{j\omega T}) \quad [33a, b]$$

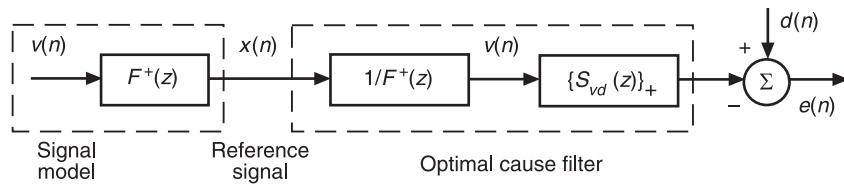

Figure 3 Signal model for the reference signal, $x(n)$, in which it assumed to be generated by passing a white-noise signal, $v(n)$, through a shaping filter, $F(z)$, and the optimal causal filter, which then takes the form of a prewhitening filter, $1/F(z)$, and the Fourier transform of the causal part of the cross-correlation function between $v(n)$ and $d(n)$, $\{S_{vd}(z)\}^+$.

The reference signal can also be transformed back into a white-noise signal of unit variance, $v(n)$, by passing it through the inverse of the shaping filter, which is stable since $F^+(z)$ is minimum phase, in which case the z transform of $v(n)$ is given by:

$$V(z) = \frac{X(z)}{F^+(z)} \quad [34]$$

Thus the complete form of the z transform of the optimum causal filter is equal to:

$$W_{\text{opt}}(z) = \frac{1}{F^+(z)} \{S_{vd}(z)\}_+ \quad [35]$$

as illustrated in Figure 3.

Using the definition of the cross-spectral density, we can also write:

$$\begin{aligned} S_{vd}(z) &= E[V^*(z)D(z)] \\ &= \frac{1}{F^-(z)} E[X^*(z)D(z)] = \frac{S_{xd}(z)}{F^-(z)} \end{aligned} \quad [36]$$

so that the optimum causal filter can be written in terms of the cross-spectral density between the reference and disturbance signal and the spectral factors of the reference signal's power spectral density as:

$$W_{\text{opt}}(z) = \frac{1}{F^+(z)} \left\{ \frac{S_{xd}(z)}{F^-(z)} \right\}_+ \quad [37]$$

The frequency domain expression for the optimum causal filter can be found by letting $z = e^{j\omega T}$ in eqn [37] and noting that $F^+(e^{j\omega T}) = F(e^{j\omega T})$ and $F^-(e^{j\omega T}) = F^*(e^{j\omega T})$ so that:

$$W_{\text{opt}}(e^{j\omega T}) = \frac{1}{F(e^{j\omega T})} \left\{ \frac{S_{xd}(e^{j\omega T})}{F^*(e^{j\omega T})} \right\}_+ \quad [38]$$

Eqn [38] can be used as the basis for the practical calculation of the optimum filter from measured data, although some care needs to be taken with the

discrete frequency form of this equation for the optimal filter because of the circular nature of the discrete Fourier transform. The frequency response of the shaping filter may be calculated in practice from the measured power spectral density by using the Hilbert transform to calculate the minimum-phase component of the frequency response of a system whose magnitude is equal to $\sqrt{S_{xx}(e^{j\omega T})}$.

Both the time and frequency domain formulations of the optimal filter may be extended to the multi-channel case and to the case of the feedforward and feedback controllers used in active control.

Nomenclature

A	Hessian matrix
c	scalar constant
$d(n)$	desired signal
$e(n)$	error signal
E	expectation operator
$U(m)$	discrete step function
$v(n)$	white-noise signal
$x(n)$	reference signal

PACKAGING

doi:10.1006/rwvb.2001.0161

Most packaging systems are designed to protect products from the hazards of the distribution environment. To properly design a packaging system, a packaging engineer needs to identify design parameters from three areas: the distribution environment, the product, and the packaging material. Among the many hazards of the distribution environment that can cause product damage, shock, vibration and compression forces are of high significance and should be addressed in design. This article covers the identification of these forces in (i) the distribution environment; (ii) the product; and (iii) the packaging materials. In addition, it also covers how this information is used to design a protective packaging system for a fragile product, and how to test the packaging system to verify that it in fact works as designed.

Information Required for Structural Packaging Design

Although many hazards exist in distribution, those indicated in Table 1 are usually the three most used for a proper packaging design. In Table 1, the first column represents the nature of the hazard (shock, vibration or compression). The second column indicates the type of information that is required to identify the hazards in the distribution environment.

These can be extended to the use of the product, or to moving it from one place to another anytime in its life. The third column represents the information that is required about the product. This is important because the design needs to cover only what is required by the product. Designing a package that overprotects the product is wasteful. For example, if a product can sustain without damage, drops of up to 25 cm and it is known that in distribution, drops from up to 75 cm are expected, then the protective package needs to account for the difference (50 cm). The information required for design is combined as shown in Figure 1. Initially, the information needs to be acquired. As seen in Figure 1, information about the distribution environment is used for the design of the protective packaging system as well as for the testing of the final system. Information about product

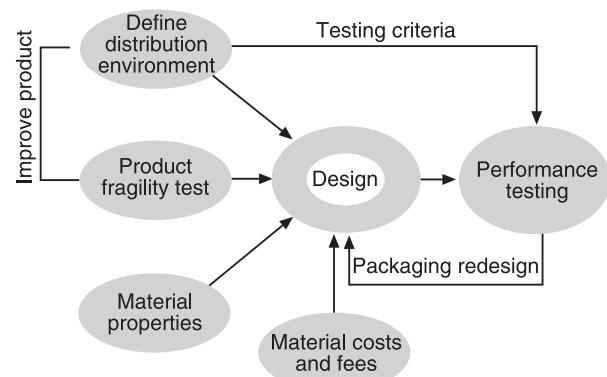

Figure 1 The structural development process for protective packaging.

Table 1 Information required for structural packaging design

Hazard	Distribution environment	Product	Packaging material
Shock	Equivalent free fall drop height	Shock fragility	Shock transmission characteristics
Vibration	Power spectrum density envelope	Resonance of components	Vibration transmission characteristics
Compression	Stacking height in storage and transport	Compression strength and creep load share allowed	Compression strength and creep

testing may be used for product improvement if the packaging development occurs in parallel with the development of the product. Packaging redesign is often necessary due to design oversights, since the procedure used for structural packaging design is rather simplified.

Obtaining Information about the Distribution Environment

Information about the distribution environment may be obtained in the following ways: (i) direct measurement and observation; (ii) applicable standards and specific industry requirements; or (iii) available literature. The most accurate way to obtain this information is by direct measurement and observation, since the conditions change with time. However, for the information to be reliable and truly representative of the distribution environment, the measurement procedure must account for all variables, which in many cases may be impractical.

Obtaining shock information about the distribution environment In essence, what a designer needs to know is the ‘equivalent drop height’, a quantity that represents not only free fall drops but also all other kinds of impacts a package receives in distribution (see **Shock**).

Obtaining vibration information about the distribution environment Vibration information may be obtained from the literature. It may also be measured with accelerometers and further processed using spectral analysis (Figure 2). Many studies have shown that the most severe levels of vibration in road transport are encountered above the rear axle of vehicles. Also, studies have shown that the vertical vibration is generally more severe than lateral or longitudinal. Most vibration data reported in the literature refer to vertical vibration. When designing packages, engineers look for significant frequencies in the spectrum. Vibration intensity, although important, is not used often in the design process. However, it is used in testing packaging and packaging systems for performance in distribution. Table 2 shows the most significant frequencies encountered in the

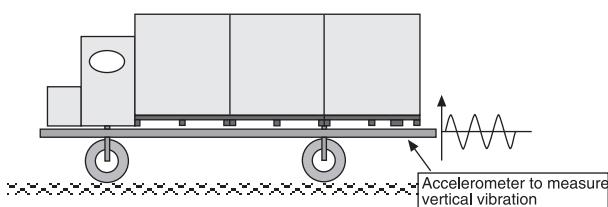

Figure 2 Measuring vibration in vehicles.

literature, and Figure 3 shows a power spectrum density (PSD) for a loaded semitrailer measured when traveling at speeds between 60 and 80 km h⁻¹ on a variety of pavements (in the PSD shown, the bandwidth used was 1 Hz, as in most vibration measurements for packaging applications).

Obtaining compression information about the distribution environment Compression forces are usually split into static and dynamic forces. Static forces are usually found in warehouse storage and dynamic forces in vehicles for transport. Static forces are determined by calculating the weight imposed on the lowest package in a stack. Simply, for a stack of packages with n packages, the static force is given by:

$$F_s = (n_s - 1)m_p g \quad [1]$$

In cases when the packages to be stacked are unknown, a common density of 10 lb ft⁻³ (160 kg m⁻³) may be used to calculate the static force. In this case the static force becomes:

$$F_s = \delta_L g (H_s - H_p) L_p W_p \quad [2]$$

Dynamic force is calculated by incorporating a dynamic factor, and using the stack heights encountered in

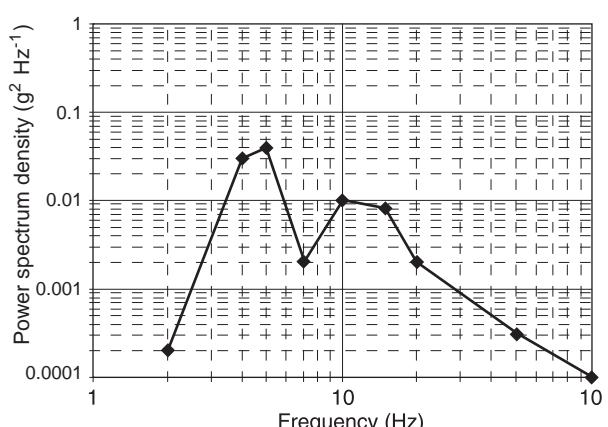

Figure 3 Random vibration spectrum for ISTA testing.

vehicles for transport. The dynamic force may be calculated by:

$$F_d = (n_t - 1)m_p g D_f \quad [3]$$

For mixed or unknown loads, the dynamic force is:

$$F_d = \delta_L g (H_t - H_p) L_p W_p D_f \quad [4]$$

The dynamic factor has been determined experimentally and is shown in Table 3, and is related to the intensity of vibration and the conditions of the road.

Obtaining Information about the Product

Products are tested, without any packaging, to determine their inherent ability to sustain shock, vibration and compression forces. In many cases, due to the lack of prototypes for testing, the information may be estimated, based on the properties of the components of the product. However, due to the complexity of most products, it is best to perform product testing in order to obtain the most accurate data possible. This is important because any inaccurate information used about the product will produce a nonoptimal design, which will result either in product damage or overpackaging (often never detected).

Obtaining information about the product shock fragility Typically, one determines the ability of

the product to sustain impacts without damage. This level, in acceleration units, g , is the 'product shock fragility' (see **Shock**).

Obtaining information about the product vibration sensitivity To obtain vibration data about the product, a prototype is placed on a vibration tester and a test is conducted to identify the resonant frequency of its components, in each of the orthogonal directions (Figure 4). There are basically two methods for this; resonance search using a sine sweep test, and monitored component random vibration. In the sine sweep test, components of the product are observed for resonance (visually or audibly). In the random vibration method, components need to be monitored by mounting a small accelerometer on the components, and determining the vibration transmission between product and component. The added mass of the accelerometer needs to be taken into account, using:

$$\omega_{Rc} = \omega_{Rca} (m_c + m_a/m_c)^{0.5} \quad [5]$$

Obtaining information about the product compression resistance A compression test may be used to determine the product's ability to sustain compression forces. This is done by applying orthogonal compression forces until product failure or some other predetermined limit is achieved.

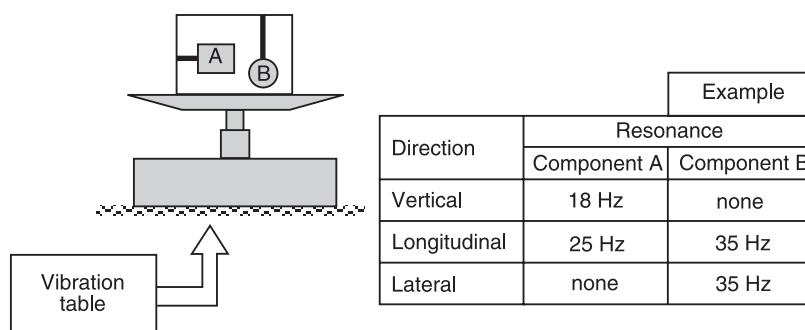

Figure 4 Product fragility – vibration sensitivity.

Table 3 Dynamic factor vs road condition and RMS g vertical vibration

Road surface Typical condition	Smooth New pavements		Some roughness Joints, cracks		Rough Damaged pavement	
$RMS\ g$ D_f	0.2 2	0.35 3	0.4 4	0.5 5	0.6 7	0.7 10

Obtaining Information about the Packaging Material

Packaging material, usually expanded foams and corrugated pads, are tested to determine their ability to absorb impacts, attenuate vibration and resist compression forces. An important factor to observe is that these tests are highly influenced by ambient conditions, therefore proper conditioning is important. For most packaging applications, cushioning for vibration attenuation is not the main goal. Packages are designed for shock protection and must be verified that they do not amplify vibration in ranges that are critical for the vehicles used in transport, or for the product. Figure 5 shows what a designer is looking for, for a frequency that either (i) has a high intensity input from the vehicle, or (ii) makes components in the product resonate. If the frequency in which either (i) or (ii) occur will make the material amplify vibration (Figure 6), then the design needs to be modified. Figure 7 shows a typical effect of cushioning a product.

Obtaining shock data about packaging materials

Typically, the information required is the shock transmission through the material to the product, during an impact (see Shock).

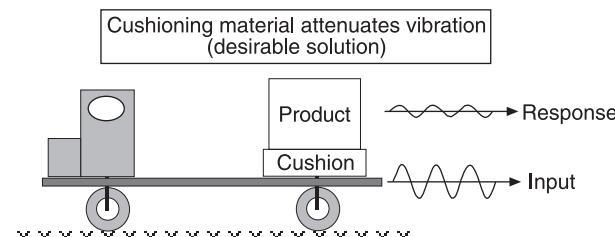

Figure 5 Vibration transmission attenuation.

Obtaining vibration data about packaging materials Vibration transmission properties of packaging materials are obtained by determining the range of frequencies where vibration is amplified or attenuated (Figures 8 and 9). The results are presented in the form of vibration transmissibility curves, as shown in Figure 10. The tests used to obtain this curve are conducted using samples of the packaging material, with a specified weight on top (Figure 8). The assembly is subjected to vibration and the vibration transmissibility is measured between the vibration table and the weight on top of the cushion. The three lines in Figure 10 represent: (i) the boundary between coupling and amplification; (ii) the maximum amplification, or resonance; and (iii) the boundary between amplification and attenuation.

Obtaining compression data about packaging materials Two pieces of data are needed from materials: compression resistance and creep. Compression resistance may be determined by applying a quasi-static force at a speed of approximately 12 mm min^{-1} , as most standards specify. This is used to obtain force-deflection information or modulus of elasticity of the

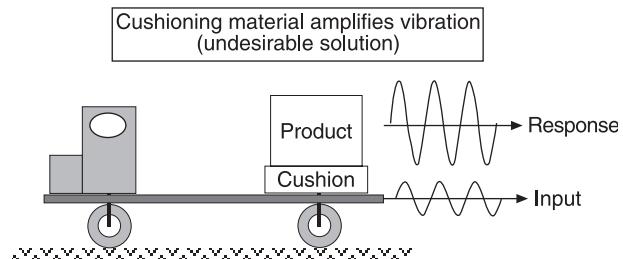

Figure 6 Vibration transmission amplification.

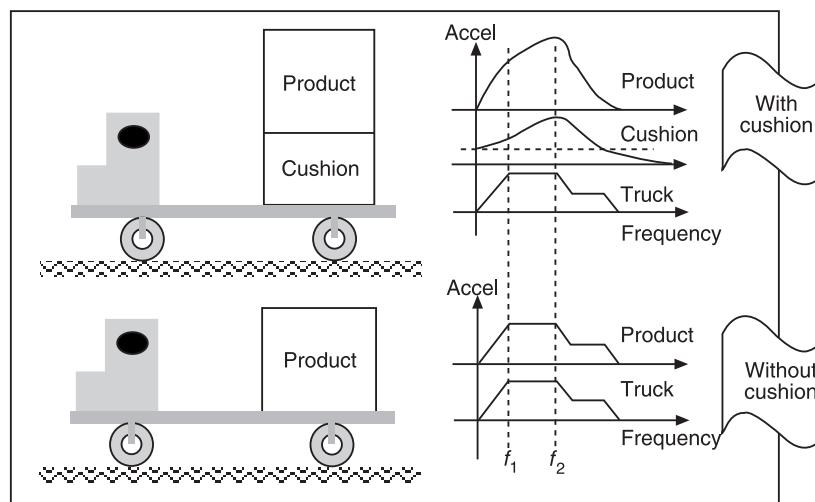

Figure 7 Vibration transmissibility – effect of cushioning a product.

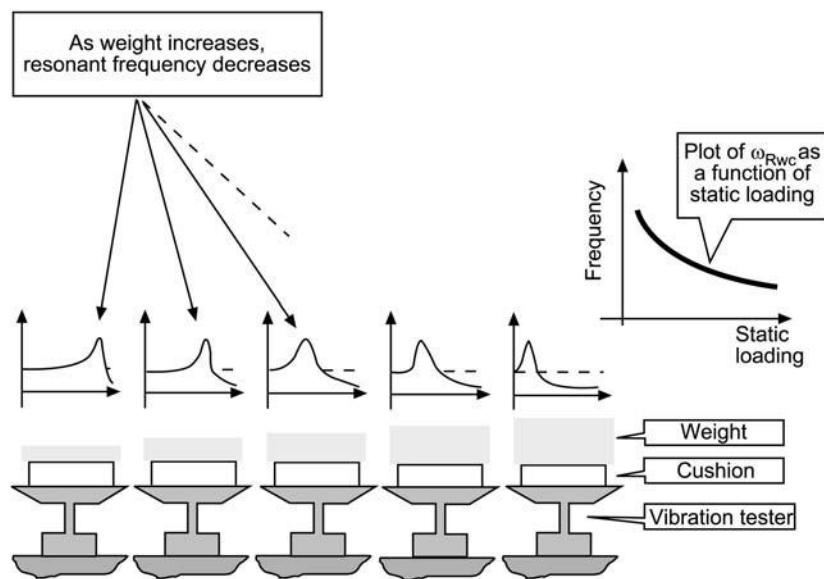

Figure 8 Building transmissibility curves.

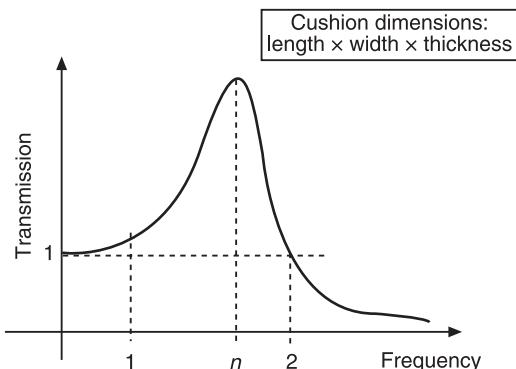

Figure 9 Data for constructing transmissibility curves.

material. Most materials have different behaviors as force is applied in different directions, so it is important to note the direction of force application. Creep data is determined by measuring slow deformation over time as a constant force is applied on the material.

Different materials have different properties. For all practical purposes, there is not such a thing as a good or bad cushioning material, neither an overall ‘superior’ cushioning material. What one may find is a bad design, using incorrect information. As long as a material deflects when a dynamic force is imposed on it, it should work as a cushion for product protection. In design, one is to find the range of conditions in which the material will work satisfactorily.

Packaging Design

The package is designed by combining all nine elements of data obtained (last three rows in Table 1). Usually the first thing to do is to determine the range of static loading (product weight over cushion bearing area) that will provide maximum product protection against impacts. Then, the material chosen is studied for vibration transmission and creep. The result must be a material configuration that works for all three factors: shock, vibration and compression. Figures 11–13 show how the static loading is picked from cushion curves and vibration transmissibility curves and how the information is combined to determine the proper static loading for product protection. This procedure is done for each face of the product. After the static loading for each product face

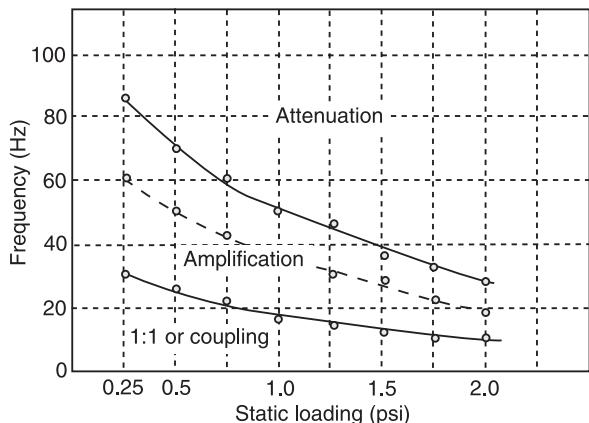

Figure 10 Vibration transmissibility curves for data in **Figure 9**.

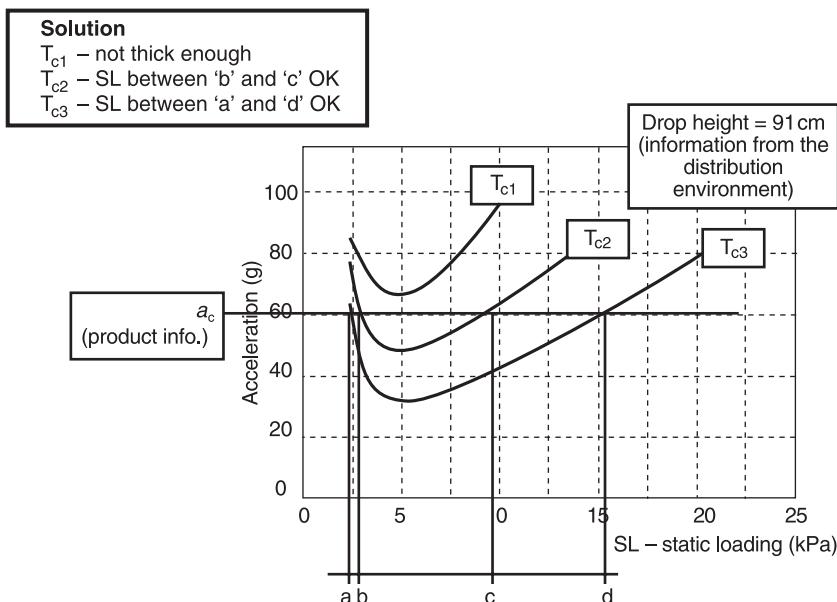

Figure 11 Selecting static loading for shock.

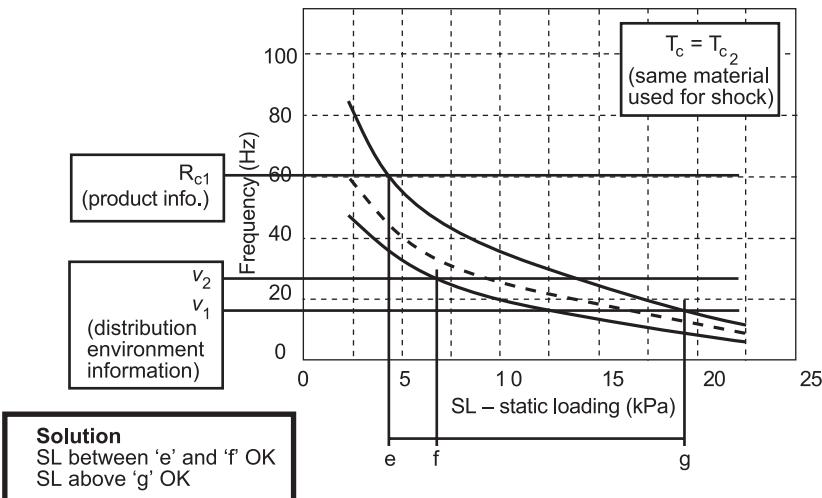

Figure 12 Selecting static loading for vibration.

is selected, as shown in Figure 13, the designer determines how the required cushion area is to be distributed on the product's face. At this point, care is taken that the area is distributed according to the location of the center of gravity, and that the area of individual cushion blocks are not too small compared to the cushion thickness, otherwise buckling may occur during impacts.

Packaging Testing

Packaging performance testing is a common procedure, used to determine the performance of the

packaging system when subjected to tests that simulate the conditions used for design. Tests may be performed according to general standards (such as American Society for Testing and Materials, ASTM, International Safe Transit Association, ISTA, or International Standards Organization, ISO), or to specific protocols, that are generally company-specific. Most testing protocols include the following tests: free fall drop, random vibration, and compression.

There are various types of testers that may be used. The combination of testing equipment available and the knowledge about the distribution environment hazards usually define the testing protocol used. An

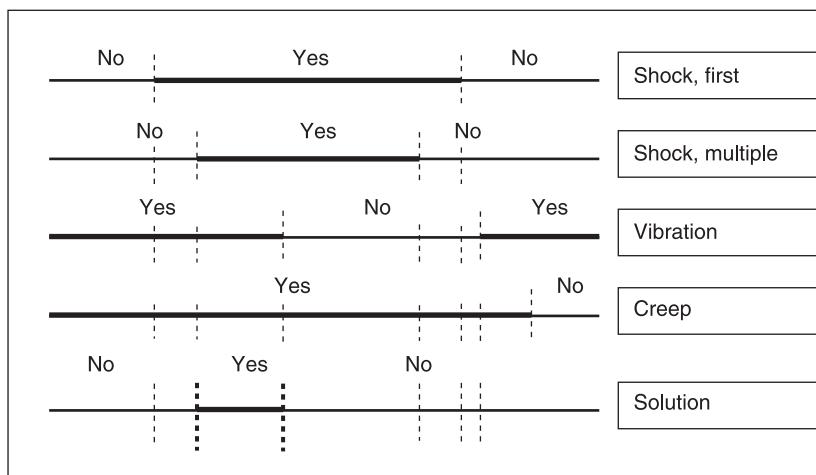

Figure 13 Choosing static loading.

important issue to be considered is the clear definition of the acceptance criteria, or damage. Sometime this is rather straightforward, but for some products it may be quite difficult to draw the line between pass and fail.

Nomenclature

a_c	product critical acceleration or shock fragility
D_f	dynamic factor
F_d	dynamic vertical force on bottom package
F_s	static vertical force on bottom package
g	acceleration of gravity
H_p	height of a package
H_s	height of a stack of identical packages in storage
H_t	height of a stack of identical packages in transport
L_p	length of a package
m_a	mass of an accelerometer
m_c	mass of a products component
m_p	mass of each of the identical packages in the stack
n_s	number of identical packages in a stack in storage
n_t	number of identical packages in a stack in transport
SL	static loading
T_c	cushion thickness
W_p	width of a package
δ_L	load density
ω_{Rc}	resonant frequency of a products component
ω_{Rca}	measured resonant frequency of a products component plus accelerometer attached to it

ω_{Rwc}	resonant frequency of a weight/cushion combination
$\omega\nu_1$	lower end of a frequency range with high vibration intensity in a vehicle
$\omega\nu_2$	upper end of a frequency range with high vibration intensity in a vehicle
ω_1	boundary between coupling and amplification in transmissibility curves
ω_2	boundary between amplification and attenuation in transmissibility curves

Introduction

To perform numerical simulations of complex systems, powerful computing systems are required. Computational speed and memory size are continuously improving thanks to breakthroughs in electronic ship technologies and to advanced computer architecture (vector instructions, RISC processors, caching ...). So-called supercomputing systems can be obtained by teaming together several computing units in order to increase the computing power and the memory that can be managed. It is not the intention of this text to review the technology of parallel computers, but it is essential to understand the architecture of such machines in order to make good use of their high-performance computing (HPC) capabilities.

Parallel computers are mainly characterized according to the following aspects:

- **Granularity.** Coarse grain computers have a small number of processors (e.g., 32) and are used for applications where the problem to be solved calls for multitasking with a high degree of interdependence between tasks. Fine grain supercomputers contain up to several thousands of processors and are suitable for applications involving highly independent tasks such as in neural networks.
- **Memory organization.** For a shared memory machine, the same memory is accessible to all the processors, meaning that a data has a single address for all processors. In distributed memory machines, every processor manages its memory locally and data are exchanged between processors by sending messages (message passing paradigm). To handle the message passing and synchronization between processors, users rely on specific instructions provided by the computer manufacturer or use standard packages such as MPI (message passing interface). It should be noted that in shared

memory machines, memory is also physically distributed among the processors in order to avoid saturation of the communication network between processors and memories. But the data handling is then performed by the operating system and is transparent to the user. The advantage of shared memory machines is that it simplifies programming and ensures that a data exists only once, but the user has a better control on the data traffic in distributed memory machines.

- **Interconnectivity.** The topology of the network connecting all the processors and memory locations is of primordial importance to the user in order to make efficient use of the hardware. Some of the basic interconnectivity topologies are described in Figure 1. The computing modules are in a single box (supercomputers) or separated such as in a cluster of interconnected computers.

For some applications, it is sufficient if every processor performs the same task but on different data (single instruction/multiple data (SIMD)). For most scientific computing applications however, MIMD (multiple instructions/multiple data) computers are used.

The fundamental question in parallel computing is ‘Do we compute faster if we run the job on more processors?’ Parallel performance is measured by the speed-up S_p and the parallel efficiency E_p defined as:

$$S_p = t_1/t_p \quad \text{and} \quad E_p = S_p/p \quad [1]$$

where t_1 and t_p are the time required to perform the computation on one processor and on p processors, respectively.

The parallel efficiency that can be achieved depends on the fraction f of work that must be performed sequentially. The maximum speed-up that can be obtained when increasing the number of processors used to solve a given problem is $S_p = 1/f$ and the parallel efficiency E_p goes to zero (Amdahl’s law). Hence it is essential to design algorithms with a minimum fraction of sequential work. If we now assume that the size of the problem to be solved

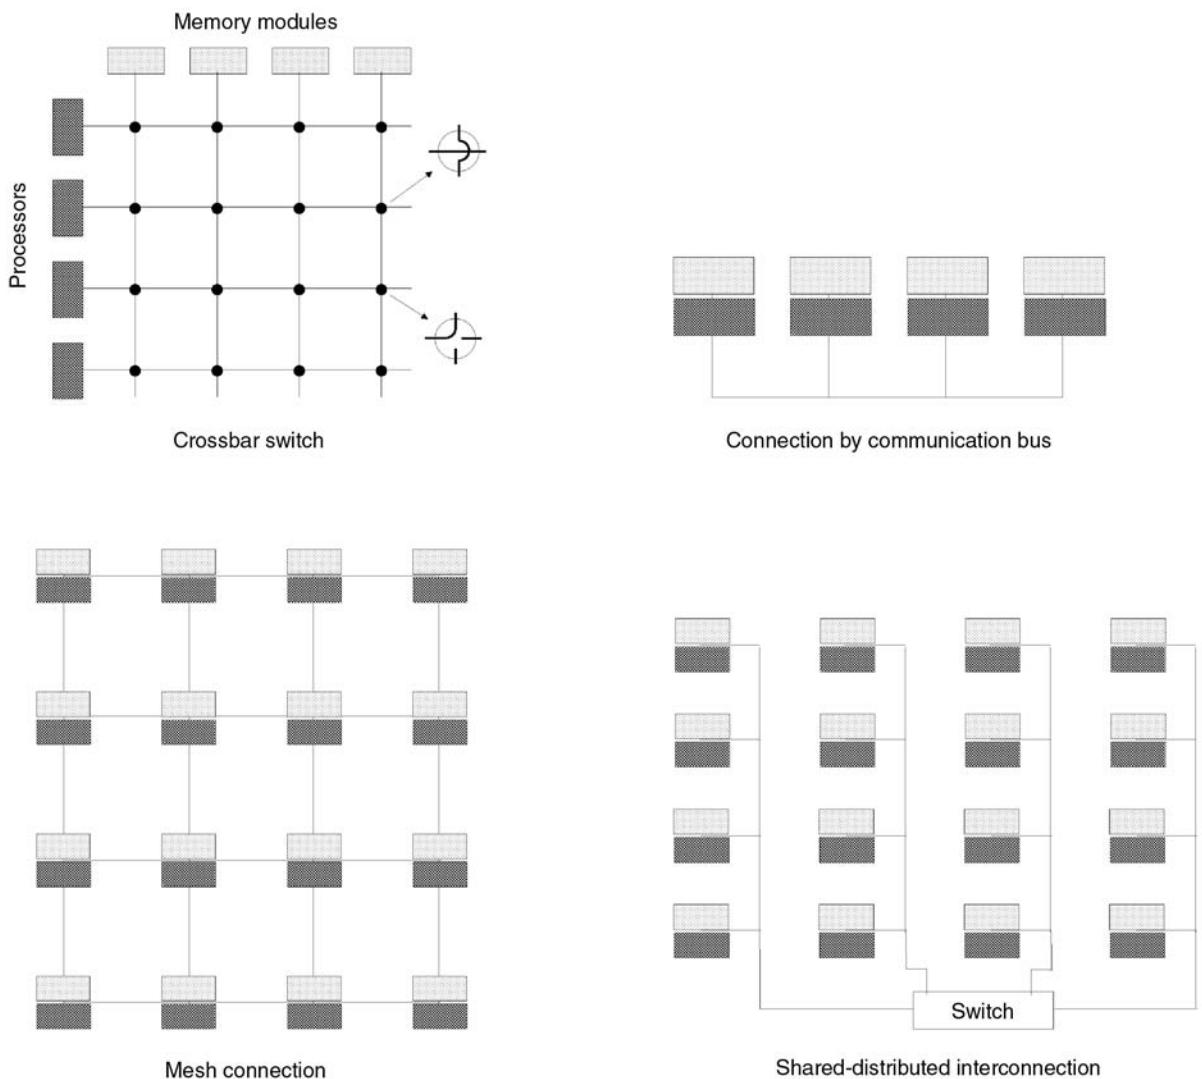

Figure 1 Network topology of parallel computers.

increases proportionally to the number of processors used (e.g. because memory size increases with the number of processors), the maximum speed-up that can be achieved tends towards $S_p = p(1 - f)$ which is a more optimistic perspective (Gustafson's model). Let us note that communication costs are not included in this simple analysis.

Reorganizing in parallel subtasks the way the final result will be computed can lead to an increase in the number of operations, hence jeopardizing the desired parallel efficiency. The property of an algorithm to incur a constant (or nearly constant) number of operations when the number of processors is increased is known as numerical scalability. Although numerical scalability is an essential property of a parallel algorithm, it will exhibit parallel scalability, i.e. deliver larger speed-up for a larger number of processors only if the communication costs and man-

agement overhead are small. Unfortunately, numerical scalability is usually obtained by transferring data among processors and thus numerical and parallel scalability are generally conflicting objectives.

Some operations can be parallelized in a straightforward manner such as multiplying and adding matrices. Indeed basic matrix operations can be distributed among processors by partitioning the matrices into blocks. Most machines are provided with a library of matrix routines optimized for the specific processor and network architecture (basic linear algebra subprograms (BLAS)). However, in engineering computations, most of the computing time is spent in solving systems of equations. Designing efficient parallel solvers is not easy and is usually problem dependent. In the next section we will discuss the different approaches advocated for building parallel solvers.

Direct and Iterative Parallel Solvers

For some special engineering problems, naturally independent tasks can be easily defined (e.g., computing the coefficients of the Fourier expansion of the solution in an axisymmetric structure or evaluating simultaneously different designs in optimization). However, in general, a single system or a sequence of nonsimultaneous systems of equations must be solved. Solving large linear systems on parallel computers has been, and still is, a challenging research field since algorithms that are highly efficient for sequential machines usually perform poorly on parallel computers. Parallel solvers can be constructed in different ways as explained next. First by re-organizing classical factorization methods and secondly by applying iterative solvers. Some of the most efficient methods, however, are found by combining direct and iterative solvers.

Direct Solvers

Consider the linear system:

$$\mathbf{K}\mathbf{u} = \mathbf{f} \quad [2]$$

where \mathbf{K} is for instance a stiffness matrix, a dynamic

time-stepping operator or a tangent matrix in nonlinear analysis, and where \mathbf{u} is the set of degrees of freedom (DOF). Direct solvers perform the factorization of \mathbf{K} (e.g., Gaussian factorization) and forward/backward substitutions to find \mathbf{u} . The looping sequence on rows and columns within the factorization and substitutions can be organized in order to maximize the amount of independent (i.e., parallel) tasks. However, as the number of processors increases, the parallel efficiency becomes very poor due to the large amount of communications required by the inherently sequential factorization and substitution algorithm.

A better alternative is then to use an approach similar to multifrontal or block-LU methods. Assuming that the structure is subdivided into N_s subparts (called substructures or subdomains) as in Figure 2, each part $\Omega^{(s)}$ has internal DOF $\mathbf{u}_i^{(s)}$ and boundary DOF $\mathbf{u}_b^{(s)}$ on the interface. Calling $\mathbf{f}_i^{(s)}$ and $\mathbf{f}_b^{(s)}$ the forces applied on the internal and boundary DOF, the local equilibrium of a subdomain $\Omega^{(s)}$ is:

$$\begin{bmatrix} \mathbf{K}_{ii}^{(s)} & \mathbf{K}_{ib}^{(s)} \\ \mathbf{K}_{bi}^{(s)} & \mathbf{K}_{bb}^{(s)} \end{bmatrix} \begin{bmatrix} \mathbf{u}_i^{(s)} \\ \mathbf{u}_b^{(s)} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_i^{(s)} \\ \mathbf{f}_b^{(s)} + \mathbf{g}^{(s)} \end{bmatrix} \quad [3]$$

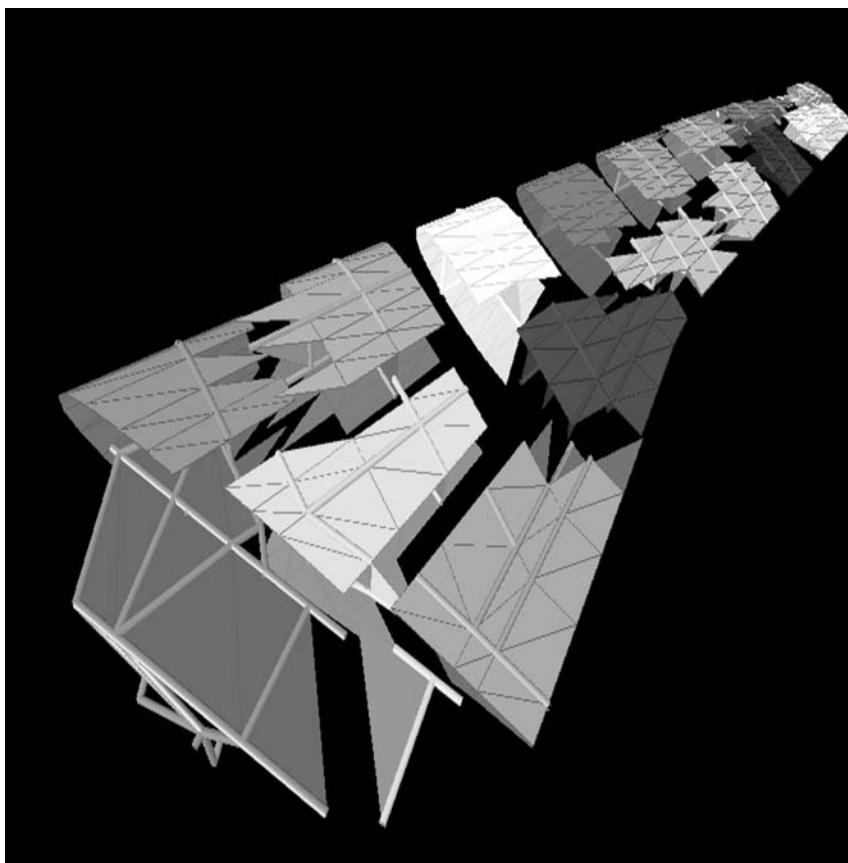

Figure 2 (See Plate 50). Nonoverlapping decomposition of a finite element model. (Courtesy of the Center for Aerospace Structures, University of Colorado, Boulder.)

where $\mathbf{g}^{(s)}$ are the connection forces to the neighboring domains. The local DOF are then identified to the global set \mathbf{u} by:

$$\begin{bmatrix} \mathbf{u}_i^{(s)} \\ \mathbf{u}_b^{(s)} \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \cdots & \mathbf{0} & \mathbf{I} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{L}_b^{(s)} \end{bmatrix} \begin{bmatrix} \mathbf{u}_i^{(1)} \\ \vdots \\ \mathbf{u}_i^{(N_s)} \\ \mathbf{u}_b \end{bmatrix} \quad [4]$$

or:

$$\mathbf{u}^{(s)} = \mathbf{L}^{(s)}\mathbf{u} \quad [5]$$

where $\mathbf{L}_b^{(s)}$ is a Boolean matrix expressing the assembly of the subdomains on the interface. The initial problem (eqn [2]) can now be expressed as if it results from the assembly of the substructures, namely:

$$\left(\sum_{s=1}^{N_s} \mathbf{L}^{(s)\top} \mathbf{K}^{(s)} \mathbf{L}^{(s)} \right) \mathbf{u} = \sum_{s=1}^{N_s} \mathbf{L}^{(s)\top} \mathbf{f}^{(s)} \quad [6]$$

or:

$$\begin{bmatrix} \mathbf{K}_{ii}^{(1)} & \mathbf{0} & \mathbf{0} & \mathbf{K}_{ib}^{(1)} \mathbf{L}_b^{(1)} \\ \mathbf{0} & \ddots & \mathbf{0} & \vdots \\ \mathbf{0} & \mathbf{0} & \mathbf{K}_{ii}^{(N_s)} & \mathbf{K}_{ib}^{(N_s)} \mathbf{L}_b^{(N_s)} \\ \mathbf{L}_b^{(1)\top} \mathbf{K}_{bi}^{(1)} & \cdots & \mathbf{L}_b^{(N_s)\top} \mathbf{K}_{bi}^{(N_s)} & \sum_{s=1}^{N_s} \mathbf{L}_b^{(s)\top} \mathbf{K}_{bb}^{(s)} \mathbf{L}_b^{(s)} \end{bmatrix} \times \begin{bmatrix} \mathbf{u}_i^{(1)} \\ \vdots \\ \mathbf{u}_i^{(N_s)} \\ \mathbf{u}_b \end{bmatrix} = \begin{bmatrix} \mathbf{f}_i^{(1)} \\ \vdots \\ \mathbf{f}_i^{(N_s)} \\ \sum_{s=1}^{N_s} \mathbf{L}_b^{(s)\top} \mathbf{f}_b^{(s)} \end{bmatrix} \quad [7]$$

This expression indicates that the internal stiffness matrices $\mathbf{K}_{ii}^{(s)}$ can be factorized independently, which is equivalent to eliminating all internal DOF to build the condensed interface problem for \mathbf{u}_b . Computing \mathbf{u}_b then requires the factorization of the global interface operator. Thus, the decomposition should be such that the number of interface DOF is small in order to minimize the size of the global interface problem. Also the work load between processors when factorizing $\mathbf{K}_{ii}^{(s)}$ must be well balanced. This approach is efficient on a small number of processors, but it does not scale well on massively parallel computers because the condensed interface problem can-

not be efficiently factorized in parallel and its size increases as the decomposition is refined, thereby putting the overall speed-up in jeopardy.

Iterative Methods

Factorization schemes are inherently sequential since they are based on Gaussian elimination where the solution is obtained for one variable after the other. In contrast, iterative solvers search for approximations of all unknowns simultaneously and involve simple matrix operations. They are thus naturally parallel. Iterative methods use only a small amount of memory space since the matrices need not be explicitly assembled or factorized. For that reason, they are commonly used in computational fluid mechanics to solve large nonlinear problems. In structural analysis, direct solvers have been favored for their robustness compared to iterative methods where fast convergence can be difficult to achieve in practice. With the advent of parallel computing however, iterative methods have gained new momentum.

Iterative solvers look for a solution in a subspace $\mathbf{v}_k = \text{span}\{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_k\}$ where the dimension of the search space increases at every iteration. For symmetric positive-definite systems, the most effective algorithm is the conjugate gradient method. It can be interpreted as successive Rayleigh–Ritz approximations: at iteration k , find the best solution in subspace \mathbf{v}_k spanning the columns of $\mathbf{Y}_k = [\mathbf{y}_1 \mathbf{y}_2 \dots \mathbf{y}_k]$ as:

$$\mathbf{u}_k = \mathbf{Y}_k \boldsymbol{\eta}_k \quad [8]$$

$$(\mathbf{Y}_k^\top \mathbf{K} \mathbf{Y}_k) \boldsymbol{\eta}_k = \mathbf{Y}_k^\top \mathbf{f} \quad [9]$$

In the next step $k+1$, a new search direction \mathbf{y}_{k+1} related to the residual $\mathbf{r}_k = \mathbf{f} - \mathbf{K}\mathbf{u}_k$ is then added to the subspace. If the new direction \mathbf{y}_{k+1} is orthogonalized with respect to the previous subspace such that $\mathbf{Y}_k^\top \mathbf{K} \mathbf{y}_{k+1} = \mathbf{0}$, the new approximation is easily found as:

$$\begin{aligned} \mathbf{u}_{k+1} &= \mathbf{Y}_{k+1} \boldsymbol{\eta}_{k+1} = [\mathbf{Y}_k \quad \mathbf{y}_{k+1}] \begin{bmatrix} \eta_k \\ \eta_{k+1} \end{bmatrix} \\ &= \mathbf{u}_k + \eta_{k+1} \mathbf{y}_{k+1} \end{aligned} \quad [10]$$

where:

$$\eta_{k+1} = \frac{\mathbf{y}_{k+1}^\top \mathbf{f}}{\mathbf{y}_{k+1}^\top \mathbf{K} \mathbf{y}_{k+1}} = \frac{\mathbf{y}_{k+1}^\top \mathbf{r}_k}{\mathbf{y}_{k+1}^\top \mathbf{K} \mathbf{y}_{k+1}} \quad [11]$$

A conjugate gradient iteration step involves simple matrix operations that can be performed for instance by BLAS routines or based on domain decomposition

as indicated by the splitting (eqn [6]). Hence iterative schemes are naturally parallel.

The iterations are stopped when the relative norm $\|\mathbf{r}_k\|/\|\mathbf{f}\|$ is below a user defined tolerance ε . For the iterations to converge quickly, the search directions \mathbf{y}_{k+1} are chosen as:

$$\mathbf{y}_{k+1} = \tilde{\mathbf{K}}^{-1} \mathbf{r}_k + Y_k \boldsymbol{\beta} \quad [12]$$

where $\tilde{\mathbf{K}}^{-1}$ is an approximation of the inverse of \mathbf{K} called the preconditioner and where $\boldsymbol{\beta}$ are the coefficients of orthogonalization with respect to previous directions. Note that because of recursive orthogonality properties between conjugate gradient directions, \mathbf{y}_{k+1} needs to be orthogonalized only with respect to the previous direction \mathbf{y}_k . Nevertheless, due to round-off errors, full re-orthogonalization is required in practice. The algorithm is summarized in Table 1.

For the conjugate gradient algorithm, the preconditioner $\tilde{\mathbf{K}}^{-1}$ must be symmetric positive definite and the cost of computing $\tilde{\mathbf{K}}^{-1} \mathbf{r}_k$ must be small. The convergence of the iteration is function of the condition number $\kappa(\tilde{\mathbf{K}}^{-1} \mathbf{K})$, namely the better $\tilde{\mathbf{K}}^{-1}$ approximates the inverse of \mathbf{K} , the better the convergence. Efficient preconditioners $\tilde{\mathbf{K}}^{-1}$ such as those obtained by incomplete factorization of \mathbf{K} or by multigrid methods, are required to solve global problems and are not suitable for parallel computation with a high number of processors. Note that parallel incomplete block factorization schemes have been proposed, but their effectiveness becomes poor as the number of processors increases.

When using direct solvers, once the matrix has been factorized, low cost forward and backward substitutions are used to solve problems with multiple right-hand sides. This is an essential feature for instance when computing linear static solutions for multiple load cases, in inverse power iterations for eigenvalue computations and when performing implicit time-integration. For the iterative conjugate gradient method, computations performed to solve the system with the first right-hand side can be reused as follows.

Let us call \mathbf{Y}_{k_1} the matrix of the search directions of the iterations for the first right-hand side \mathbf{f}_1 , and let us assume that the results $\mathbf{K} \mathbf{Y}_{k_1}$ computed during those iterations have been stored. An initial guess for the solution relative to a second right-hand side \mathbf{f}_2 is then searched in the subspace \mathbf{Y}_{k_1} , such that:

$$\mathbf{u}_0 = \mathbf{Y}_{k_1} \boldsymbol{\eta}_0 \quad [13]$$

$$\mathbf{r}_0 = \mathbf{f}_2 - (\mathbf{K} \mathbf{Y}_{k_1}) \boldsymbol{\eta}_0 \quad [14]$$

where:

$$\boldsymbol{\eta}_0 = (\mathbf{Y}_{k_1}^T \mathbf{K} \mathbf{Y}_{k_1})^{-1} (\mathbf{Y}_{k_1}^T \mathbf{f}_2) \quad [15]$$

Finding this initial approximation is a low cost operation since $\mathbf{Y}_{k_1}^T \mathbf{K} \mathbf{Y}_{k_1}$ is a diagonal matrix. Then, starting from \mathbf{u}_0 , conjugate gradient iterations can be performed and the new search directions will be orthogonalized to all previous ones, including \mathbf{Y}_{k_1} . Obviously, once the number of search directions in \mathbf{Y} is equal to the dimension of the system, the exact solution will be found.

Similarly to the Lanczos method, the search directions of the conjugate gradient iterations belong to the so-called Krylov space $\mathcal{K} = \text{span } \{\mathbf{y}_1, \mathbf{K} \mathbf{y}_1, \dots, \mathbf{K}^k \mathbf{y}_1\}$. For nonsymmetric systems, similar ideas can be used to design iterative solvers such as the biconjugate gradient algorithm and the popular generalized minimum residual (GMRES) method.

Domain Decomposition Methods and Semi-iterative solvers

Direct solvers are very robust but do not scale well on parallel computers because the factorization process and the substitutions are inherently sequential procedures. On the other hand, iterative solvers are naturally parallel but obtaining parallel scalability is difficult because efficient preconditioners are expensive and not parallel. Hence, some of the most efficient and useful parallel solvers rely on domain decomposition of the structure and use a blend of direct solvers to solve independent local problems

and iterative solvers to solve the globally coupled interface problem.

The first domain decomposition method goes back to Schwarz in 1870. The Schwarz method iterates between overlapping subdomains (i.e. where DOF in the vicinity of the interface belong to more than one partition) and is mathematically similar to the Gauss–Seidel algorithm. Most algorithms in use today consider nonoverlapping decompositions as in Figure 2.

In order to simplify the discussion, let us consider the case of a structure divided into two subdomains (Figure 3). The compatibility between the two parts can be enforced in two different ways leading to two different approaches of domain decomposition.

The Primal Schur Complement Method

The compatibility between the two parts in Figure 3 can be enforced by stating that the boundary DOF in each subdomain are unique. Assuming that the boundary DOF $\mathbf{u}_b^{(1)}$ and $\mathbf{u}_b^{(2)}$ are numbered in the same order:

$$\mathbf{u}_b^{(1)} = \mathbf{u}_b^{(2)} = \mathbf{u}_b \quad [16]$$

and the assembled system can be written as:

$$\begin{bmatrix} \mathbf{K}_{ii}^{(1)} & \mathbf{K}_{ib}^{(1)} & \mathbf{0} \\ \mathbf{K}_{bi}^{(1)} & \mathbf{K}_{bb}^{(1)} + \mathbf{K}_{bb}^{(2)} & \mathbf{K}_{bi}^{(2)} \\ \mathbf{0} & \mathbf{K}_{ib}^{(2)} & \mathbf{K}_{ii}^{(2)} \end{bmatrix} \begin{bmatrix} \mathbf{u}_i^{(1)} \\ \mathbf{u}_b \\ \mathbf{u}_i^{(2)} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_i^{(1)} \\ \mathbf{f}_b \\ \mathbf{f}_i^{(2)} \end{bmatrix} \quad [17]$$

Eliminating the internal DOF, we find:

$$\mathbf{u}_i^{(s)} = \mathbf{K}_{ii}^{(s)-1} \left(-\mathbf{K}_{ib}^{(s)} \mathbf{u}_b + \mathbf{f}_i^{(s)} \right) \quad [18]$$

and the following condensed interface problem is obtained:

$$\mathbf{S}_{bb} \mathbf{u}_b = \mathbf{f}_b^{(1)*} + \mathbf{f}_b^{(2)*} \quad [19]$$

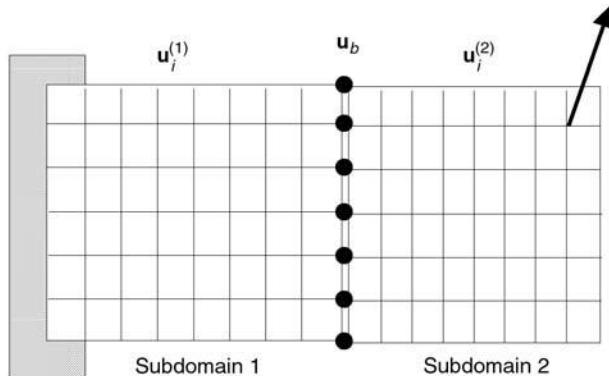

Figure 3 A simple structure partitioned into two subdomains.

where:

$$\begin{aligned} \mathbf{S}_{bb} &= \left(\mathbf{S}_{bb}^{(1)} + \mathbf{S}_{bb}^{(2)} \right) \\ \mathbf{S}_{bb}^{(s)} &= \mathbf{K}_{bb}^{(s)} - \mathbf{K}_{bi}^{(s)} \mathbf{K}_{ii}^{(s)-1} \mathbf{K}_{ib}^{(s)} \\ \mathbf{f}_b^{(s)*} &= \mathbf{f}_b^{(s)} - \mathbf{K}_{bi}^{(s)} \mathbf{K}_{ii}^{(s)-1} \mathbf{f}_i^{(s)} \end{aligned} \quad [20]$$

The operators $\mathbf{S}_{bb}^{(s)}$ are the local operators condensed on the interface and correspond to the mathematical concept of Schur complements, and \mathbf{S}_{bb} represents the assembled interface operator. An efficient parallel procedure based on eqn [19] then consists in factorizing the internal matrices $\mathbf{K}_{ii}^{(s)}$ independently on different processors and solving the interface problem (eqn [19]) for \mathbf{u}_b iteratively.

For an approximate solution $\mathbf{u}_{b,k}$ found at iteration k , the corresponding interface forces $\mathbf{r}^{(s)} = \mathbf{f}^{(s)*} - \mathbf{S}_{bb}^{(s)} \mathbf{u}_{b,k}$ are computed on each side of the interface and assembling these forces on the interface, the interface equilibrium $\mathbf{r}_k = \mathbf{r}^{(1)} + \mathbf{r}^{(2)}$ is evaluated (see left-hand side of Figure 4). A correction $\Delta \mathbf{u}_{b,k+1}$ to the interface unknowns $\mathbf{u}_{b,k}$ is then estimated in the preconditioning step as follows.

The difference between $\mathbf{u}_{b,k}$ and the exact solution is $\Delta \mathbf{u}_{b,k+1} = \mathbf{S}_{bb}^{-1} \mathbf{r}_k$ which is approximated by:

$$\Delta \mathbf{u}_{b,k+1} = \frac{1}{2} \left(\mathbf{S}_{bb}^{(1)-1} + \mathbf{S}_{bb}^{(2)-1} \right) \frac{\mathbf{r}_k}{2} \quad [21]$$

This correction can be computed in parallel and its mechanical interpretation is described in the right part of Figure 4: apply half of the residual force \mathbf{r}_k on the boundary of each subdomain and compute the corresponding interface displacement $\Delta \mathbf{u}_b^{(s)} = \mathbf{S}_{bb}^{(s)} (\mathbf{r}_k / 2)$. The correction for the interface displacement is then the average of the displacements on each side of the interface. This step involves solving local Neumann problems (force applied on the interface) and is therefore called the Neumann preconditioner.

In the expression [21] of the preconditioner, it is assumed that the local operators $\mathbf{S}_{bb}^{(s)}$ are nonsingular. When $\mathbf{K}^{(s)}$ is a stiffness matrix of a subdomain that possesses modes of zero deformation energy (rigid body modes or kinematical modes), then the associated Schur complement is singular. For instance in Figure 3, the right subdomain has not enough constraints on its external boundaries to prevent it from floating when it is not connected to the left subdomain. In that case, the problem of finding $\Delta \mathbf{u}_b^{(2)}$ when the force $\mathbf{r}_k / 2$ is applied on its interface has a solution only if $\mathbf{r}_k / 2$ is self-equilibrated. Calling $\mathbf{R}_b^{(2)}$ the matrix which columns are the restriction on

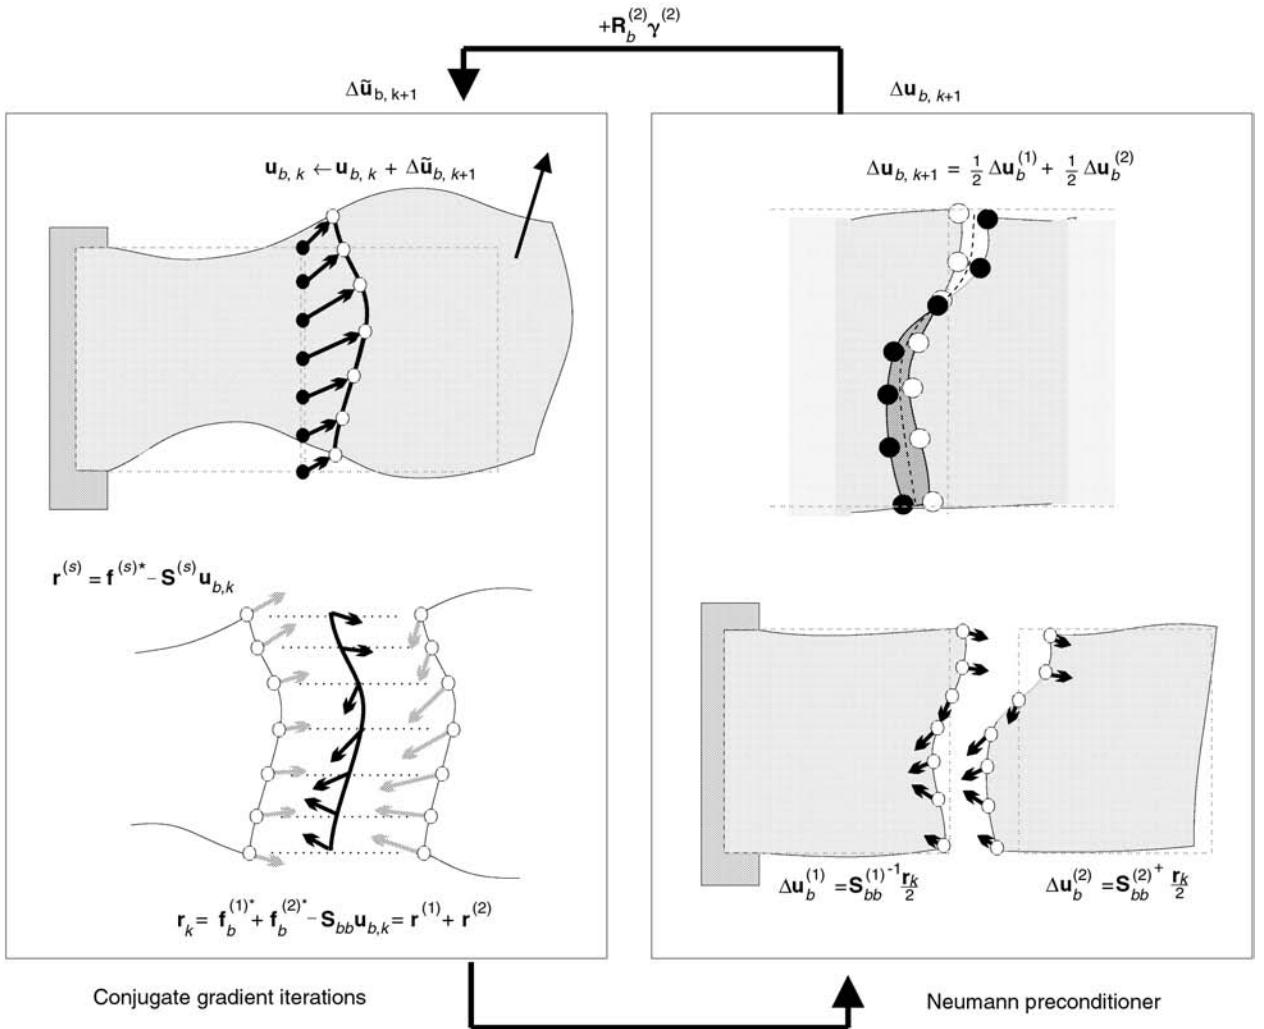

Figure 4 The balanced primal Schur complement method.

the interface of the local rigid modes (i.e., the nullspace of $\mathbf{S}_{bb}^{(2)}$):

$$\mathbf{S}_{bb}^{(2)} \Delta \mathbf{u}_b^{(2)} = \frac{\mathbf{r}_k}{2} \quad [22]$$

has a solution only if:

$$\mathbf{R}_b^{(2)\top} \frac{\mathbf{r}_k}{2} = 0 \quad [23]$$

If this condition is satisfied, the Neumann preconditioning step can be written as:

$$\Delta \mathbf{u}_{b,k+1} = \frac{1}{2} \left(\mathbf{S}_{bb}^{(1)-1} + \mathbf{S}_{bb}^{(2)+} \right) \frac{\mathbf{r}_k}{2} \quad [24]$$

where $\mathbf{S}_{bb}^{(2)+}$ is a generalized inverse of $\mathbf{S}_{bb}^{(2)}$. Rigid body displacements are then added to $\Delta \mathbf{u}_{b,k+1}$ to construct the modified correction:

$$\begin{aligned} \Delta \tilde{\mathbf{u}}_{b,k+1} \\ = \left(\mathbf{I} - \mathbf{R}_b^{(2)} \left(\mathbf{R}_b^{(2)\top} \mathbf{S}_{bb} \mathbf{R}_b^{(2)} \right)^{-1} \mathbf{R}_b^{(2)\top} \mathbf{S}_{bb} \right) \Delta \mathbf{u}_{b,k+1} \end{aligned} \quad [25]$$

such that $\mathbf{R}_b^{(2)\top} (\mathbf{S}_{bb} \Delta \tilde{\mathbf{u}}_{b,k+1}) = \mathbf{0}$ and thus, such that the next residual satisfies eqn [23].

Since the iterative solver is applied to the interface problem expressed for the primal variables \mathbf{u}_b , this method is known as the balanced primal Schur complement method. It is summarized in Figure 4.

For N_s subdomains, the method is generalized as follows. Assuming as described in eqn [4] that all local boundary DOF $\mathbf{u}_b^{(s)}$ are linked to the unique interface set by $\mathbf{u}_b^{(s)} = \mathbf{L}_b^{(s)} \mathbf{u}_b$, the interface problem (eqn [19]) can be written as:

$$\mathbf{S}_{bb} \mathbf{u}_b = \mathbf{f}^* \quad [26]$$

where:

$$\mathbf{S}_{bb} = \sum_{s=1}^{N_s} \mathbf{L}_b^{(s)\top} \mathbf{S}_{bb}^{(s)} \mathbf{L}_b^{(s)}$$

$$\mathbf{f}_b^* = \sum_{s=1}^{N_s} \mathbf{L}_b^{(s)\top} \mathbf{f}_b^{(s)*}$$

where $\mathbf{S}_{bb}^{(s)}$ are the Schur complements of the subdomains as defined in eqn [20]. Note that this corresponds to assembling the subdomains as if they were macro-elements and is equivalent to the multifrontal form [7] where the internal DOF have been condensed out. The primal Schur complement method then consists in applying conjugate gradient iterations to solve for \mathbf{u}_b in eqn [26].

Calling m_i the multiplicity of a boundary DOF (i.e., the number of subdomains connecting on the node) and calling $\mathbf{D}^{(s)}$ the diagonal matrix $\text{diag}(1/m_i)$, the Neumann preconditioner is expressed by:

$$\Delta \mathbf{u}_{b,k+1} = \left(\sum_{s=1}^{N_s} \mathbf{L}_b^{(s)\top} \mathbf{D}^{(s)} \mathbf{S}_{bb}^{(s)+} \mathbf{D}^{(s)} \mathbf{L}_b^{(s)} \right) \mathbf{r}_k \quad [27]$$

where \mathbf{r}_k is the residual of [26] and $\mathbf{S}_{bb}^{(s)+}$ is a generalized inverse if subdomain s is floating or, otherwise, the inverse. Calling $\bar{\mathbf{R}}_b^{(s)}$ the rigid modes of subdomain s , the balancing procedure (eqn [25]) becomes:

$$\Delta \tilde{\mathbf{u}}_{b,k+1} = \Delta \mathbf{u}_{b,k+1} + \sum_{s=1}^{N_s} \bar{\mathbf{R}}_b^{(s)} \boldsymbol{\gamma}^{(s)} \quad [28]$$

where:

$$\bar{\mathbf{R}}_b^{(s)} = \mathbf{L}_b^{(s)\top} \mathbf{D}^{(s)} \mathbf{R}_b^{(s)} \quad [29]$$

The amplitudes $\boldsymbol{\gamma}^{(s)}$ of the rigid modes are solution of the coarse grid:

$$\mathbf{S}_{RR} \begin{bmatrix} \boldsymbol{\gamma}^{(1)} \\ \vdots \\ \boldsymbol{\gamma}^{(N_s)} \end{bmatrix} = - \begin{bmatrix} \bar{\mathbf{R}}_b^{(1)\top} \\ \vdots \\ \bar{\mathbf{R}}_b^{(N_s)\top} \end{bmatrix} \mathbf{S}_{bb} \Delta \mathbf{u}_{b,k+1}$$

where:

$$\mathbf{S}_{RR} = \begin{bmatrix} \bar{\mathbf{R}}_b^{(1)\top} \mathbf{S}_{bb} \bar{\mathbf{R}}_b^{(1)} & \cdots & \bar{\mathbf{R}}_b^{(1)\top} \mathbf{S}_{bb} \bar{\mathbf{R}}_b^{(N_s)} \\ \vdots & \ddots & \vdots \\ \bar{\mathbf{R}}_b^{(N_s)\top} \mathbf{S}_{bb} \bar{\mathbf{R}}_b^{(1)} & \cdots & \bar{\mathbf{R}}_b^{(N_s)\top} \mathbf{S}_{bb} \bar{\mathbf{R}}_b^{(N_s)} \end{bmatrix} \quad [30]$$

The algorithm is outlined in Table 2. Let us note that computing the residual \mathbf{r}_k and performing the preconditioning step are naturally parallel operations. The balancing step requires however solving a globally coupled system, but as shown by eqn [30], computing the amplitudes of the rigid body modes is a coarse problem of small dimension.

FETI, the Dual Schur Complement Method

In the primal Schur complement method described above, the compatibility between subdomains was enforced by assembling the interface DOF. Another approach is to introduce connecting forces in order to enforce the compatibility conditions. The interface compatibility is expressed as:

$$\sum_{s=1}^{N_s} \mathbf{B}^{(s)} \mathbf{u}^{(s)} = \mathbf{0} \quad [31]$$

where $\mathbf{B}^{(s)}$ are signed Boolean matrices. For the simple case of two subdomains (Figure 5):

$$\mathbf{B}^{(1)} = [\mathbf{0} \quad \mathbf{I}] \quad \text{and} \quad \mathbf{B}^{(2)} = [\mathbf{0} \quad -\mathbf{I}] \quad [32]$$

Table 2 The balanced primal Schur complement method

$k = 0, \mathbf{u}_{b,0} = \sum_{s=1}^{N_s} \bar{\mathbf{R}}_b^{(s)} \boldsymbol{\gamma}^{(s)}$, where $\begin{bmatrix} \boldsymbol{\gamma}^{(1)} \\ \vdots \\ \boldsymbol{\gamma}^{(N_s)} \end{bmatrix} = \mathbf{S}_{RR}^{-1} \begin{bmatrix} \bar{\mathbf{R}}_b^{(1)\top} \\ \vdots \\ \bar{\mathbf{R}}_b^{(N_s)\top} \end{bmatrix} \mathbf{f}_b^*$ $\mathbf{r}_0 = \mathbf{f}_b^* - \mathbf{S}_{bb} \mathbf{u}_{b,0}$ while $\ \mathbf{r}_k\ > \varepsilon \ \mathbf{f}_b^*\ $ do
-Preconditioning- $\Delta \mathbf{u}_{b,k+1} = \left(\sum_{s=1}^{N_s} \mathbf{L}_b^{(s)\top} \mathbf{D}^{(s)} \mathbf{S}_{bb}^{(s)+} \mathbf{D}^{(s)} \mathbf{L}_b^{(s)} \right) \mathbf{r}_k$
-Balancing- $\Delta \tilde{\mathbf{u}}_{b,k+1} = \Delta \mathbf{u}_{b,k+1} + \sum_{s=1}^{N_s} \bar{\mathbf{R}}_b^{(s)} \boldsymbol{\gamma}^{(s)}$ where $\begin{bmatrix} \boldsymbol{\gamma}^{(1)} \\ \vdots \\ \boldsymbol{\gamma}^{(N_s)} \end{bmatrix} = -\mathbf{S}_{RR}^{-1} \begin{bmatrix} \bar{\mathbf{R}}_b^{(1)\top} \\ \vdots \\ \bar{\mathbf{R}}_b^{(N_s)\top} \end{bmatrix} \mathbf{S}_{bb} \Delta \mathbf{u}_{b,k+1}$
-Orthogonalization of directions- for $i = 1, \dots, k$ do $\beta_i = \frac{\mathbf{y}_i^\top \mathbf{S}_{bb} \Delta \tilde{\mathbf{u}}_{b,k+1}}{\mathbf{y}_i^\top \mathbf{S}_{bb} \mathbf{y}_i}, \quad \mathbf{y}_{k+1} = \Delta \tilde{\mathbf{u}}_{b,k+1} - \beta_i \mathbf{y}_i$ end for $\eta_{k+1} = \frac{\mathbf{y}_{k+1}^\top \mathbf{r}_k}{\mathbf{y}_{k+1}^\top \mathbf{S}_{bb} \mathbf{y}_{k+1}}$ $\mathbf{u}_{b,k+1} = \mathbf{u}_{b,k} + \eta_{k+1} \mathbf{y}_{k+1}$ $\mathbf{r}_{k+1} = \mathbf{r}_k - \eta_{k+1} \mathbf{S}_{bb} \mathbf{y}_{k+1}$ $k = k + 1$ end while

Introducing Lagrange multipliers λ to enforce the compatibility constraints, the initial problem (eqn [2]) can be expressed in the equivalent form:

$$\begin{bmatrix} \mathbf{K}^{(1)} & \mathbf{0} & \mathbf{B}^{(1)\top} \\ \mathbf{0} & \ddots & \vdots \\ \mathbf{B}^{(1)} & \dots & \mathbf{B}^{(N_s)\top} \end{bmatrix} \begin{bmatrix} \mathbf{u}^{(1)} \\ \vdots \\ \mathbf{u}^{(N_s)} \\ \lambda \end{bmatrix} = \begin{bmatrix} \mathbf{f}^{(1)} \\ \vdots \\ \mathbf{f}^{(N_s)} \\ \mathbf{0} \end{bmatrix} \quad [33]$$

where, as shown in Figure 5 for the case of two subdomains, $\mathbf{B}^{(s)\top} \lambda$ are the connecting forces. To find the interface problem, we solve eqn [33] for the local DOF $\mathbf{u}^{(s)}$:

$$\mathbf{u}^{(s)} = \mathbf{K}^{(s)+} (\mathbf{f}^{(s)} - \mathbf{B}^{(s)\top} \lambda) - \mathbf{R}^{(s)} \alpha^{(s)} \quad [34]$$

As before, $\mathbf{K}^{(s)+}$ is the inverse of $\mathbf{K}^{(s)}$ for subdomains with no rigid modes or a generalized inverse if subdomain s is floating, in which case $\mathbf{R}^{(s)}$ are the rigid modes. The forces applied to a floating subdomain must be in self-equilibrium, namely:

$$\mathbf{R}^{(s)\top} (\mathbf{f}^{(s)} - \mathbf{B}^{(s)\top} \lambda) = \mathbf{0} \quad [35]$$

Substituting in the compatibility conditions [31] the expression [34] of $\mathbf{u}^{(s)}$ in terms of λ , and taking into account eqn [35], we find:

$$\begin{bmatrix} \mathbf{F}_I & \mathbf{G}_I \\ \mathbf{G}_I^\top & \mathbf{0} \end{bmatrix} \begin{bmatrix} \lambda \\ \alpha \end{bmatrix} = \begin{bmatrix} \mathbf{d} \\ \mathbf{e} \end{bmatrix} \quad [36]$$

where:

$$\begin{aligned} \mathbf{F}_I &= \sum_{s=1}^{N_s} \mathbf{B}^{(s)\top} \mathbf{K}^{(s)+} \mathbf{B}^{(s)} \\ \mathbf{d} &= \sum_{s=1}^{N_s} \mathbf{B}^{(s)\top} \mathbf{K}^{(s)+} \mathbf{f}^{(s)} \\ \mathbf{G}_I &= \begin{bmatrix} \mathbf{B}^{(1)\top} \mathbf{R}^{(1)} & \dots & \mathbf{B}^{(N_s)\top} \mathbf{R}^{(N_s)} \end{bmatrix} \\ \alpha &= \begin{bmatrix} \alpha^{(1)} \\ \vdots \\ \alpha^{(N_s)} \end{bmatrix} \quad \text{and} \quad \mathbf{e} = \begin{bmatrix} \mathbf{R}^{(1)\top} \mathbf{f}^{(1)} \\ \vdots \\ \mathbf{R}^{(N_s)\top} \mathbf{f}^{(N_s)} \end{bmatrix} \end{aligned}$$

\mathbf{F}_I is the interface flexibility operator, \mathbf{d} is the interface gap created by the applied loads, \mathbf{G}_I is the restriction of the rigid modes on the interface and \mathbf{e} is the default of self-equilibrium of the applied loads. The interface problem (eqn [36]) expresses that the connecting forces should be such that they fill the interface gap created by the external loads, and such

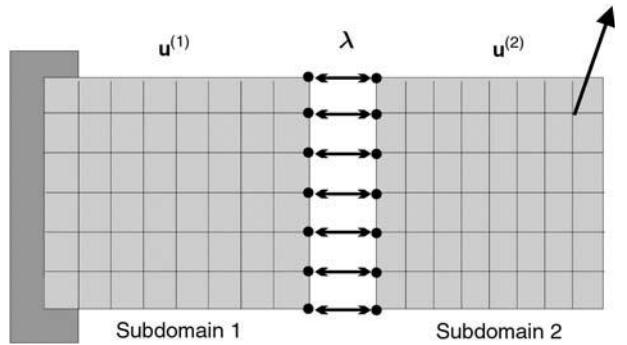

Figure 5 A structure partitioned into two subdomains: the dual approach.

that, together with the applied loads, they are in equilibrium with respect to the local rigid modes (self-equilibrium). Eqn [36] is called the dual interface problem because it is expressed in terms of the dual variables λ representing the interface connecting forces.

In order to reduce the interface to a positive form, the Lagrange multipliers are split as:

$$\lambda = \lambda_0 + \mathbf{P} \bar{\lambda} \quad [37]$$

where:

$$\begin{aligned} \mathbf{P} &= \mathbf{I} - \mathbf{G}_I (\mathbf{G}_I^\top \mathbf{G}_I)^{-1} \mathbf{G}_I^\top \\ \lambda_0 &= \mathbf{G}_I (\mathbf{G}_I^\top \mathbf{G}_I)^{-1} \mathbf{e} \end{aligned}$$

such that the self-equilibrium is satisfied for any λ and the interface problem is finally written as:

$$(\mathbf{P}^\top \mathbf{F}_I \mathbf{P}) \bar{\lambda} = \mathbf{P}^\top (\mathbf{d} - \mathbf{F}_I \lambda_0) \quad [38]$$

An efficient parallel solver then consists in solving the latter equation for λ by conjugate gradient iterations. Indeed, the projection operator \mathbf{P} requires solving only a small coarse grid problem related to the rigid body modes whereas multiplication by \mathbf{F}_I involves solving for $\mathbf{u}^{(s)}$ locally as in eqn [34].

For the convergence of the iterations to be rapid, a good preconditioner is found by observing that the residual \mathbf{r}_k at iteration k on the dual interface problem (eqn [38]) is a compatibility gap on the interface (Figure 6). A good correction for λ in the two sub-domain case is then found as follows: prescribed on both sides of the interface a displacement equal to $\mathbf{r}_k/2$ to bridge the gap. In each subdomain, compute the interface forces required to prescribe those interface displacements as $\Delta f_b^{(s)} = S_{bb}^{(s)} \mathbf{r}_k/2$. A good correction for λ is then given by the average of $\Delta f_b^{(s)}$ on both sides of the interface. This mechanical description is depicted in (Figure 6). Since the estimation of the correction is based on solving Dirichlet problems

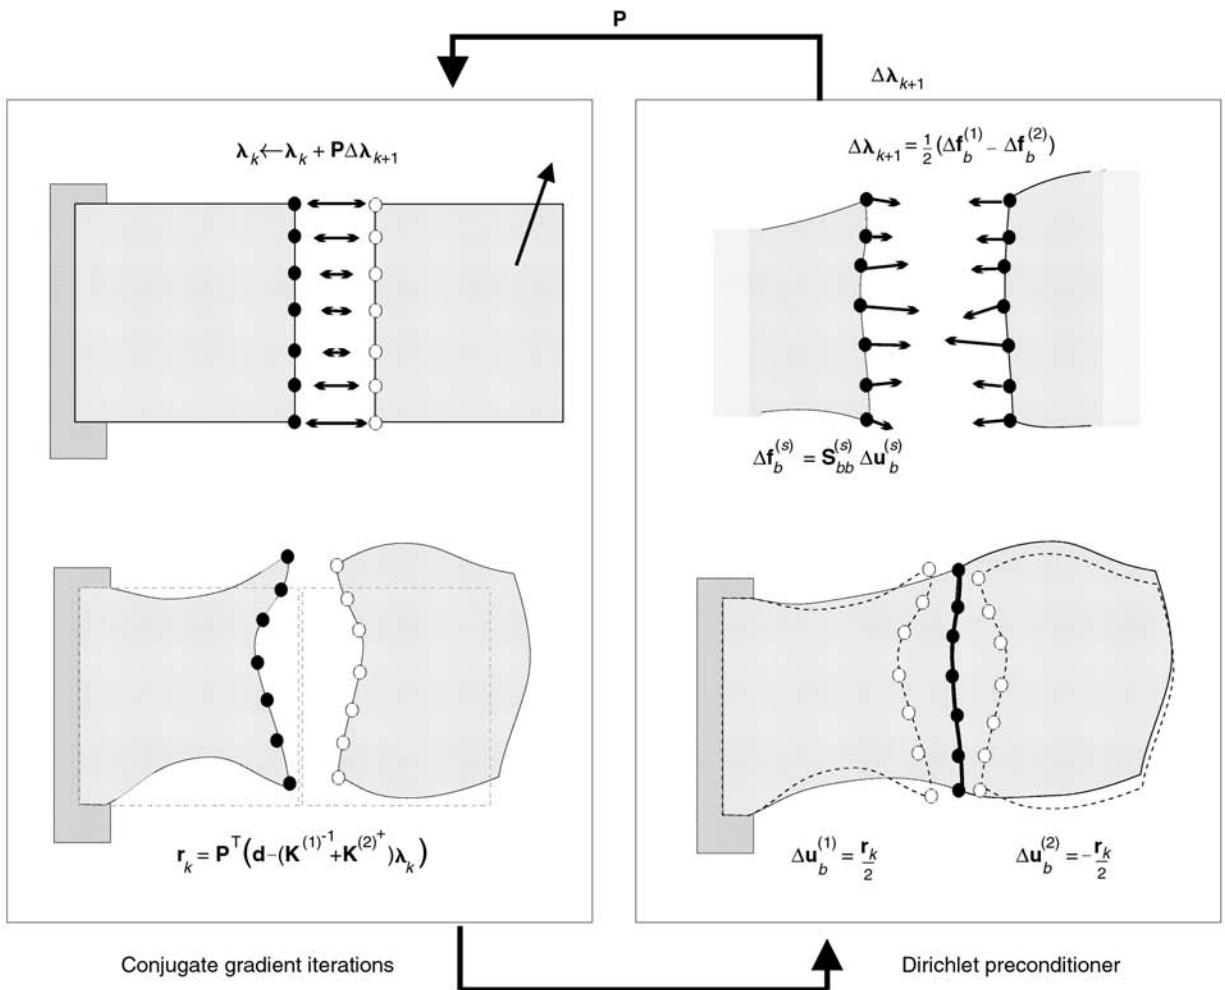

Figure 6 The FETI method.

in each subdomain (prescribed displacements on the interface), the preconditioner is called the Dirichlet preconditioner.

For N_s subdomains the Dirichlet preconditioner is expressed by:

$$\Delta\lambda_{k+1} = \tilde{\mathbf{F}}_I^{-1} \mathbf{r}_k \quad [39]$$

where

$$\tilde{\mathbf{F}}_I^{-1} = \sum_{s=1}^{N_s} \mathbf{B}^{(s)} \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{S}_{bb}^{(s)} \end{bmatrix} \mathbf{B}^{(s)\top}$$

and where it is assumed for the sake of writing the matrix form, that the boundary DOF are numbered last in every subdomain. It is obviously a naturally parallel preconditioner since it involves solving local Dirichlet problems.

The algorithm described above is summarized in Table 3. Since it consists in tearing apart the domains and then ‘gluing them together’ by computing the interconnecting forces, this algorithm is

called finite element tearing and interconnecting (FETI). The method is the dual of the primal Schur complement method and is also called the dual Schur complement method.

Note that the Dirichlet preconditioning step (eqn [39]) can be modified into a low cost variant called the lumped preconditioner:

$$\Delta\lambda_{k+1} = \left(\sum_{s=1}^{N_s} \mathbf{B}^{(s)} \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{K}_{bb}^{(s)} \end{bmatrix} \mathbf{B}^{(s)\top} \right) \mathbf{r}_k \quad [40]$$

It assumes that the internal DOF remain fixed when prescribing interface displacements. Although it yields slower convergence of the iterations on the interface problem, this low cost preconditioner is often used because it reduces the overall computing time.

Primal and Dual Schur Complement Methods in Practice

From the description of the balanced primal Schur complement method and the FETI algorithm, it is

Table 3 The FETI or Dual Schur Complement method.

```

 $k = 0, \lambda_0 = \mathbf{G}_l(\mathbf{G}_l^T \mathbf{G}_l)^{-1} \mathbf{e}$ 
 $\mathbf{r}_0 = \mathbf{P}^T(\mathbf{d} - \mathbf{F}_l \lambda_0)$ 
while  $\|\mathbf{r}_k\| > \varepsilon \|\mathbf{d}\|$  do
    –Preconditioning–
     $\Delta \lambda_{k+1} = \tilde{\mathbf{F}}_l^{-1} \mathbf{r}_k$ 
    –Orthogonalization of directions–
    for  $i = 1, \dots, k$  do
         $\beta_i = \frac{\mathbf{y}_i^T \mathbf{F}_l \Delta \lambda_{k+1}}{\mathbf{y}_i^T \mathbf{F}_l \mathbf{y}_i}, \quad \mathbf{y}_{k+1} = \Delta \lambda_{k+1} - \beta_i \mathbf{y}_i$ 
    end for
     $\eta_{k+1} = \frac{\mathbf{y}_{k+1}^T \mathbf{r}_k}{\mathbf{y}_{k+1}^T \mathbf{F}_l \mathbf{y}_{k+1}}$ 
     $\lambda_{k+1} = \lambda_k + \eta_{k+1} \mathbf{y}_{k+1}$ 
     $\mathbf{r}_{k+1} = \mathbf{P}^T(\mathbf{r}_k - \eta_{k+1} \mathbf{F}_l \mathbf{y}_{k+1})$ 
     $k = k + 1$ 
end while
 $\alpha = (\mathbf{G}_l^T \mathbf{G}_l)^{-1} \mathbf{G}_l^T \mathbf{r}_k$ 
 $\mathbf{u}^{(s)} = \mathbf{K}^{(s)}_{\perp} (\mathbf{f}^{(s)} - \mathbf{B}^{(s)\top} \lambda) - \mathbf{R}^{(s)} \alpha^{(s)}$ 

```

clear that these methods are very similar. For instance, the balanced primal Schur complement iterates on an interface problem involving local Dirichlet solves and has a Neumann preconditioner, whereas the FETI algorithm iterates on a dual interface problem involving local Neumann solves and has a Dirichlet preconditioner. Moreover, the similarity between the balancing step (eqn [30]) for the primal method and the projection \mathbf{P} in FETI is striking: they both define a coarse grid problem where an exact interface solution is computed in the subspace of the rigid body modes. This coarse grid can be understood as solving at every iteration a global problem where the domains are given rigid displacement modes.

The condition number of the preconditioned interface problems of both methods have been shown to be of the order of:

$$\kappa = O(1 + \log(H/h))^2 \quad [41]$$

for regular decompositions and meshes, where H is a characteristic dimension of the domains and where h describes the characteristic dimension of the finite elements. This result indicates that as the number of domains (i.e., H) varies or as the mesh size (i.e., h) is changed, the number of preconditioned iterations on the primal or dual interface problem will only be weakly affected. Both methods are therefore numerically scalable. Moreover, they involve local operations except for the small size coarse grids. Therefore they also exhibit good parallel scalability. It should be noted that the scalability of these methods results from the efficient preconditioners and from the fact that a coarse grid is solved at every iteration similarly to multigrid methods.

Schur complement methods have been successfully used to solve very large problems on several hundred processors. Even on one processor, using domain decomposition and Schur complement methods can speed up the computation.

Several improvements to the basic algorithms described here have been proposed for instance to handle fourth-order problems (shell structures), models with multipoint constraints, and for transient dynamics. Also, for problems where important heterogeneities are present (e.g., structures made of steel and rubber), the methods can be made efficient by changing the multiplicity scaling in the preconditioners into scaling with respect to relative stiffness on the interface. A FETI-H method has been proposed to solve Helmholtz problems arising in acoustics.

To solve problems with multiple right-hand sides, the projection/re-orthogonalization technique described in the section on iterative methods can be used. For problems with several similar left-hand sides such as encountered in nonlinear solvers or in sensitivity analysis, namely when the operator \mathbf{K} changes, the search directions computed for the interface problem in previous solves can be used in a preconditioning step to speed up the convergence.

Decomposing in Domains

The efficiency of domain decomposition solvers highly depends on the subdomain decomposition itself. Several issues must be taken into account when defining a decomposition of a domain, such as load balancing between processors, minimization of the number of interface unknowns and of subdomain interconnectivity, and subdomain aspect ratios.

Finding the optimum decomposition for a large system can be costly. Therefore a quasioptimum decomposition is searched for in two steps: a crude decomposition is first computed and it is then optimized according to a cost function including load balancing, interface size and subdomain aspect ratio.

Decomposition algorithm can be based on simple heuristics such as in the greedy algorithm which simply accumulates a certain number of neighboring nodes to build subdomains. They can also rely on graph partitioning methods.

Introduction

Excitation of a dynamic system is called parametric when the effect of the forcing appears as a coefficient of a variable in the governing equations of motion. This phenomenon leads to the family of time-varying (or nonautonomous) equations, whose coefficients are explicit functions of time. In most of the applications the nature of the explicit time dependence is periodic or can be modeled to be periodic as a good approximation to the true excitation. As a very simple example, consider a child playing on a swing. In order to drive the swing the child leans back and forth rhythmically, providing excitation that destabilizes the vertical equilibrium position of the swing. Although the excitation is not perfectly periodic, it is still a sufficiently accurate model of the motion.

Time-periodic systems play an important role in sciences and engineering, and have been the subject of investigation since 1868, when Mathieu first studied such a system, while analyzing the vibrations of an elliptical membrane. Since that time, the study of time-periodic equations has found applications in many areas such as dynamic stability of structures, circuit theory, systems and control, satellite dynamics, rotating shafts, helicopter rotor blades, quantum mechanics, and biomechanics (human or animal locomotion or modeling the function of the heart). Some physical examples are shown in Figure 1. In many

situations modeling of these systems leads to nonlinear differential equations with periodic coefficients.

In general, it is not possible to obtain exact solutions of time-periodic nonlinear systems, except in a few very special cases. However, in most applications, it may suffice to obtain approximate solutions or information about the stability. The most natural idea is to somehow eliminate the explicit time dependence, and make the system autonomous and amenable to applications of a large number of theories developed for time-invariant systems. This is the basic motivation of point-mapping techniques, which are mainly used in stability and bifurcation theory. In the averaging method an approximate time-invariant system is constructed by averaging the equation over the period. Perturbation techniques seek approximate solutions under various conditions such as resonance, or limit cycle solutions after bifurcations, by assuming the periodic and nonlinear terms of the equation to be small perturbations of a linear time-invariant system. The Liapunov–Floquet transformation (L–F transformation) approach makes the linear part of a periodic equation time-invariant and thus retains the stability and bifurcation characteristics of the original system in the entire parameter space. The resulting equation can then be studied via standard techniques. The method of time-dependent normal form reduction aims to simplify the nonlinear equations by reducing the number of nonlinear terms to a minimum, even make them linear or time-invariant in some cases. The goal of time-periodic center manifold reduction is to reduce the dimension of the systems for the purpose of stability analysis in critical cases. These are the most current tools of analysis. In the following sections each method will be described and discussed briefly.

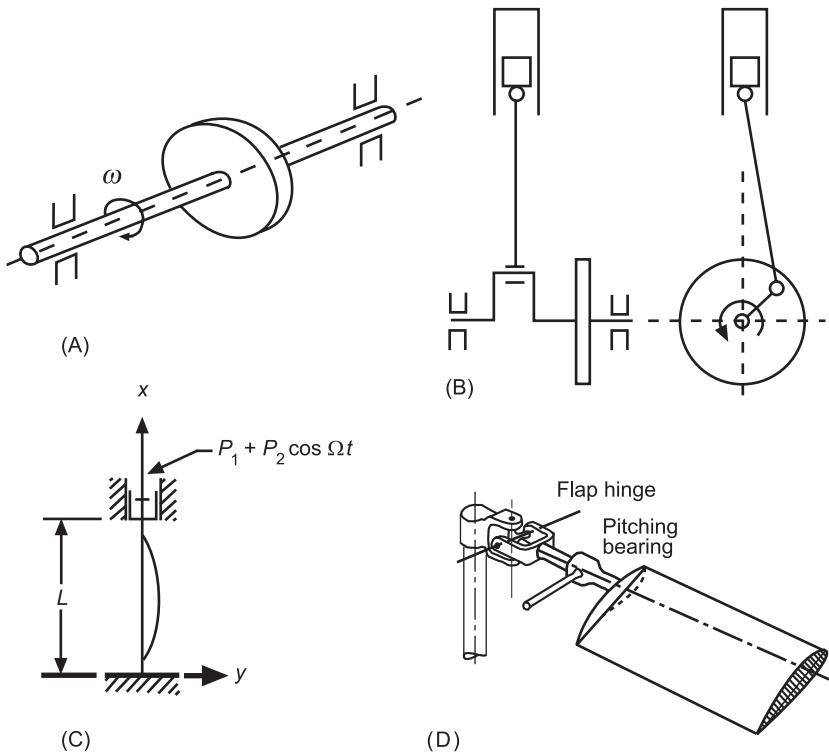

Figure 1 (A) Rotor-bearing system; (B) connecting rods; (C) periodically loaded column; (D) helicopter rotor blade.

Problem Formulation

The general form of nonlinear time-periodic systems is given by the equation:

$$\dot{x} = f(x, t) \quad [1]$$

where x and f are n real vectors and $f(x, t) = f(x, t + T)$. T is called the principal period of the system. If we restrict ourselves to studying moderately large vibrations only, then we can expand the above equation in Taylor series about an equilibrium position or a known periodic solution of eqn [1] and obtain:

$$\dot{x} = \mathbf{A}(t)x + f_2(x, t) + \dots + f_k(x, t) + O(|x^{k+1}|, t) \quad [2]$$

or:

$$\dot{x} = \mathbf{A}(t)x + F(x, t) \quad [3]$$

where \mathbf{A} is an $n \times nT$ -periodic matrix, and the vector functions f_i , $i = 2 \dots k$, contain i th order monomials of x and are T -periodic in time. F is suitably defined in terms of f_i 's. The index k is the highest order considered. The goal is either to predict stability and

analyze bifurcations or to find the system response (most often steady-state solutions). Stability of the equilibrium position or the known periodic solution can be studied by Floquet theory if in the linear equation:

$$\dot{x} = \mathbf{A}(t)x \quad [4]$$

matrix \mathbf{A} is not critical, that is, it does not have Floquet multipliers on the unit circle. If the system is critical, a nonlinear analysis is necessary. Floquet theory is also useful for finding the response of linear time-periodic equations.

Floquet Theory

Consider the linear periodic system given by eqn [4]. Let $\Phi(t)$ denote the fundamental solution matrix or state transition matrix (STM) that contains n linearly independent solutions of eqn [4] with the initial conditions $\Phi(0) = \mathbf{I}$ where \mathbf{I} is the $n \times n$ unit matrix. Then the following statements hold:

1. $\Phi(t + T) = \Phi(T)\Phi(t) \quad 0 \leq t \leq T$ and, consequently
2. $\Phi(t + jT) = \Phi(T)^j\Phi(t) \quad 0 \leq t \leq T, j = 2, 3 \dots$
3. $x(t) = \Phi(t)x(0) \quad t \geq 0$

These results imply that, if the solution is known for the first period, it can be constructed for all

time t . The matrix $\Phi(T)$ is called the Floquet transition matrix (FTM). The next statement considers the stability of eqn [4].

4. Let $\zeta_i (i = 1, \dots, n)$ denote the eigenvalues of $\Phi(T)$. System (4) is asymptotically stable if all ζ_i 's lie inside the unit circle of the complex plane. The system is unstable if at least one of the eigenvalues of the FTM has magnitude greater than one. The eigenvalues ζ_i are called the Floquet multipliers. The above statements briefly summarize the results of Floquet theory.

The Necessity of Nonlinear Analysis: Bifurcations and other Nonlinear Phenomena

In nonlinear systems a number of phenomena can occur which are impossible to predict from the linear analysis. Linear theory can predict the instants when a system goes through a change of stability characteristics, called bifurcation, but it cannot predict what kind of motion follows and whether or not the system is stable in critical situations. The nonlinear phenomena of time-periodic systems include cyclic bifurcations of equilibria and periodic orbits. When one Floquet multiplier of the system leaves the unit circle of the complex plane at -1 , a period doubling (or flip) bifurcation occurs, the equilibrium or limit cycle changes its stability characteristic and a new limit cycle with twice the period of the original is born. When a multiplier crosses the unit cycle at $+1$, there are several possibilities, depending on the structure of the nonlinearities. Transcritical bifurcation occurs in the presence of quadratic terms, while cubic terms without any quadratics imply symmetry-breaking bifurcation. In transcritical bifurcation a stable and an unstable limit cycle (or an equilibrium point and a limit cycle) that exist together, switch their stability. Symmetry-breaking bifurcation is similar to flip bifurcation, without the doubling of the period. The cyclic-fold bifurcation, which also occurs when a multiplier becomes $+1$, is a phenomenon when a stable and an unstable cycle collide and disappear. For instance, two cyclic-fold bifurcations cause the jump phenomenon of resonance. If a pair of complex multipliers leave the unit circle, a quasiperiodic solution arises in a secondary Hopf (or Neumann–Sacker) bifurcation. The stability and bifurcation diagram is shown in Figure 2. Chaos can occur in these systems as well, through common routes, a series of period-doubling bifurcations or through secondary Hopf bifurcations. Intermittent chaos is also often observed. Features such as limit cycles and chaos observed in nonlinear systems have great significance in both theory and practical

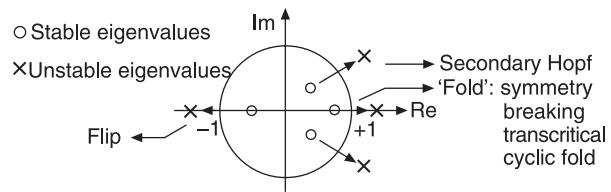

Figure 2 Stability and bifurcation diagram.

applications and can be treated only by means of nonlinear analysis techniques.

Tools of Nonlinear Analysis

Perturbation Methods

Perturbation theory has been widely used to obtain approximate solutions of many problems, in various branches of science and engineering. The basic idea is that if the problem at hand differs from a simple solvable problem only by small additional terms, then we could assume that the solutions of the two problems will be close as well. Therefore we can start from the solution of the simple problem, called the ‘unperturbed problem’ and try to find a series of corrections, in order to construct the solution of the original problem. The corrections are most often expressed as a power series of a small quantity called the ‘perturbation parameter’. In the last step one needs to show that a few terms in the series will provide a useful approximate solution.

In the case of time-periodic nonlinear differential equations, perturbation techniques are only generally applicable if there exists a small parameter multiplying the periodic linear and nonlinear terms. Since the periodic linear terms as well as the nonlinear terms are small compared to the time-invariant linear part, the solution can be composed as slowly varying vibrations superimposed on the well-known periodic steady-state solution of the time-invariant linear system. The solution is written as a power series in terms of the small parameter. Substituting the series into the original equation and equating the coefficients of powers of the small parameter on both sides of the equations, a set of linear differential equations is obtained. These equations are solved to yield an approximate solution up to some desired power of the small parameter.

If eqn [3] can be written as:

$$\dot{x} = \mathbf{B}x + \varepsilon[A_1(t)x + F(x, t)] \quad [5]$$

where \mathbf{B} is a constant matrix, $A_1(t)$ is the periodic part of matrix $\mathbf{A}(t)$, $F(x, t)$ is an n vector containing the nonlinear terms and ε is a small parameter. Then

we seek a uniform expansion of the solution of the form:

$$x(t) = x_0(t) + \varepsilon x_1(t) + \varepsilon^2 x_2(t) + \dots \quad [6]$$

After substituting this expression into eqn [5] and collecting the coefficients for powers of ε , we obtain a set of linear differential equations in x_i . The equation for ε^0 is obviously given by the solution of which is $x_0 = \Phi(t)a$, where a is a constant vector and $\Phi(t)$ is the fundamental solution matrix of $\dot{x} = Bx$. Now, we let $a = a(t)$ be the modulation, an unknown function of time. An approximation of $a(t)$ can be obtained from the equation corresponding to ε^1 , by eliminating the resonant (so-called the secular) terms. This elimination is necessary in all problems with excitation in order to obtain a uniform expansion. Once again, to refine the approximation further, we assume that the coefficient of $a(t)$ is an unknown function of time, to be determined from the ε^2 equation, and so on, until we obtain a ‘reasonably good’ approximation.

A modification of this method called the method of multiple scales makes special use of the fact that the corrections superimposed on the solution of the linear time-invariant system are relatively ‘slow’ vibrations with much smaller frequencies. Because of the limitation on the size of the parameter ε , however, the applicability of these methods is limited. They also seem to yield poor approximations for the locations of bifurcation points as well as for steady-state solutions in the neighborhood of bifurcations for time-periodic equations.

Averaging Method

The averaging method is based on the same basic idea as the perturbation methods. Once again, the periodic and nonlinear terms are assumed to be small compared to the constant linear part and are treated as slowly varying perturbation of the time-invariant linear equation. The solution of the nonlinear problem can be treated as a slowly varying modulation added to the solution of the time-invariant part, which can be constructed as before. The aim of averaging is to obtain an approximate solution based on these assumptions. In eqn [5] if we let $x = \Phi(t)z$, then it can be transformed into the standard form:

$$\dot{z} = \varepsilon \Phi^{-1}(t)g(\Phi(t)z, t) \quad [8]$$

where $g(x, t) = \mathbf{A}_1(t)x + F(x, t)$ and the variable $z(t)$ represents the modulation. Since an exact solution of eqn [8] is not possible, the theorem of averaging allows us to construct the following averaged system:

$$\dot{\bar{z}} = \varepsilon \bar{g}(\bar{z}) \quad [9]$$

where:

$$\bar{g}(\bar{z}) = \frac{1}{T} \int \Phi^{-1}(t)g(\Phi(t)z, t) dt \quad [10]$$

The error between $z(t)$ and $\bar{z}(t)$, can be expressed as:

$$z(t) - \bar{z}(t) = O(\varepsilon), \quad \varepsilon \rightarrow 0, \quad t \in \left[0, \frac{1}{\varepsilon}\right] \quad [11]$$

This implies that for small ε the solution of the averaged equation is a good approximation of the solution of eqn [5], but only in a finite time interval depending on ε . Eqn [9] is a quasilinear autonomous differential equation in the slowly varying averaged coefficient \bar{z} . Although it is quasilinear, in general, an exact analytical solution is still not possible, except in some cases the averaged equation may become solvable in a closed form. Further simplification is possible via normal form theory and in some cases an approximate analytical solution is possible. Like the perturbation methods, the applicability of the method is limited due to the small parameter assumption.

Liapunov–Floquet transformation

According to the Liapunov–Floquet theorem, the fundamental matrix (or STM) $\Phi(t)$ of eqn [4] can be written as a product of two matrices as:

$$\Phi(t) = \mathbf{L}(t)e^{Ct} \quad [12]$$

where $\mathbf{L}(t)$ is T -periodic and \mathbf{C} is a constant matrix, both, in general, are complex. There also exists a real factorization of the same form as eqn [12], where $\mathbf{L}(t)$ is real $2T$ -periodic and \mathbf{C} is a real constant matrix. $\mathbf{L}(t)$ is called the (T or $2T$ -periodic) Liapunov–Floquet (LF) transformation matrix. Applying the transformation:

$$x = \mathbf{L}(t)y \quad [13]$$

results in:

$$\dot{y} = \mathbf{C}y \quad [14]$$

which is a dynamically equivalent autonomous form of eqn [4], either complex or real. After applying eqn [13], the nonlinear system (eqn [2]) becomes:

$$\dot{y} = \mathbf{C}y + \mathbf{L}^{-1} \left(f_2(y, t) + \dots + f_k(y, t) + O(|y^{k+1}|, t) \right) \quad [15]$$

Eqn [15] is dynamically equivalent to eqn [2] and it has a time-invariant linear part. This form allows one to apply the method of normal forms and/or center

manifold reduction, which can provide considerable simplifications.

However, in general, it is not possible to obtain the L-F transformation in a closed form because for this purpose one needs to compute the fundamental solution matrix $\Phi(t)$ of the linear periodic differential eqn [4] (cf., eqn [12]). On the other hand, recent developments suggest that the elements of the solution matrix $\Phi(t)$ can be obtained as a sum of Chebyshev polynomials to a desired accuracy. The L-F transformation $L(t)$ and matrix C can then be obtained by a factorization of $\Phi(t)$. Since $L(t)$ is a periodic function of time, it can be expressed as a Fourier series.

Time-dependent Normal Form Theory

The idea of normal form reduction is to simplify nonlinear equations by eliminating as many nonlinear terms as possible, while keeping the linear part (and therefore the stability and bifurcation characteristics) unchanged. This is achieved by a series of near-identity transformations. Because $A(t)$ in eqn [2] is time-dependent, a direct application of normal form theory is not possible. Therefore, first the $2T$ -periodic L-F transformation is used to transform eqn [2] to a vector field where the linear part is time-invariant. Then the resulting eqn [15] can be handled by the method of ‘time-dependent normal forms’ (TDNF). Eqn [15] can be written in the Jordan canonical form as:

$$\dot{y} = Jy + w_2(y, t) + \dots + w_k(y, t) + \dots + O(|y|^{k+1}, t) \quad [16]$$

where J is the Jordan form of the real matrix C and w_r 's ($r = 2 \dots k$) are $2T$ -periodic functions which contain homogeneous monomials of y of order r . Now one can construct a sequence of transformations which successively removes the nonlinear terms w_r . The transformation is of the form:

$$y = v + h_r(v, t) \quad [17]$$

where h_r is a formal power series in v of degree r with $2T$ -periodic coefficients. Applying the above change of coordinates, one can establish the conditions for eliminating each nonlinear term, and solve for h_r . These conditions are expressed in the form of a set of partial differential equations for h_r , called the homological equation. Since the coefficients of w_r and the unknown nonlinear transformation h_r can be expressed in finite Fourier series, one only needs to solve a set of algebraic equations for the coefficients of h_r , instead of solving the differential equations. Following this procedure it is not always possible to eliminate all of the nonlinear terms. The nonlinear

terms corresponding to the resonance condition remain in the normal form that is the simplest possible nonlinear form of eqn [2]. In some cases it can even be linear, or, although nonlinear, completely time-invariant. In many instances, the resulting normal form equations can be analyzed analytically and the stability and bifurcation characteristics can be examined. Usually, some algebraic manipulations and/or transformation to polar coordinates render closed-form solutions for simple nonlinear equations. Thus, the solutions of the original quasilinear time-periodic equations can be obtained in the original coordinates by substituting back all the transformations, including the L-F transformation. Usually these computations are tedious due to the presence of a large number of periodic terms in eqn [16]. In order to simplify the procedure, without any significant compromise in the quality of solutions, only time-invariant terms in w_r may be retained and the periodically varying terms may be neglected. Then eqn [16] takes the form:

$$\dot{\bar{y}} = J\bar{y} + \bar{w}_2(\bar{y}) + \dots + \bar{w}_k(\bar{y}) + O(|\bar{y}|^{k+1}) \quad [18]$$

which is autonomous and \bar{y} and $\bar{w}_r(\bar{y})$ are the approximate states and nonlinear functions, respectively. Then the solution can be obtained by application of the time-independent normal form (TINF) theory.

Time-periodic center manifold reduction

In situations where some of the eigenvalues of matrix C in eqn [15] are critical, the stability can be discussed in the local center manifold via the time-periodic center manifold theorem. The idea of center manifold theorem is to reduce the dimension of the system to the minimum possible, i.e., to the dimension of the invariant manifold associated with the critical eigenvalues. All ‘critical’ dynamics take place in this manifold. The center manifold theorem states that if the reduced system on the center manifold is stable (unstable) then the original n -dimensional system is also stable (unstable). Due to the periodic nature of eqn [2], a direct application of the center manifold theorem is not possible, but it can certainly be applied to eqn [15]. Let us assume that eqn [15] has n_1 eigenvalues that are critical and n_2 eigenvalues that have negative real parts. Then it can be rewritten in the form:

$$\begin{pmatrix} \dot{y}_c \\ \dot{y}_s \end{pmatrix} = \begin{bmatrix} J_c & 0 \\ 0 & J_s \end{bmatrix} \begin{pmatrix} y_c \\ y_s \end{pmatrix} + \begin{pmatrix} w_{c2} \\ w_{s2} \end{pmatrix} + \begin{pmatrix} w_{c3} \\ w_{s3} \end{pmatrix} + \dots \quad [19]$$

where the subscripts c and s represent the critical and stable vectors, respectively. At this point a nonlinear

relation is sought to decouple the nonlinear terms of the equations corresponding to the critical and stable states, in the form of:

$$y_s = h(y_c, t) \quad [20]$$

such that $h(y_c, t)$ is a polynomial of y_c with $2T$ -periodic unknown coefficients. The relation for y_s can be obtained by substituting eqn [19] into the set of n_2 equations associated with the stable eigenvalues in eqn [18]. The substitution results in a set of partial differential equations for the coefficients of h . Since these coefficients have to be periodic, we can assume a formal Fourier series form with unknown coefficients. Then the differential equations reduce to a set of linear algebraic equations for the Fourier coefficients. After solving for the coefficients, substitution of eqn [19] in eqn [18] decouples stable and critical states and hence the problem reduces to the investigation of stability of an n_1 -dimensional system in the center manifold. If necessary, the center manifold equations can be simplified further by the time-dependent normal form theory as described earlier. For certain types of bifurcation they become completely time-invariant and solvable in a closed form.

Point-Mapping Techniques

For periodic systems, one could also represent the motion of the system as events in discrete time instants. The goal here is to eliminate the explicit time dependence from the equation by replacing the dynamic system as a set of difference equations sampled at period T . This process links the state of the system at the beginning of a period to the state of the system at the end of the period by a point-mapping transformation. The advantage of the discrete time approach is that by introducing this formulation, one eliminates the explicit continuous dependence on time. This feature allows, at least in principle, an easier determination of the various solutions and their stability properties. Another advantage is that difference equations are easy to simulate on digital computers. One of the main obstacles in applying point-mapping techniques to real problems is in obtaining the corresponding difference equations. In order to obtain the complete difference equation representation one has to find a solution of a nonautonomous nonlinear system of differential equations over one period. This is not possible except in a few special cases. Thus, in general, one is forced to accept an approximation to the point mapping.

Consider a nonlinear dynamic system described by eqn [1], i.e.:

$$\dot{x}(t) = f(t, x(t)) \quad [21]$$

where x and f are real vectors and f is periodic in time with period T . The state of the system is observed at discrete instances of T units of time. The dynamic relationship between the state of the system at $t = nT$ and the state at $t = (n+1)T$ results in a set of difference equations which are independent of time. If such a relationship can be found, the discrete counterpart to the set of equations in eqn [21] can be written as:

$$x(n+1) = G(x(n)), \quad n = 1, 2, 3 \dots \quad [22]$$

where $x(n+1)$ and $x(n)$ are the state of the system at $t = (n+1)T$ and $t = nT$, respectively. The representation of the system dynamics given by eqn [22] is called the Poincaré map. An equilibrium point or a T -periodic orbit of eqn [21] is represented as a fixed point of the map. A periodic solution of period KT consists of K distinct points $x^*(j)$, $j = 1 \dots K$, such that:

$$\begin{aligned} x^*(m+1) &= G(x^*(m)), \quad m = 1, 2, \dots, K-1 \\ x^*(1) &= G^K(x^*(1)) \end{aligned} \quad [23]$$

Approximations of the map are usually obtained numerically, for example, by the Runge–Kutta method for solving systems of ordinary differential equations. By keeping track of the various coefficients, an approximation up to any desired degree can be obtained. Point-mapping methods are mostly used to study the local as well as global stability and bifurcation characteristics of a system. Unlike the perturbation and averaging methods, this technique is not restricted to systems with small parameters. The main disadvantage of this method is that the construction of the Poincaré map requires knowledge of either the exact or an approximate solution of the original problem. Further, the discretized system dynamics cannot be transformed back to the original continuous state. Computational problems may also arise as the system dimension becomes larger.

Illustrative Examples

In this section some simple examples are considered to demonstrate the application of the methods discussed above. First, consider a Mathieu equation with cubic nonlinearity in the form:

$$\begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix} = \begin{bmatrix} 0 & 1 \\ -(\alpha + \beta \cos \omega t) & -\delta \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} + \begin{Bmatrix} 0 \\ -\varepsilon x_1^3 \end{Bmatrix} \quad [24]$$

where δ , α , β , ω , and ε are the parameters of the system. Results for two sets of parameters are shown

in Figures 3 and 4. As seen from Figure 3, when $\alpha(=10)$ is much larger than $\beta(=0.2)$, then the averaging method does provide meaningful results although it is not as accurate as the two normal form methods, viz., TINF and TDNF. However, when $\alpha(=0.5)$ is small compared to $\beta(=4)$, the averaging method incorrectly predicts unbounded solution while TINF and TDNF provide very good results (Figure 4). As an example of the application of time-dependant center manifold reduction, the bifurcation analysis of a base-excited simple pendulum shown in Figure 5 is considered:

$$\ddot{\theta} + d\dot{\theta} + (a + b \sin \omega t) \sin \theta = 0 \quad [25]$$

where $a = g/L$, $b = A\omega^2/L$, and $d = c/ML^2$. Writing $\{x_1 x_2\} = \{\theta \dot{\theta}\}$ and expanding $\sin \theta$ in a Taylor series about the zero equilibrium point up to the cubic terms, yields:

$$\begin{cases} \dot{x}_1 \\ \dot{x}_2 \end{cases} = \begin{bmatrix} 0 & 1 \\ -(\alpha + \beta \sin \omega t) & \alpha \end{bmatrix} \begin{cases} x_1 \\ x_2 \end{cases} + \begin{cases} 0 \\ (a + b \sin \omega t) \frac{x_1^3}{6} \end{cases} \quad [26]$$

Letting a be the bifurcation parameter; for $b = 4$, $d = 0.31623$, and $\omega = 2$, the system undergoes a

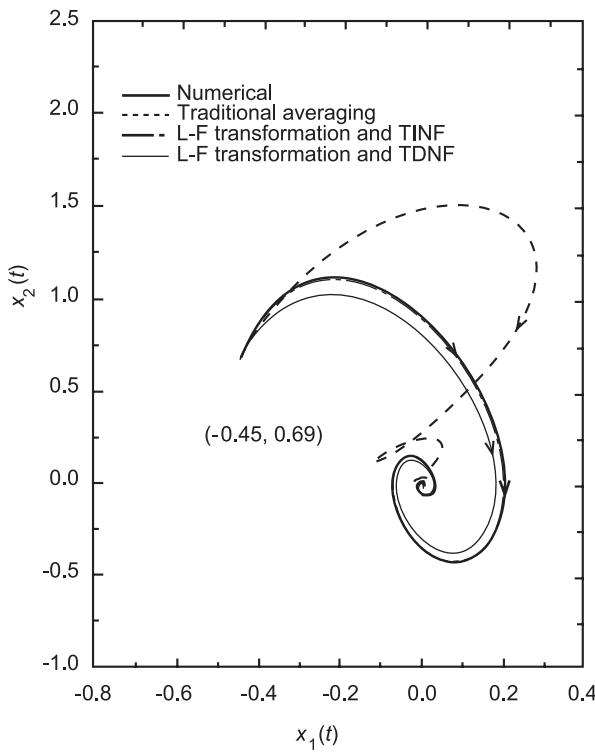

Figure 3 Solutions of Mathieu equation with cubic nonlinearity ($\alpha=10.0$, $\beta=0.2$, $\delta=1.8974$, $\varepsilon=3.0$).

symmetry breaking bifurcation (one of the Floquet multipliers is $0.999999 \approx 1$, the other being 0.370292) at $\alpha_c = 3.917787$. After applying the L-F and modal transformations, the time-dependent center manifold reduction is used to decouple the critical equation from the other. The center manifold equation is further simplified via normal form theory to yield:

$$\dot{\nu} = -0.4306\nu^3 \quad (\nu \text{ is a new variable}) \quad [27]$$

indicating that the equilibrium of the nonlinear system is asymptotically stable at the critical point. The versal deformation of eqn [27] yields the normal form of symmetry breaking bifurcation for this system as:

$$\dot{\nu} = \mu\nu - 0.4306\nu^3 \quad [28]$$

where μ is the unfolding parameter. It is solvable in a closed form; the solution for the initial condition $\nu(0) = \nu_0$ being:

$$\nu(t) = \left(\left(\frac{1}{\nu_0^2} + \frac{-0.4306}{\mu} \right) e^{-2\mu t} - \frac{-0.4306}{\mu} \right)^{-1/2} \quad [29]$$

Unlike the case of autonomous systems, here the normal form does not contain all the information

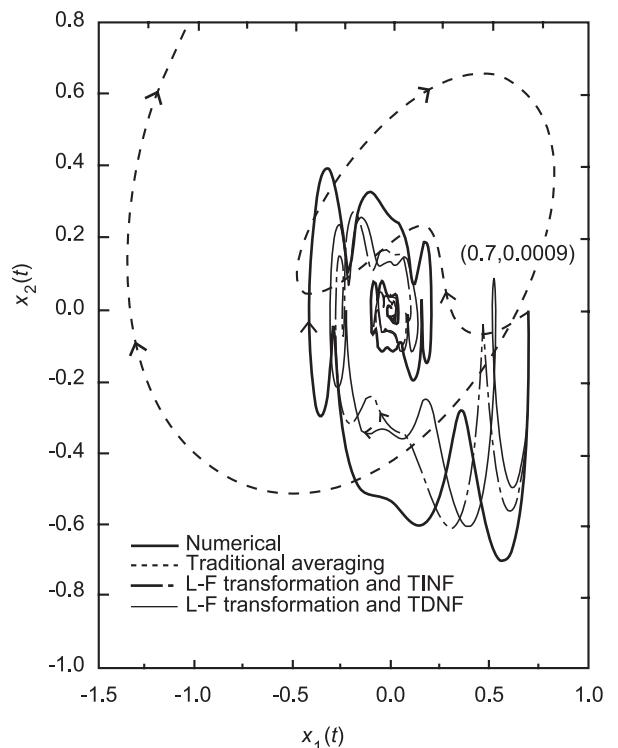

Figure 4 Solutions of Mathieu equation with cubic nonlinearity ($\alpha=0.5$, $\beta=4.0$, $\delta=0.4243$, $\varepsilon=3.0$).

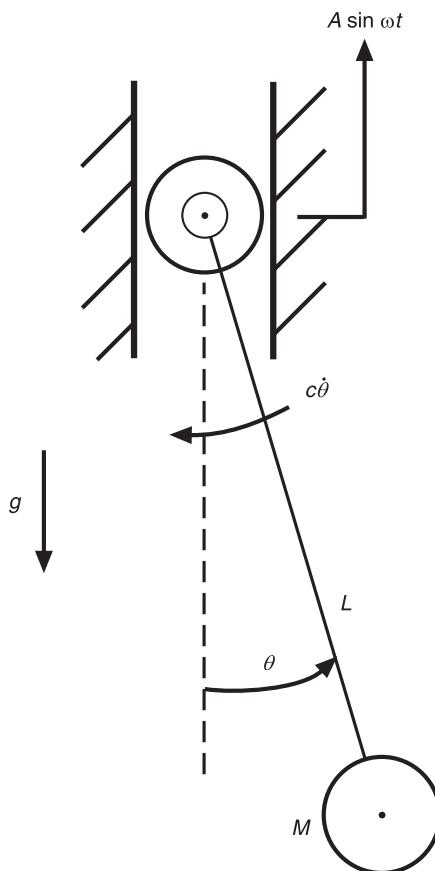

Figure 5 Base-excited simple pendulum.

about the bifurcation and the L-F transformation also plays an important role. From eqn [29] one can conclude the following about the dynamics in the neighborhood of the bifurcation. For $\mu < 0$ the $v = 0$ equilibrium is stable and there are no other limit sets in the neighborhood. For $\mu > 0$ the zero equilibrium becomes unstable and there is a stable nonzero equilibrium born. This equilibrium point becomes a stable T -periodic limit cycle in the original domain because the real L-F transformation is T -periodic in this case. So we say that the stability has been lost softly. This limit cycle is the boundary of the small attractive domain around the unstable equilibrium. By computing the amplitude of the limit cycle we have estimated the size of the stable region, and we can also estimate the rate of its growth as the bifurcation parameter goes further away from the critical value. The limit cycle is obtained by substituting the initial condition:

$$v_0 = -\left(\frac{\mu}{-0.4306}\right) \quad [30]$$

into eqn [29] and applying the necessary transformations to yield the original state $x(t)$. However, one

must establish a relationship between μ and η ($\equiv a - a_c$) which represents the change in the bifurcation parameter a . By performing a sensitivity analysis of the Floquet transition matrix (FTM), one can obtain a relationship between μ and η . However, the FTM must be computed in a symbolic form. One can also obtain such a relationship numerically by the curve-fitting technique. Using:

$$\mu = 0.865\eta - 1.635\eta^2 \quad [31]$$

the postbifurcation limit cycles for $\eta = 0.01$ and $\eta = 0.1$ are shown in Figures 6A and B, respectively. Numerical results are included for a comparison.

Phenomena Associated with Time-periodic Nonlinear Systems

The time-periodic nonlinear systems contain typical features of parametric excitation and other phenomena associated with nonlinear systems. The para-

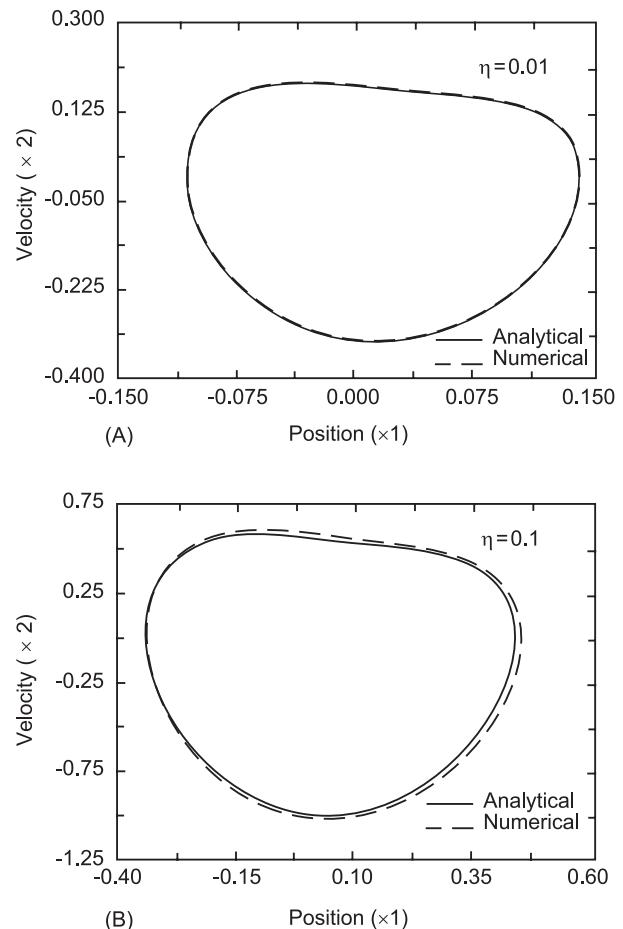

Figure 6 Postbifurcation limit cycles.

metric excitation can cause resonance which, in nonlinear systems, is associated with the jump phenomenon, the amplitude of vibration grows as the excitation frequency grows in the neighborhood of the resonant frequency, but at a certain frequency it drops suddenly, and the system vibrates with a much smaller amplitude. Near resonance another interesting feature, synchronization (or entrainment of frequencies) can also occur in these systems due to nonlinearities. The existence of limit cycles, quasiperiodic, and chaotic attractors is also observed in these systems.

These features can be analyzed by the use of the methods described above. Perturbation, averaging, point-mapping methods, and the L-F transformation with a subsequent use of normal form reduction have been employed to construct periodic, quasiperiodic, and even chaotic solutions. For bifurcation analysis, the L-F transformation combined with center manifold reduction and normal form theory appears to be very useful. The L-F transformation also appears to be a powerful tool in control of time-periodic systems. These are the current subjects of research.

Nomenclature

a	bifurcation parameter
A	$n \times n$ T -periodic matrix
B	constant matrix
C	constant matrix
I	$n \times n$ unit matrix
$L(t)$	Liapunov–Floquet transformation matrix
T	principal period
$\Phi(t)$	fundamental solution matrix
$\Phi(T)$	Floquet transition matrix

PERTURBATION TECHNIQUES FOR NONLINEAR SYSTEMS

S Shaw, Michigan State University, East Lansing, MI, USA

doi:10.1006/rwvb.2001.0042

Summary

Perturbation techniques are a class of analytical methods for determining approximate solutions of nonlinear equations for which exact solutions cannot be obtained. They are useful for demonstrating,

predicting, and describing phenomena in vibrating systems that are caused by nonlinear effects. They can also be applied to nonlinear and linear systems with variable coefficients and/or complex boundary conditions where closed form exact solutions are not known. They are useful for determining solutions that are ‘close’ in some sense to a known solution, and provide results that are perturbations of that known solution. These approximate solutions are obtained by carrying out expansions in terms of a small parameter, where the known solution is recovered when the parameter is zero, and the higher-order terms in the expansion contain the additional information. There are a number of different types of expansions involving the (unknown) solution and, in some cases, the independent variable(s) in the problem (e.g., time). The range of physical applications of perturbation techniques covers virtually all of theoretical physics; here we provide a brief summary of topics specific to nonlinear vibrations.

Perturbation techniques complement numerical simulations, with certain advantages and disadvantages. Their primary disadvantage is that they are limited to relatively narrow, but important, classes of mathematical problems. Their distinct advantage is that they provide analytical formulas that describe the influence and role of system parameters on the response. This is very important when exploring behavior that is fundamentally different from that observed in linear systems. In fact, many of the classic problems solved by perturbation techniques play a role in nonlinear vibrations analogous to that of forced harmonic oscillators in linear vibration theory; that is, they set the framework for a wide range of applications by demonstrating fundamental behavior and show how system parameters influence that behavior.

One important class of systems where perturbation techniques are very useful are those that are weakly nonlinear. Here perturbation techniques allow one to explore phenomena that cannot be captured by linear system models: the existence of multiple stable steady state responses in a system; the existence of self-excited oscillations, i.e., responses that do not arise from an external time-dependent excitation; subharmonic and superharmonic resonances, in which the system response is dominated by a harmonic different from that of the excitation; and internal resonances, where commensurability between natural frequencies in a system can lead to energy exchange that often results in quite complex behavior. Perturbation techniques can also be applied to systems where a nonlinear solution is known at a particular set of parameter values, whereby the solution is extended to nearby parameter values, often leading to new and

important responses. An example of this is the case of adding damping and periodic forcing to conservative nonlinear oscillators. The interaction of the underlying, unforced system with the excitation and dissipation can lead to a multitude of resonance conditions that are captured by such an approach. Another class of problems amenable to perturbation techniques is those in which behavior occurs on significantly different time scales. For example, one may have a stiff structure with high natural frequencies to which are attached relatively soft subsystems with relatively low frequencies. In such a case, the methods of singular perturbation can be applied in order to attack the different timescales in a systematic manner.

Many books have been written on these topics, and many more include these techniques as part of the toolbox one must have in hand when investigating nonlinear systems. There are differing philosophies about perturbation techniques, depending on whether one simply wants an answer or has a desire to understand the deeper implications of the methods and how these affect the results obtained. The book by Nayfeh is a good starting point, since it covers a wide range of problems that can be tackled using these methods, and it demonstrates the steps used in the calculations. A complementary book by Murdock, demonstrates the methods, but asks deeper questions and places the methods in a more mathematical setting where the underlying principles can be understood and explored. Perturbation analyses require careful calculations and are ideally suited for computer-assisted symbolic manipulation, such as Mathematica, MACSYMA, or Maple. Rand and Armbruster’s book takes the reader on an instructive tour of some classical perturbation calculations using MACSYMA. The emphasis in many texts is on the mathematical expressions obtained, but there is an important and useful connection between these analytical techniques and topological approaches for nonlinear systems; issues that are explored in a number of books, e.g., Nayfeh and Mook, and Guckenheimer and Holmes.

A crucial step in any perturbation analysis is the identification of the small parameter and the scaling required to set the equations of interest in the proper form for application of the method. This is not always straightforward; experience, physical insight and the literature for the specific application at hand are useful aids in this regard, since the textbooks tend to focus on the mathematical steps of the analysis.

PIEZOELECTRIC MATERIALS AND CONTINUA

H S Tzou, University of Kentucky, Lexington, KY, USA

doi:10.1006/rwvb.2001.0076

Smart materials are active materials whose properties can be actively tuned and controlled via electromechanical, magnetic, electrical, temperature, and high-energy light means. Furthermore, synergistically integrating smart materials, structures, sensors, actuators, control electronics, and artificial intelligence yields an active or adaptive (lifelike) structronic (*structure + electronic*) system with inherent self-sensing, diagnosis, and control capabilities. These new smart structures and structronic systems could revolutionize many engineering systems.

Piezoelectric material is one kind of smart material and piezoelectricity is an electromechanical phenomenon coupling the elastic field and the electric field (Figure 1). (Note that *piezo* means press in Greek.) Ever since the discovery of piezoelectric behavior by the Curie brothers (Jacques and Pierre) in 1880, this coupled electromechanical characteristic has brought a new dimension in transducer (sensor and actuator) applications. In general, a piezoelectric material responds to mechanical force/pressure and generates an electric charge/voltage, which is called the direct piezoelectric effect. Conversely, an electric charge/field applied to the material induces mechanical stresses or strains, and this is called the converse piezoelectric effect. The direct effect is usually the basis in sensor and measurement applications; the converse effect is for precision actuation and manipulation in control applications.

Piezoelectric materials have been applied to engineering applications since 1917. Recent research activities involving smart materials, smart (intelligent) structures, structronic systems, precision

mechatronic systems, and microelectromechanical systems (MEMS) further renew a widespread interest in traditional piezoelectric materials and continua, elastic/piezoelectric composites, and thin-layer piezoelectric devices due to their high potentials in many advanced static and dynamic applications, e.g., aerospace/aircraft structures, robot manipulators, vibration/noise control and isolation, high-precision devices, microsensors/actuators, thin-film devices, MEMS, and microdisplacement actuation and control. This article provides an overview of the historic background, material varieties, fundamental piezoelectric theories, sensor and actuator applications, piezoelectric continua, outlook, and prospects. See also **Sensors and actuators** for distributed sensing and control applications.

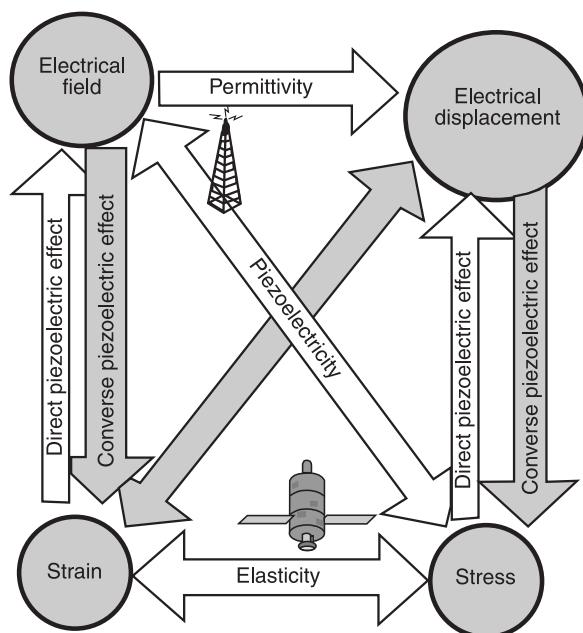

Figure 1 Piezoelectric effect.

Piezoelectric Materials

Many natural and synthetic materials exhibit piezoelectric behavior; Table 1 summarizes popular natural and synthetic piezoelectric materials. Certain materials naturally exhibit piezoelectric behavior; however, other, especially synthetic, materials require an artificial poling process. The poling process involves applying a high electric field at an elevated temperature. The field aligns the molecular dipoles in the material and the dipoles are fixed into the aligned orientation when the material cools down while the strong field is still maintained. The poled piezoelectric material becomes anisotropic and it deforms when subject to an electric field and polarizes when subject to mechanical stress, although the original raw material was nonpiezoelectric and isotropic.

In general, synthetic materials can be fabricated into arbitrary shapes and geometries, while natural crystals usually remain in their natural formations and appearances. Accordingly, synthetic piezoelectric ceramics (e.g., lead zirconate titanate and lead lanthanum zirconate titanate) and polymers (e.g., polyvinylidene fluoride) are widely used in many sensor and actuator applications. Note that for low electric fields ($<0.1 \text{ MV m}^{-1}$ approximately), the linear proportionality between the strain and electric field is valid. However, for higher ac fields ($>0.6 \text{ MV m}^{-1}$ approximately), significant electromechanical hysteresis can occur as the response domain grows, which can cause servo-displacement control problems in precision piezoelectric actuator devices. These materials still have certain limitations, such as being fairly weak mechanically, and nonreproducible effects (e.g., hysteresis on the order of 10% or greater). While the

range of piezoelectric applications is well documented, there are other desired applications that these materials cannot achieve effectively due to their properties, such as hysteresis, and low stroke. New high-authority materials, e.g., single crystal piezoelectric materials, are continuously being composed and evaluated. Fundamental piezoelectricity theory is presented next, followed by practical applications. Other advanced topics on piezoelectric continua are presented subsequently.

Linear Piezoelectricity

Linear piezoelectric theory indicates the coupling between the electric field (static coupling) and the mechanical (dynamic coupling) field (Figure 1), which is a first-order effect implying that an induced strain is proportional to the electric field and the direction of the displacement is dependent on the sign of the electric field. In this section, the linear piezoelectric theory is reviewed, and the relations among various elastic and electric constants are defined. Note that the pyroelectric effect – the temperature effect – will be discussed in a later section.

The linear piezoelectricity theory is based on a quasistatic assumption in which the electric field is balanced with the elastic field so that these two fields can be decoupled at a given time instant. The direct and converse piezoelectric effects are written as:

$$\mathbf{D} = e\mathbf{S} + \varepsilon^S \mathbf{E} \quad [1]$$

$$\mathbf{T} = c^E \mathbf{S} - e^t \mathbf{E} \quad [2]$$

where \mathbf{D} is the electric displacement vector¹; \mathbf{T} is the stress tensor (second-order); \mathbf{S} is the strain tensor (second-order); \mathbf{E} is the electric field vector; e is a tensor of piezoelectric stress coefficients (third-order); e^t is the transposed tensor of e ; ε^S is the dielectric tensor (second-order) evaluated at constant strain; and c^E is the elasticity tensor (fourth-order) evaluated at constant electric field. If the piezoelectric tensor e is set to zero, eqns [1] and [2] become the conventional dielectric and Hooke's equations. Note that the stress \mathbf{T} and strain \mathbf{S} are represented in column vectors:

$$\mathbf{T} = [T_1 \ T_2 \ T_3 \ T_4 \ T_5 \ T_6]^t \quad [3]$$

$$\mathbf{S} = [S_1 \ S_2 \ S_3 \ S_4 \ S_5 \ S_6]^t \quad [4]$$

¹ IEEE piezoelectricity notation.

where the superscript t denotes the vector or matrix transpose. Subscripts 1–3 denote the normal components and 4–6 denote the shear components. The electric field **E** and the electric displacement (flux density) **D** are also written in column vectors:

$$\mathbf{E} = [E_1 \ E_2 \ E_3]^t \quad [5]$$

$$\mathbf{D} = [D_1 \ D_2 \ D_3]^t \quad [6]$$

Four Sets of Fundamental Equations

There are a number of ways to write the elastic, piezoelectric, and dielectric governing equations in which (1) stress and electric field, (2) strain and electric displacement, (3) strain and electric field are respectively used as dependent and/or independent variables. Table 2 summarizes the four sets of representations, including the equations defined above.

s^D is the compliance matrix defined at constant dielectric displacement (note $s = c^{-1}$); d is the piezoelectric strain constant matrix; g matrix relates the open-circuit voltage at a given stress; e is the piezoelectric stress constant matrix; h matrix relates the open-circuit voltage at a given strain; β^T is a free dielectric impermeability matrix evaluated at constant stress and β^T can be obtained from the inverse of the dielectric matrix ε . The superscript T (inside the matrix) denotes the properties measured at constant stress T. (Recall that ^t denotes a vector or matrix transpose and ⁻¹ denotes the matrix inverse.). Table 3 shows that the four piezoelectric coefficient matrices d , e , g , and h are all related. Note that an adiabatic condition ensures that no heat is added or removed from a given space or volume. The elastic constants are defined at the adiabatic conditions. The piezoelectric and dielectric constants of a piezoelectric material are defined at isothermal and adiabatic conditions. The piezoelectric material is assumed to be nonpyroelectric in this case. Again, the superscripts T, S, E, and D denote the matrix/tensor defined at constant stress, strain, electric field, and dielectric displacement, respectively.

Table 2 Four sets of piezoelectric equations

No.	Elastic relationship	Electric relationship
1	$\mathbf{T} = c^D \mathbf{S} - h^D \mathbf{D}$	$\mathbf{E} = -h \mathbf{S} + \beta^S \mathbf{D}$
2	$\mathbf{T} = c^E \mathbf{S} - e^t \mathbf{E}$	$\mathbf{D} = e \mathbf{S} + \varepsilon^S \mathbf{E}$
3	$\mathbf{S} = s^D \mathbf{T} + g^D \mathbf{D}$	$\mathbf{E} = -g \mathbf{T} + \beta^T \mathbf{D}$
4	$\mathbf{S} = s^E \mathbf{T} + d^t \mathbf{E}$	$\mathbf{D} = d \mathbf{T} + \varepsilon^T \mathbf{E}$

Table 3 Relations among elastic, piezoelectric, and dielectric constants

No.	Elastic	Piezoelectric	Dielectric
1	$s^D = s^E - d^t g$	$g = \beta^T d$	$\beta^T = \varepsilon^{T-1}$
2	$c^E = s^{E-1}$	$e = d c^E$	$\varepsilon^S = \varepsilon^T - e d^t$
3	$c^D = c^E - e^t h$	$h = \beta^S e$	$\beta^S = \beta^T + h g^t$
4	$c^D = s^{D-1}$	$h = g c^D$	$\beta^S = \varepsilon^{S-1}$

Piezothermoelasticity

Certain piezoelectric materials are also temperature-sensitive, i.e., an electric charge or voltage is generated when exposed to temperature variations. This effect is called the pyroelectric effect. (Note that *pyro* originally means fire in Greek.) When temperature influences the piezoelectricity, the fundamental piezoelectric equations need to expand to include the temperature components, e.g., pyroelectricity and thermal elasticity. Thus, the fundamental piezoelectric equations become the piezothermoelasticity equations:

$$\mathbf{T} = c \mathbf{S} - e^t \mathbf{E} - \boldsymbol{\lambda} \theta \quad [7]$$

$$\mathbf{D} = e \mathbf{S} + \varepsilon \mathbf{E} + \mathbf{p} \theta \quad [8]$$

$$\mathfrak{S} = \boldsymbol{\lambda}^t \mathbf{S} + \mathbf{p}^t \mathbf{E} + \alpha_v \theta \quad [9]$$

where $\boldsymbol{\lambda}$ is the thermal stress constant vector; θ is the temperature; \mathbf{p} is the pyroelectric constant; \mathfrak{S} is the thermal entropy; α_v is a material constant ($\alpha_v = \rho c_v \theta$ where ρ is the material density and c_v is the specific heat at constant volume).

Engineering Applications

The discovery of piezoelectricity took place in 1880; however, it wasn't until 1917 that Langevin invented the first engineering application – the depth-sounding device designed with Rochelle salt. Over the years, sophisticated piezoelectric theories have been proposed and refined; new piezoelectric materials have been discovered or synthesized; and novel piezoelectric devices have been continuously invented and applied to a variety of engineering systems. Table 4 summarizes a number of typical sensor and actuator applications. As discussed previously, sensor application is based on the direct piezoelectric effect; actuator application is based on the converse piezoelectric effect. A number of sample application areas are also summarized in Table 5. Note that these areas

Table 4 Sensor and actuator applications

Sensors	Accelerometer, pressure transducer, force transducer, noise/acoustic sensor, microphone, impact transducer, distributed sensor, orthogonal (modal) sensor, health monitoring
Actuators	Precision manipulator, pressure generator, ink/fuel injection, displacement actuator, vibration isolation, vibration and noise control, ultrasonic motors, distributed control, constrained layer damping, passive shunt damping, orthogonal (modal) actuator, self-sensing actuator, active structures, smart composites

Table 5 Sample application areas

Structures	Vibration, noise, stress, strain, health monitoring, measurements (e.g., flow, pressure, force, impact)
Machines and mechanical systems	Vibration and noise (monitoring and control), strength, stress, strain, health monitoring and diagnosis, optical systems, measurements (e.g., force, acceleration, pressure, impact, noise), rotor control
Medical and biomedical applications	Disposable sensors, ultrasonic devices, precision drives and control (e.g., scanning tunneling microscopes, manipulators)
Robotics and mechatronic systems	Precision actuation, manipulation, control, precision/micro robots, robot grippers, flexible robot control, microelectromechanical systems (MEMS), microsensor/actuator
Smart structures and strucronic systems	Adaptive structures and composites, structural control, adaptive geometry and shape control, adaptive aircraft wings or helicopter blades, noise and vibration control, damage detection, health monitoring, self-sensing actuators, damage repairs, precision truss structures, positioning, aerospace structures and satellites, reinforced vehicle structures

are artificially categorized and lots of them are actually interrelated and somehow overlapped. In many cases, both sensor and actuator functions are often incorporated in these application areas. Advanced topics on (linear and nonlinear) piezoelectric shell continua and their derivatives are discussed next. For distributed sensing and vibration control of elastic continua (e.g., shells, plates, etc.) using distributed thin piezoelectric sensor/actuator layers, see **Sensors and actuators**.

Piezoelectric Continua and Advanced Theories

The Curie brothers initiated the studies of piezoelectric continua in 1880. Advances have continuously been made over the years (e.g., Mason, Cady, Mindlin, Tiersten, Sesseler, Dökmeci, Tzou, and Rogacheva). Although studies of piezoelectric shells of specific shapes have advanced in the last few decades, most of them have primarily been concerned with wave propagation (i.e., in-plane motions), electromechanics, and vibrations of specific geometries with finite and infinite dimensions, such as thin rods, plates, rings, disks, and circular cylindrical shells. Later, more advanced geometries (such as spherical shells, shells of revolution, hollow ceramic cylinders, radially polarized composite piezoceramic cylinders, piezoelectric solid cylinder guided by a thin film, and

wave propagations in a piezoelectric solid cylinder of arbitrary cross-sections) were investigated. Recent development of smart structures and strucronic systems reveals the need to derive a more generic linear and nonlinear piezoelectric continuum theory applicable to distributed sensors and actuators in control of elastic continua and distributed parameter systems. Accordingly, piezoelectric theories based on a generic double-curvature deep shell with triclinic or hexagonal crystal structures have been investigated. Figure 2 illustrates a generic piezoelectric double-curvature deep shell defined in a triorthogonal coordinate system, in which α_1 and α_2 define the neutral surface and α_3 defines the normal direction; R_1 and R_2 are the radii of curvature of the α_1 and α_2 axes, respectively. Theories related to the generic shell can be, in general, applied to a number of common configurations and geometries.

Generic theories on piezoelectric shells of arbitrary shape are of importance in many applications. Theories derived based on the generic shell continuum can easily be simplified and applied to other common geometries (e.g., shells of revolution, spherical shells, conical shells, cylinders, cylindrical shells, plates, arches, rings, and beams) using four geometric parameters: two radii of curvatures (R_1 and R_2) and two Lamé parameters (A_1 and A_2). (See **Sensors and actuators** for detailed simplification procedures.) Advanced (linear and nonlinear) theories of generic (triclinic and hexagonal) piezoelectric (thin, thick,

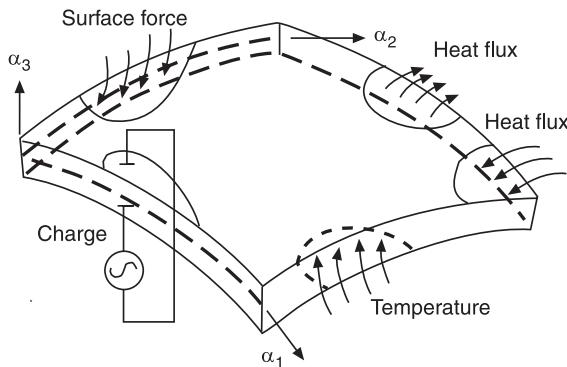

Figure 2 A generic piezothermoelastic shell continuum subjected to multifield excitations.

and composite) (deep or shallow) shells have recently been proposed. System equations coupling electric, elastic, and temperature fields are derived using the energy-based Hamilton's principle. Generic equations of mechanical motion and mechanical boundary conditions, as well as a charge equation of electrostatics and electric boundary conditions are formulated. Temperature effects to these piezoelectric shell continua are also discussed and its effects on system characteristics and sensing/control effectiveness are evaluated. These concepts are briefly outlined next.

Thermomechanical system equations of a nonlinear piezothermoelastic shell continuum, i.e., the von Karman-type geometric nonlinearity, are also presented to illustrate multifield coupling (Figure 2).

Thermoelectromechanical Coupling of Nonlinear Piezoelectric Shell Continuum

Hamilton's principle is used in deriving the shell thermomechanical equations and boundary conditions of the piezothermoelastic shell continuum. Hamilton's principle assumes that the energy variations over an arbitrary time period are zero. Considering all energies associated with a piezothermoelastic shell continuum subjected to mechanical, temperature, and electric inputs, one can write Hamilton's equation:

$$\delta \int_{t_0}^{t_1} \left\{ \left(\int_V \frac{1}{2} \rho \dot{U}_j \dot{U}_j dV - \left[\int_V (H(S_i, E_i, \Theta) + \Im \Theta) dV - \int_S (t_j U_j - Q_j \phi) dS \right] dt \right) \right\} = 0 \quad [10]$$

where ρ is the mass density; H is the electric enthalpy; t_j is the surface traction in the α_j direction; Q_j is the surface electric charge; ϕ is the electrical potential; V and S are the volume and surface of the piezothermoelastic shell continuum, respectively; and U_j and \dot{U}_j are the displacement and velocity vectors. It is assumed that only the transverse electric field E_3 is considered in the analysis and a linear variation of the displacement field in the shell, i.e., $U_i = u_i + \beta_i$. Substituting all energy expressions into Hamilton's equation and imposing the thin-shell assumptions, one can derive the nonlinear piezothermoelastic shell equations and boundary conditions of the continuum.

$$-\frac{\partial(N_{11}A_2)}{\partial\alpha_1} + N_{22}\frac{\partial A_2}{\partial\alpha_1} - \frac{\partial(N_{21}A_1)}{\partial\alpha_2} - N_{12}\frac{\partial A_1}{\partial\alpha_2} - \frac{1}{R_1} \left[\frac{\partial(M_{11}A_2)}{\partial\alpha_1} - M_{22}\frac{\partial A_2}{\partial\alpha_1} + \frac{\partial(M_{21}A_1)}{\partial\alpha_2} + M_{12}\frac{\partial A_1}{\partial\alpha_2} \right] + A_1 A_2 \rho h \ddot{u}_1 = A_1 A_2 F_1 \quad [11]$$

$$-\frac{\partial(N_{22}A_1)}{\partial\alpha_2} + N_{11}\frac{\partial A_1}{\partial\alpha_2} - \frac{\partial(N_{12}A_2)}{\partial\alpha_1} - N_{21}\frac{\partial A_2}{\partial\alpha_1} - \frac{1}{R_2} \left[\frac{\partial(M_{22}A_1)}{\partial\alpha_2} - M_{11}\frac{\partial A_1}{\partial\alpha_2} + \frac{\partial(M_{12}A_2)}{\partial\alpha_1} + M_{21}\frac{\partial A_2}{\partial\alpha_1} \right] + A_1 A_2 \rho h \ddot{u}_2 = A_1 A_2 F_2 \quad [12]$$

$$-\frac{\partial}{\partial\alpha_1} \left[\frac{1}{A_1} \left(\frac{\partial(M_{11}A_2)}{\partial\alpha_1} - M_{22}\frac{\partial A_2}{\partial\alpha_1} + \frac{\partial(M_{21}A_1)}{\partial\alpha_2} + M_{12}\frac{\partial A_1}{\partial\alpha_2} \right) \right] - \frac{\partial}{\partial\alpha_2} \left[\frac{1}{A_2} \left(\frac{\partial(M_{22}A_1)}{\partial\alpha_2} - M_{11}\frac{\partial A_1}{\partial\alpha_2} + \frac{\partial(M_{12}A_2)}{\partial\alpha_1} + M_{21}\frac{\partial A_2}{\partial\alpha_1} \right) \right] + A_1 A_2 \left(\frac{N_{11}}{R_1} + \frac{N_{22}}{R_2} \right) + A_1 A_2 \rho h \ddot{u}_3 - \left\{ \left[\frac{\partial(N_{11}A_2/A_1)}{\partial\alpha_1} + \frac{\partial N_{12}}{\partial\alpha_2} \right] \frac{\partial u_3}{\partial\alpha_1} + \left[\frac{\partial(N_{22}A_1/A_2)}{\partial\alpha_2} + \frac{\partial N_{12}}{\partial\alpha_1} \right] \frac{\partial u_3}{\partial\alpha_2} + 2N_{12} \frac{\partial^2 u_3}{\partial\alpha_1 \partial\alpha_2} + N_{11} \frac{A_2}{A_1} \frac{\partial^2 u_3}{\partial\alpha_1^2} + N_{22} \frac{A_1}{A_2} \frac{\partial^2 u_3}{\partial\alpha_2^2} \right\} = A_1 A_2 F_3 \quad [13]$$

where u_i is the displacement in the α_i direction; ρ is the mass density; F_i is the external input; A_1 and A_2

are the Lamé parameters; and R_1 and R_2 are the radii of curvature. Note that all terms inside the braces are contributed by the nonlinear effects, showing that the nonlinear influence on the transverse equation u_3 is significant. Also, the thermoelectromechanical equations are similar to standard shell equations. However, the force and moment expressions defined by mechanical, thermal, and electric effects are much more complicated than the conventional elastic expressions. Membrane force resultants N_{ij} and bending moments M_{ij} can be derived based on the induced strains (i.e., membrane strains s_i^0 and bending strains k_i).

$$\begin{bmatrix} N_{11} \\ N_{22} \\ N_{12} \\ M_{11} \\ M_{22} \\ M_{12} \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & 0 & 0 & 0 \\ A_{12} & A_{22} & A_{26} & 0 & 0 & 0 \\ A_{16} & A_{26} & A_{66} & 0 & 0 & 0 \\ 0 & 0 & 0 & D_{11} & D_{12} & D_{16} \\ 0 & 0 & 0 & D_{12} & D_{22} & D_{26} \\ 0 & 0 & 0 & D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{bmatrix} s_1^0 \\ s_2^0 \\ s_6^0 \\ k_1 \\ k_2 \\ k_6 \end{bmatrix}$$

$$- \begin{bmatrix} N_{11}^e \\ N_{22}^e \\ N_{12}^e \\ M_{11}^e \\ M_{22}^e \\ M_{12}^e \end{bmatrix} - \begin{bmatrix} N_{11}^\theta \\ N_{22}^\theta \\ N_{12}^\theta \\ M_{11}^\theta \\ M_{22}^\theta \\ M_{12}^\theta \end{bmatrix} \quad [14]$$

It is observed that there are three components, mechanical, electric, and temperature, in the force/moment expressions. Superscripts e and θ respectively denote the electric and temperature components; N_{ij}^e and N_{ij}^θ are the electric- and temperature-induced forces; and M_{ij}^e and M_{ij}^θ are the electric- and temperature-induced moments, respectively. In actuator applications, these electric forces and moments are used to control the static and dynamic characteristics of shells. A_{ij} and D_{ij} are the extensional and bending stiffness constants. (Note that all zeroes in the force matrix are replaced by the coupling constants B_{ij} in a piezoelectric *composite laminated* shell. The membrane strains and bending strains are coupled by the coupling stiffness coefficients B_{ij} in the elastic force/moment resultants.) Substituting the expressions of $N_{11}, N_{22}, N_{12}, M_{11}, M_{22}, M_{12}$ into the shell equations leads to the thermoelectromechanical shell equations defined in the neutral surface displacements u_1, u_2 , and u_3 . The transverse shear deformation and rotary inertia effects are not considered. The electric terms, forces and moments, can also be used in controlling the mechanical- and/or temperature-induced excitations.

Based on Hamilton's equation, one can also derive all admissible mechanical and electric boundary conditions. Admissible mechanical boundary conditions on the boundary surfaces defined by a distance α_2 and α_1 are respectively summarized in **Table 6** and **Table 7**. The superscript * denotes the boundary forces, moments, displacements, and slopes. Usually, only either the force/moment boundary conditions or the displacement/slope boundary conditions are selected for a given physical boundary condition. In addition, additional transverse shear force terms Q_{13} are nonlinear components induced by large deformations. These force terms do not appear in the linear case. The shear stress resultants are defined as:

$$V_{12} = N_{12} + \left(\frac{M_{12}}{R_1} \right) \quad [15]$$

$$V_{21} = N_{21} + \left(\frac{M_{21}}{R_1} \right) \quad [16]$$

$$V_{13} = Q_{13} + \frac{\partial}{\partial \alpha_2} \left(\frac{M_{12}}{A_2} \right) \quad [17]$$

Table 6 Boundary conditions (α_1 axis)

	Force/moment	Displacement
1	$N_{11} = N_{11}^*$	$u_1 = u_1^*$
2	$M_{11} = M_{11}^*$	$\beta_1 = \beta_1^*$
3	$N_{12} + \frac{M_{12}}{R_2} = V_{12}^*$ $Q_{13} + \frac{\partial}{\partial \alpha_2} \left(\frac{M_{12}}{A_2} \right)$	$u_2 = u_2^*$
4	$+ \left[N_{11} \left(\frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \right) + N_{12} \left(\frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \right) \right] = V_{13}^*$	$u_3 = u_3^*$

Table 7 Boundary conditions (α_2 axis)

	Force/moment	Displacement
1	$N_{22} = N_{22}^*$	$u_2 = u_2^*$
2	$M_{22} = M_{22}^*$	$\beta_2 = \beta_2^*$
3	$N_{21} + \frac{M_{21}}{R_1} = V_{21}^*$	$u_1 = u_1^*$
4	$Q_{23} + \frac{\partial}{\partial \alpha_1} \left(\frac{M_{21}}{A_1} \right) + \left[N_{22} \left(\frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \right) + N_{21} \left(\frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \right) \right] = V_{23}^*$	$u_3 = u_3^*$

$$V_{23} = Q_{23} + \frac{\partial}{\partial \alpha_1} \left(\frac{M_{21}}{A_1} \right) \quad [18]$$

where V_{13} and V_{23} are the Kirchhoff effective shear stress resultants of the first kind; V_{12} and V_{21} are the Kirchhoff effective shear stress resultants of the second kind. Note that all elastic-, electric-, and thermal-related terms are included in the force and moment expressions. These electric terms can be used, in conjunction with control algorithms, as control forces/moments counteracting mechanical- and temperature-induced vibrations in distributed structural control of shells. The nonlinear piezothermoelastic shell equations can be further simplified based on (1) linear approximation, (2) material simplification, and (3) geometry simplifications.

In order to assist design and application of piezoelectric devices in industry, new finite element formulations (thick and thin solid elements, shell/plate elements, and composite elements) and computer codes have been developed in recent years. Accordingly, thermoelectromechanics, vibration behavior, sensing, and control encompassing all possible directions (e.g., three translational and two rotatory coordinates) of the generic piezoelectric shell continuum (and its derived geometries) and applications to smart structures and strucronic systems are further explored and evaluated. Furthermore, distributed sensor and actuator can be surface- or thickness-shaped using the modal strain functions. In this case, the shaped sensor or actuator is only sensitive to the designated natural mode (i.e., the orthogonal modal sensor or actuator) and it is insensitive to other natural modes, based on the modal orthogonality of natural modes. (See **Sensors and actuators** for details on distributed sensor and actuator applications and their related theories.)

Summary

Piezoelectricity is one of the most important electromechanical coupling phenomena successfully applied to engineering applications today. Practical applications range from micro- (e.g., MEMS and microsensors and actuators) to macrosystems (e.g., smart structures and strucronic systems, aerospace structures, satellite systems, and gossamer systems) and many other applications in between (e.g., force/pressure sensors, precision actuators, robotics and mechatronic systems, and vibration/noise isolation and control). However, the performance of today's piezoelectric devices is still limited to material properties and deficiencies, e.g., nonlinearity, hysteresis effects, limited strain rates, breakdown voltages,

and temperature instability, etc. These material properties need to be further improved in order to enhance future sensor/actuator performance and efficiency.

On the other hand, piezoelectricity typically represents the coupling of electric and elastic (mechanical) fields (Figure 1). Beyond the typical two-field coupling, there is a three-field coupling (temperature-electric-mechanical) and a four-field coupling (light-temperature-electric-mechanical; Figure 3). As the coupling complicates, the complexity of research issues increases, too. Although piezoelectricity has been around since 1880, there are still plenty of research issues that need to be addressed. Furthermore, novel applications and devices need to be continuously explored and utilized. (Note that other popular smart materials, e.g., electrostrictive materials, magnetostrictive materials, shape memory alloys, electro- and magnetorheological materials are introduced in separate articles.)

Nomenclature

A_1, A_2	Lamé parameters
c_v	specific heat at constant volume
\mathbf{D}	electric displacement vector
\mathbf{E}	electric field vector
\mathbf{P}	pyroelectric constant
R_1, R_2	radii of curvature
\mathbf{S}	strain tensor
\mathbf{T}	stress tensor
$\boldsymbol{\lambda}$	thermal stress constant vector
θ	temperature
ϕ	electrical potential
ρ	density
\mathfrak{S}	thermal entropy

Introduction

Pipes involving internal or external fluid flow can be found in many engineering applications such as power plants, chemical and petrochemical industries, heat exchangers, nuclear reactors, jet pumps, and hydraulic machinery. Pipes with fluid flow are subject to flow-induced vibration due to fluid pressure, turbulence in the flow and, sometimes, due to resonance with some periodicity in the flow. Four types of problems can be identified as: (i) pipes with internal fluid flow; (ii) pipes with external fluid flow; (iii) annular flow in systems of coaxial pipes, and (iv) cross-flow about arrays of tubes. Of these four types of problems, the first involving pipes with internal fluid flow is the oldest and best studied. Another classification of flow-induced vibration problems, based on the source of excitation, includes problems involving (i) extraneously induced excitation, (ii) instability induced excitation and (iii) movement-induced excitation. The extraneously induced vibration is caused by fluctuations in the flow or pressure, independently of any structural motion and flow instabilities. An example of this is the turbulence-induced excitation of a cylinder in fluid flow. The instability induced excitation is due to the instability of the flow as in the case of vortex shedding from a cylindrical structure. The movement induced excitation is a self-excited vibration as in the case of flutter of a cantilever pipe with internal fluid flow. The earliest work on the vibration of pipes conveying fluids is perhaps the experimental work of Aitken (1878). Housner was among the first to investigate the stability of a simply supported pipe conveying fluid.

Vibration of Pipes with Internal Fluid Flow

Some pipes with internal fluid flow, having different support conditions, are shown in Figure 1. The pipe is assumed to have an inner diameter d_i , an outer diameter d_o and Young's modulus E and the fluid is assumed to have a density ρ , pressure p and velocity v . The fluid flow imposes a pressure on the pipe walls

and causes the pipe to deflect. The fluid is subject to centrifugal acceleration as it passes through the deflected pipe due to the changing curvature of the pipe. In the absence of gravity and internal damping effects, the equation of motion of the pipe can be obtained as:

$$EI \frac{\partial^4 y}{\partial x^4} + (pA - T) \frac{\partial^2 y}{\partial x^2} + m_f \left(\frac{\partial}{\partial t} + v \frac{\partial}{\partial x} \right)^2 y + m \frac{\partial^2 y}{\partial t^2} = 0 \quad [1]$$

where y is the transverse deflection of the pipe, I is the area moment of inertia of the pipe, A is the cross-sectional area of the pipe, T is the longitudinal tension in the pipe, $m_f = \rho A$ is the mass of the fluid per unit length, m is the mass of the pipe per unit length, x is the axial coordinate and t is time. If the tension in the pipe is zero and the fluid pressure is equal to the ambient pressure at the end of the pipe, $p = T = 0$ at $x = L$ and it can be shown that $pA - T = 0$ for all x . Setting $pA - T = 0$, eqn [1] gives the equation of motion for the free transverse vibration of a tension-free straight pipe carrying fluid as:

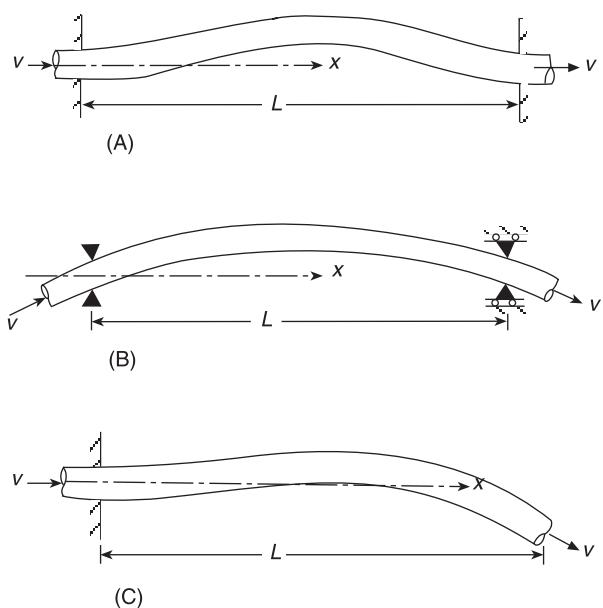

Figure 1 Pipes with internal fluid flow. (A) Clamped-clamped pipe; (B) simply supported pipe; (C) cantilever pipe.

$$EI \frac{\partial^4 y}{\partial x^4} + m_f v^2 \frac{\partial^2 y}{\partial x^2} + 2m_f v \frac{\partial^2 y}{\partial x \partial t} + M \frac{\partial^2 y}{\partial t^2} = 0 \quad [2]$$

$$\eta = \frac{\partial \eta}{\partial \xi} = 0 \text{ at } \xi = 0 \quad [8]$$

$$\frac{\partial^2 \eta}{\partial \xi^2} = \frac{\partial^3 \eta}{\partial \xi^3} = 0 \text{ at } \xi = 1 \quad [9]$$

where $M = m + m_f$ is the mass per unit length of the pipe including the fluid. Note that the first and fourth terms denote the stiffness and inertia terms that are independent of the flow velocity. The third term represents Coriolis force and causes asymmetric distortion of classical mode shapes (due to the presence of the mixed derivative) and leads to flutter like instability. The second term indicates the centrifugal force due to the acceleration of fluid passing through the deformed pipe. This term is similar to an axial compression term that produces a reduction in natural frequency and ultimately buckling of the pipe. For comparison, the equation of motion of a pipe subject to an axial compressive force P at the end (without fluid) is given by:

$$EI \frac{\partial^4 y}{\partial x^4} + P \frac{\partial^2 y}{\partial x^2} + m \frac{\partial^2 y}{\partial t^2} = 0 \quad [3]$$

It can be seen from eqns [2] and [3] that as the velocity of the fluid, v , increases, the effective stiffness of the pipe decreases and for a sufficiently large value of v , the destabilizing centrifugal force may overcome the restoring flexural force, thereby causing divergence (or buckling).

Solution

Using the dimensionless parameters:

$$\xi = \frac{x}{L}, \eta = \frac{y}{L}, \tau = \left(\frac{EI}{m + m_f} \right)^{1/2} \frac{t}{L^2} \quad [4]$$

the equation of motion, eqn [2], can be expressed as:

$$\frac{\partial^4 \eta}{\partial \xi^4} + \alpha^2 \frac{\partial^2 \eta}{\partial \xi^2} + 2\alpha\sqrt{(\beta)} \frac{\partial^2 \eta}{\partial \xi \partial \tau} + \frac{\partial^2 \eta}{\partial \tau^2} = 0 \quad [5]$$

where:

$$\alpha = vL \sqrt{\left(\frac{m_f}{EI} \right)}, \beta = \frac{m_f}{m_f + m} \quad [6]$$

The boundary conditions for a pipe simply supported at both the ends are:

$$\eta = \frac{\partial^2 \eta}{\partial \xi^2} = 0 \text{ at } \xi = 0, \text{ and } \xi = 1 \quad [7]$$

For a cantilever pipe, the boundary conditions are:

The solution of eqn [5] is assumed to be of the form:

$$\eta(\xi, \tau) = \text{Re}[U(\xi)e^{i\Omega\tau}] \quad [10]$$

where Re denotes the real part and Ω is the nondimensional frequency, defined in terms of the circular frequency, ω , as:

$$\Omega = \omega L^2 \left[\frac{m_f + m}{EI} \right]^{1/2} \quad [11]$$

In general, $\Omega = \Omega_R + i\Omega_I$ is complex [$i = \sqrt{(-1)}$] and the system will be stable (unstable) if the imaginary part, Ω_I , is positive (negative). The condition, $\Omega_I = 0$, corresponds to neutral stability of the system. Eqns [5] and [10] result in:

$$\frac{d^4 U}{d\xi^4} + \alpha^2 \frac{d^2 U}{d\xi^2} + 2i\alpha\Omega\sqrt{(\beta)} \frac{dU}{d\xi} - \Omega^2 U = 0 \quad [12]$$

Using the solution:

$$U(\xi) = A e^{i\theta\xi} \quad [13]$$

the exponent θ is determined from:

$$\theta^4 - \alpha^2 \theta^2 - 2\alpha\Omega\sqrt{(\beta)}\theta - \Omega^2 = 0 \quad [14]$$

Thus the complete solution can be expressed as:

$$\theta(\xi, \tau) = \text{Re} \left(\sum_{j=1}^4 A_j e^{i\theta_j \xi} e^{i\Omega_j \tau} \right) \quad [15]$$

The boundary conditions can be used to determine the constants A_j ($j = 1, 2, 3, 4$). For a simply supported pipe, eqns [7] and [15] yield:

$$\sum_{j=1}^4 A_j = 0 \quad [16]$$

$$\sum_{j=1}^4 \theta_j^2 A_j = 0 \quad [17]$$

$$\sum_{j=1}^4 e^{i\theta_j} A_j = 0 \quad [18]$$

$$\sum_{j=1}^4 \theta_j^2 e^{i\theta_j} A_j = 0 \quad [19]$$

Since the determinant of the coefficients of A_j in eqns [16] to [19] must vanish for a nontrivial solution of A_j , we have:

$$\begin{vmatrix} 1 & 1 & 1 & 1 \\ \theta_1^2 & \theta_2^2 & \theta_3^2 & \theta_4^2 \\ e^{i\theta_1} & e^{i\theta_2} & e^{i\theta_3} & e^{i\theta_4} \\ \theta_1^2 e^{i\theta_1} & \theta_2^2 e^{i\theta_2} & \theta_3^2 e^{i\theta_3} & \theta_4^2 e^{i\theta_4} \end{vmatrix} = 0 \quad [20]$$

Eqn [20] must be solved to find the dynamic response of the system.

Pinned–pinned pipe For this case the characteristic equation can be derived as $\sin \alpha = 0$ with roots given by $\alpha = n\pi$. Thus the first nonzero root is $\alpha = \pi$. The critical velocity of the flow that causes buckling (v_0) is:

$$v_0 = \frac{\pi}{L} \sqrt{\left(\frac{EI}{m_f}\right)} \quad [21]$$

By considering only the first two modes, the natural frequencies of the pipe can be determined as:

$$\left(\frac{\omega_i}{\omega_0}\right)^2 = \bar{\beta} \pm \left[\bar{\beta}^2 - 4\left(1 - \frac{v^2}{v_0^2}\right)\left(4 - \frac{v^2}{v_0^2}\right)\right]^{1/2}; \quad i = 1, 2 \quad [22]$$

where:

$$\bar{\beta} = \frac{17}{2} - \frac{v^2}{v_0^2} \left(\frac{5}{2} - \frac{128\rho A}{9\pi^2 M}\right) \quad [23]$$

and ω_0 is the fundamental circular natural frequency of the pipe in the absence of fluid flow:

$$\omega_0 = \frac{\pi^2}{L^2} \left(\frac{EI}{M}\right)^{1/2} \quad [24]$$

The mode shape corresponding to the fundamental frequency can be found as:

$$A_2 = -A_1 \left[\frac{8\omega_1 Lv / 3\pi^2 v_0^2}{16 - 4(v^2/v_0^2) - (\omega_1^2/\omega_0^2)} \right] \quad [25]$$

where A_1 and A_2 denote the magnitudes of the first and second modes, respectively. It is observed that for $v < v_0$, $|A_2| < 0.094A_1$ which indicates that the first sinusoidal bending mode dominates the response.

When $v = 0$ (no fluid flow), the first two natural frequencies of vibration of a pipe reduce to the natural frequencies of vibration of a rod, ω_0 and $4\omega_0$. As the fluid velocity increases, the values of natural frequencies decrease until the first frequency reduces to zero at $v = v_0$. At $v = v_0$, the force required to make the fluid conform to the deformed shape of the pipe exceeds the stiffness of the pipe and the pipe experiences divergence (buckling).

Cantilever pipe A cantilever pipe with internal fluid flow represents a nonconservative system. It can be shown that it loses stability by flutter, also known as Hopf bifurcation. This instability mechanism was first investigated by Benjamin. Qualitatively, the phenomenon can be explained as follows. The work done (ΔW) over a period of oscillation, τ , can be expressed as:

$$\Delta W = -Mv \int_0^t \left[\left(\frac{\partial y}{\partial t}\right)^2 + v \frac{\partial y}{\partial t} \frac{\partial y}{\partial x} \right]_L^0 dt \quad [26]$$

It can be observed that if both ends of the pipe are supported, then the system will be conservative (since $\Delta W = 0$). This implies that no energy is lost or gained during the oscillatory motion. On the other hand, if one end is fixed (at $x = 0$) and the other end is free (at $x = L$), the system will be nonconservative with ΔW given by:

$$\Delta W = -Mv \int_0^t \left[\left(\frac{\partial y}{\partial t}\right)^2 + v \frac{\partial y}{\partial t} \frac{\partial y}{\partial x} \right]_L dt \quad [27]$$

Thus for $v > 0$ and small, $\Delta W < 0$ and the free vibration is damped. However, if $v > 0$ and sufficiently large, the integral may be negative under certain conditions leading to $\Delta W > 0$. This implies that energy is extracted from the flow and free vibration is amplified which leads to a negative-damping type of instability (flutter).

For a quantitative analysis of the vibration of a cantilever pipe with internal fluid flow, the deflection is assumed as:

$$y(x, t) = \text{Re} \left[U \left(\frac{x}{L} \right) e^{i\omega t} \right] \quad [28]$$

The mode shapes of a cantilever pipe without fluid flow, $Y_i(x/L)$, are used to approximate the mode

shapes of a pipe with fluid flow, $U(x/L)$, as:

$$U\left(\frac{x}{L}\right) = \sum_{i=1}^{\infty} A_i Y_i\left(\frac{x}{L}\right) \quad [29]$$

where:

$$\begin{aligned} Y_i\left(\frac{x}{L}\right) &= \cosh(\lambda_i x) - \cos(\lambda_i x) \\ &- c_i [\sinh(\lambda_i x) - \sin(\lambda_i x)] ; \quad i = 1, 2, \dots \end{aligned} \quad [30]$$

where $\lambda_1 L = 1.875$, $\lambda_2 L = 4.694$, $\lambda_3 L = 7.855, \dots$, $c_1 = 0.7341$, $c_2 = 1.0185$, $c_3 = 0.9992 \dots$. Eqns [29] and [12] yield the equation of motion of the pipe with fluid flow as:

$$\sum_{j=1}^{\infty} \left(Y_j''' + i\theta^2 Y_j'' + 2\Omega\beta^{1/2} \theta_j Y_j' - \Omega^2 Y_j \right) A_j = 0 \quad [31]$$

By using the mode shapes of eqn [30] along with the property of orthogonality of mode shapes, the equations of motion of the pipe can be expressed in matrix form as:

$$[\mathbf{K} - \Omega^2 \mathbf{I}] \mathbf{A} = \mathbf{0} \quad [32]$$

By setting the determinant of the coefficient matrix in eqn [32] equal to zero:

$$|\mathbf{K} - \Omega^2 \mathbf{I}| = 0 \quad [33]$$

the natural frequencies of vibration of the pipe, Ω_j , can be determined. When the natural frequency Ω_j is expressed as a complex quantity, $\Omega_j = \Omega_{jR} + i\Omega_{jI}$ where Ω_{jR} can be seen to cause vibration with an exponentially decaying envelope and Ω_{jI} an exponentially growing envelope. The condition $\Omega_{jI} = 0$ corresponds to neutral stability. A typical stability map is shown in Figure 2. It can be seen that when the mass ratio (m_f/M) is approximately equal to 0.295, 0.67 and 0.88, an increase in the fluid velocity causes the pipe to lose stability; but soon regains the stability. When the fluid velocity exceeds a critical velocity, the cantilever pipe will not buckle as in the case of a pinned-pinned pipe, but oscillates like an unrestrained garden hose with a finite frequency.

Pipes with Unsteady Fluid Flow

The fluid flow was assumed to be steady in the previous section. If the flow is unsteady such that:

$$\nu = \nu_0(1 + c \sin \omega t) \quad [34]$$

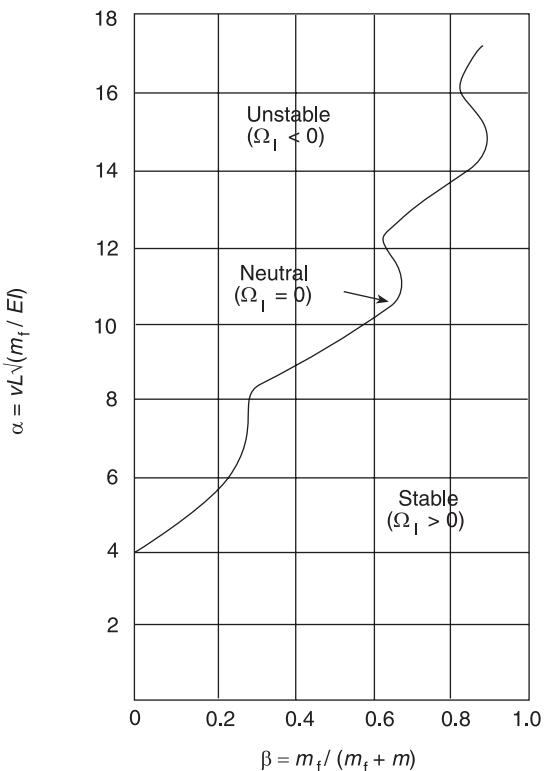

Figure 2 Typical stability map for a cantilever pipe.

where the time-dependent component involving $\sin \omega t$ is superposed on the steady component, the system can experience parametric instabilities as well. Usually c is small and the parametric instabilities are similar to those of a thin column subject to an end load of the form $P = P_0(1 - c \sin \omega t)$. If the unsteady flow in the pipe is arbitrary which cannot be expressed by eqn [34], the problem needs to be solved as a stochastic stability problem.

Vibration of Pipes with External Fluid Flow

Pipes are subject to external fluid flow in heat exchangers and nuclear reactors. The forces acting on a pipe with external axial fluid flow are shown in Figure 3. The equations of motion of such a pipe can be expressed as:

$$\begin{aligned} EI \frac{\partial^4 y}{\partial x^4} + \rho A V^2 \frac{\partial^2 y}{\partial x^2} + 2\rho A V \frac{\partial^2 y}{\partial x \partial t} \\ - \frac{1}{2} \rho V^2 d_0 C_f \left(1 + \frac{d_0}{d_h}\right) (L - x) \frac{\partial^2 y}{\partial x^2} + \frac{1}{2} \rho d_0 V C_f \frac{\partial y}{\partial t} \\ + \frac{1}{2} \rho V^2 d_0 C_f \left(1 + \frac{d_0}{d_h}\right) \frac{\partial y}{\partial x} + M \frac{\partial^2 y}{\partial t^2} = 0 \end{aligned} \quad [35]$$

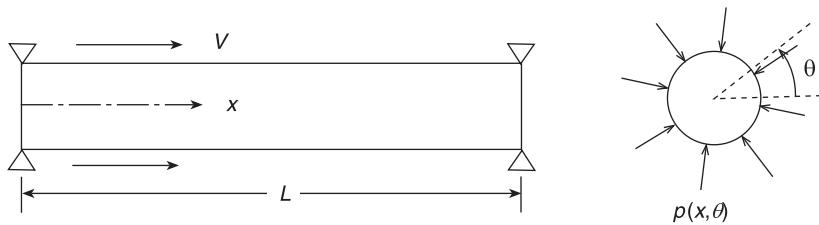

Figure 3 Pipe with external fluid flow.

where $y(x, t)$ is the transverse deflection of the pipe, V is the axial velocity of the fluid, EI is the bending stiffness of the pipe, ρ is the density of the pipe, d_0 is the outer diameter of the pipe, d_h is the hydraulic diameter = $(4 \times \text{flow area}/\text{wetted perimeter})$, C_f is the skin friction coefficient for fluid flow over the pipe and $M = m + \rho A$ is the mass of the pipe plus external added mass of fluid per unit length. It can be observed that eqn [35] reduces to the equation of motion of a pipe with internal fluid flow, eqn [2], if $C_f = 0$ and $V = v$. This indicates that the solution for a pipe with external fluid flow will be similar to that of a pipe with internal fluid flow. It can be shown that for pipes with both ends supported, divergence can occur at low velocities and coupled mode flutter instability can take place at higher velocities of the flow. The cantilever pipes, on the other hand, can lose stability by divergence and then single mode flutter can occur at higher flow velocities of the fluid.

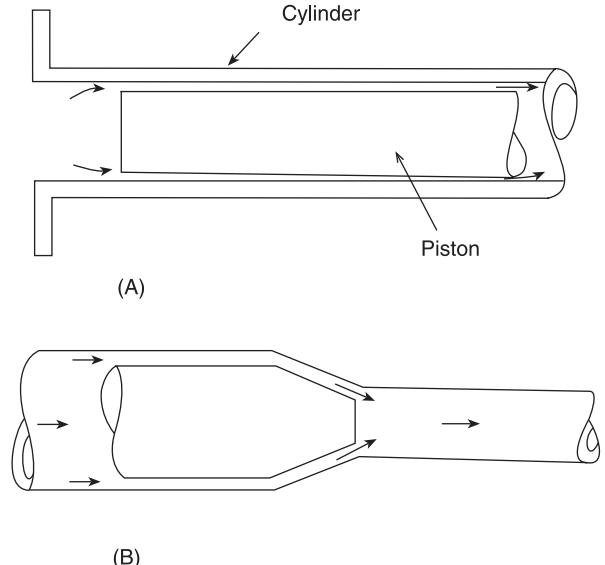

Figure 4 Annular flow due to leakage. (A) Piston and cylinder; (B) valve.

Vibration of Coaxial Pipes with Annular Fluid Flow

The problem of annular fluid flow is important in applications such as control rods in guide tubes, fuel strings in coolant channels and jet pumps, pistons and valves (Figure 4). The annular-flow induced instabilities are also known as leakage-flow induced instabilities since in most cases, the annular flow passage is quite narrow. Hobson (1982) is among the first to develop an analytical model for pipes with annular flow. For the sake of simplicity, Hobson considered a rigid cylindrical rod placed coaxially in a duct with fluid flow. He showed that, when one end of the rod is hinged, at sufficiently large fluid flow velocities, instability occurs through a negative damping mechanism. When coaxial pipes are considered with incompressible or compressible inviscid fluid in the annulus and in the inner pipe, the system will be conservative when both ends are supported. However, it can be shown that stability will be lost first by divergence followed by either divergence in another mode or by coupled-mode flutter at sufficiently large velocities of the fluid flow. For this system, two sets of

coupled modes exist; one is the symmetric set where the deformations of the two pipes will be in phase and the other is the antisymmetric set where the deformations will be in antiphase.

Vibration of Pipes with Cross-Flow

Pipes are subject to cross-flow in many applications such as heat exchangers, steam generators and condensers. Usually one type of fluid flows inside the pipes while another type of fluid flows outside the pipes in a direction normal to the pipes. In addition, the velocity of the fluid inside the pipes will be too small to induce internal-flow induced instabilities. The external cross-flow gives rise to instabilities that are commonly known as fluidelastic instabilities. The fluidelastic instability occurs when several rows of flexible pipes, arranged in a regular geometric pattern, are subject to cross-flow. At a sufficiently large velocity of the fluid flow, the pipes in one of the first few rows will experience a sudden increase in the amplitude of vibration. If the pipes are closely spaced, the large amplitude vibration leads to impact between

pipes that can cause destructive damage. At higher flow velocities, the pipes in all rows experience fluidelastic instability. The mechanism of this instability is different from the resonance that can occur due to flow periodicities associated with a wake. The mechanics of cross-flow, in general, is more difficult compared to the other three types of flows. In a cross-flow, the flow can separate forming a wake behind each of the pipes. As such, potential flow theory cannot be used in this case.

Nomenclature

A	cross-sectional area
d	diameter
E	Young's modulus
EI	bending stiffness
I	inertia
M	mass
p	pressure
P	axial compressive force
t	time
T	tension
v	velocity
ρ	density
Ω	nondimensional frequency
ΔW	work done

A plate is a flat structural element having a thickness which is much smaller than its lateral dimensions. An example is the rectangular plate shown in Figure 1, having thickness b and lateral dimensions a and b . The plate shown has two edges clamped ($x = 0$ and $y = 0$), one simply supported ($x = a$, which may be supported on knife edges, as shown, or hinged), and one free.

For a sufficiently thin plate made of linearly elastic, isotropic, homogeneous material, vibrating freely in a vacuum (i.e., neglecting the mass of its surrounding air or other media) with relatively small transverse displacement ($w < b$), the equation governing its transverse motion is:

$$D\nabla^4 w + \rho b \frac{\partial^2 w}{\partial t^2} = 0 \quad [1]$$

where $D = Eb^3/12(1 - v^2)$ is the flexural rigidity, with E and v being the modulus of elasticity (Young's modulus) and Poisson's ratio, respectively, of the material; ρ is its mass density per unit volume; t is time; and ∇^4 is the biharmonic differential operator, which is:

$$\begin{aligned} \nabla^4 &= \nabla^2 \nabla^2 = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right)^2 \\ &= \frac{\partial^4}{\partial x^4} + 2 \frac{\partial^4}{\partial x^2 \partial y^2} + \frac{\partial^4}{\partial y^4} \end{aligned} \quad [2]$$

in rectangular coordinates.

This brief summary will focus on the natural frequencies (ω) and mode shapes of the undamped, free

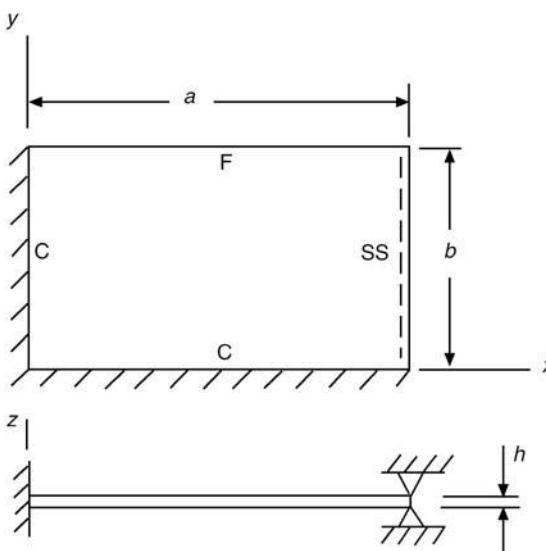

Figure 1 A clamped-clamped-simply supported-free (C-C-SS-F) rectangular plate.

vibrations, for this is typically the most important information needed in analyzing forced vibrations. That is, one needs to know the resonant frequencies of forced vibration, which are the natural frequencies, and the deformed shape of the plate at resonance, which is the corresponding free vibration mode shape. A plate may also vibrate laterally (i.e., in the x and y directions in Figure 1). But if the plate is thin, the frequencies of these modes are much greater than those of the transverse modes; hence, they are typically of little practical importance. Emphasis will be given to plates of rectangular and circular shape in what follows, for these are the shapes for which data are commonly needed.

Rectangular Plates

There are 21 possible, distinct combinations of edge conditions for rectangular plates. The clamped-clamped-simply supported-free (C-C-SS-F) plate shown in Figure 1 is one of them. The edge conditions (mathematical boundary conditions) which would be satisfied for the C-C-SS-F plate are: (1) no transverse displacement or normal rotation of the clamped edges; (2) no displacement or bending moment along the simply supported edge; and (3) no bending moment or transverse shearing force along the free edge.

For six of the 21 possible combinations, exact mathematical solutions exist for the free vibration frequencies and mode shapes. These are the cases when two opposite edges (say, for example, $x = 0$ and $x = a$) are simply supported. If the plate is vibrating freely, with no damping present, then:

$$w(x, y, t) = W(x, y) \sin(\omega t + \phi) \quad [3]$$

where $W(x, y)$ is the mode shape, a function of x and y , and ϕ is an arbitrary phase angle. When all four edges are simply supported the mode shapes are:

$$W(x, y) = \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \quad [4]$$

where m and n are both integers ranging from one to infinity ($m, n = 1, 2, \dots, \infty$). Substituting eqns [2], [3], and [4] into [1], the nondimensional frequency parameter is found:

$$\omega a^2 \sqrt{\rho h/D} = \pi^2 [m^2 + (a/b)^2 n^2] \quad [5]$$

That is, for a plate of given dimensions (a, b, h) and material properties (ρ, E, v) there is a doubly infinite number of free vibration frequencies (ω) , corresponding to the various m and n . For the SS-SS-SS-SS plate, the mode shapes take the form of half sine waves in each direction, with the lowest frequency corresponding to one half-wave in each direction.

Consider the other five cases for which the edges $x = 0$ and $x = a$ are simply supported. Then the mode shapes take the form:

$$W(x, y) = Y(y) \sin \frac{m\pi x}{a} \quad [6]$$

which satisfies the SS edge conditions exactly. Substituting eqn [6] into eqn [1], one finds that $Y(y)$, a function solely of y , consists of a linear combination of trigonometric and hyperbolic functions. Applying this to the two edge conditions which exist at $y = 0$ and $y = b$ yields the frequencies (eigenvalues) and mode shapes (eigenfunctions). For each m there is an infinite number of possible Y .

For the remaining 15 rectangular plates having other combinations of edge conditions, although no exact results may be found, approximate methods may be used (especially the Ritz method) to obtain free vibration frequencies and modes shapes as close to the exact ones as desired. Frequencies for all 21 cases are given in Table 1 for square ($a/b = 1$) and nonsquare ($a/b = 0.4$ and 2.5) plates. The lowest (fundamental) frequency is given for all three configurations, while for the square one the second and third lowest ones are also presented. Frequencies for the six cases having two opposite edges simply supported are shown first – they are exact to the number of digits shown. Accurate values for the other 15 cases are also given. All frequencies depend upon the Poisson's ratio (v) of the material, because

D contains ν , but the parameter $\omega a^2 \sqrt{\rho h/D}$ used for **Table 1** does not depend upon ν , unless at least one edge is free. For the 15 cases in **Table 1** having at least one free edge, the frequencies shown are for $\nu = 0.3$, a value close to that for most commonly used metals (e.g., steel, aluminum). Comparing the data in **Table 1** for various cases it is seen that adding constraint to a vibrating system increases its frequencies, while taking it away decreases them. For example, the C-C-C-C plate has higher frequencies than the C-C-C-SS one, whereas the C-C-C-F plate has lower ones. Much experimental data can be found which agrees closely with the theoretical data given in **Table 1**. However, it is difficult to replicate a clamped edge experimentally – the stiffness of the edge-clamping fixture must be much greater than that of the plate to approximate a clamped edge adequately.

Examples of free vibration mode shapes may be seen in **Figure 2**, these being for a completely free square plate. The modes are classified as SS, SA, AS and AA, depending upon whether they are symmetric or antisymmetric with respect to the plate centerlines, and the first two are depicted for each class. The first three frequencies given in **Table 1** (13.49, 19.79, 24.43) correspond to the AA-1, SS-1, and SS-2 modes of **Figure 2**. Contour lines of equal displacement are shown in **Figure 2**, as well as the heavier nodal lines (zero displacement).

Circular Plates

A circular plate of radius a is depicted in **Figure 3**. Also shown there is a polar (r, θ) coordinate system, which is useful for dealing with circular boundaries. In polar coordinates the Laplacian differential operator (∇^2) to be used in eqn [2] is:

$$\nabla^2 = \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} \quad [7]$$

The solution form of eqn [3] may again be used for the equation of motion [1], except now $W = W(r, \theta)$, where:

$$W(r, \theta) = R(r) \cos n\theta \quad (n = 0, 1, 2, \dots \infty) \quad [8]$$

and $R(r)$ is a function involving ordinary and modified Bessel functions. Applying the edge conditions at $r = a$ (clamped, simply supported, or free) yields an eigenvalue determinant, the roots of which are the nondimensional frequency parameters $\omega a^2 \sqrt{\rho h/D}$.

Table 2 gives $\omega a^2 \sqrt{\rho h/D}$ for a clamped circular plate, where n is the number of nodal diameters, and s the number of nodal circles, in the free vibration mode shape. **Figure 4** shows examples of the nodal patterns, consisting of diametral and circular node lines (i.e., lines where the transverse displacement

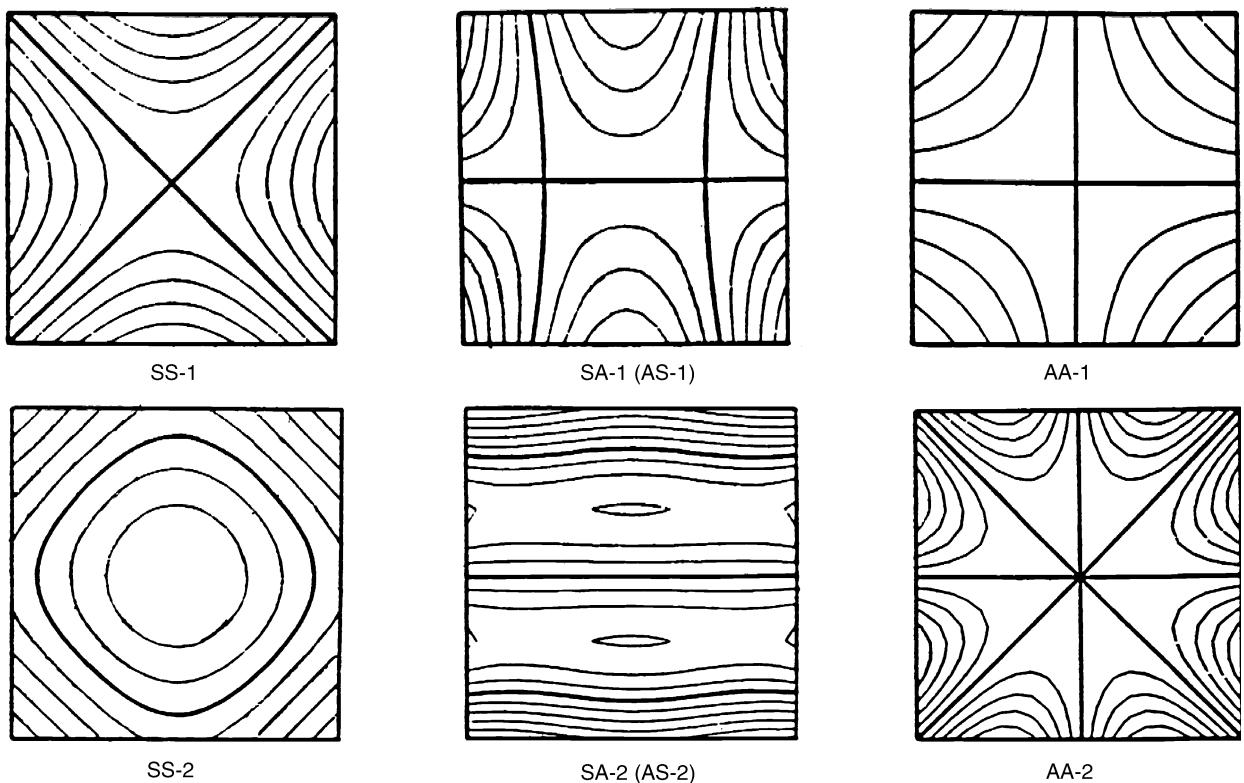

Figure 2 Contour plots of mode shapes for F-F-F-F square plates ($v = 0.3$).

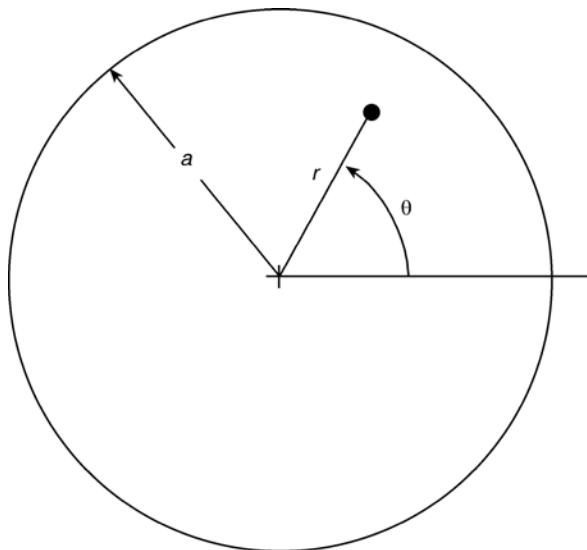

Figure 3 A circular plate.

(W) is always zero while the plate is vibrating). The plus and minus signs on the patterns are there to emphasize that, while a region on one side of a node line is moving towards the reader, on the other side it is moving away. Locations of the nodal circles, corresponding to the frequencies of Table 2, are listed in Table 3.

For simply supported plates, the zero bending moment condition at the edge involves Poisson's ratio; therefore, $\omega a^2 \sqrt{\rho h/D}$ not only contains v within it ($D = Eh^3/12(1 - v^2)$), but varies with v . Therefore, Table 4 for SS plates gives $\omega a^2 \sqrt{\rho/Eh^2}$ which does not contain v . These results show that changing v may have a large effect upon the frequency.

Other Shapes

Plates may be found in an unlimited variety of shapes; for example, they may be annular, elliptical, parallel-

ogram, trapezoidal, other quadrilaterals, triangular, or polygonal. Besides the hundreds of research papers which have been published for rectangular and circular plates, presenting natural frequencies and, to a

much lesser extent, mode shapes, numerous others present data for other shapes. Very few of these free vibration problems have exact solutions; approximate methods must typically be used to determine frequencies and node shapes.

Figure 5 depicts a cantilevered (C-F-F-F) parallelogram (or skew) plate with side lengths a and b . Table 5 shows how the frequency parameter $\omega a^2 \sqrt{\rho h/D}$ changes as the skew angle β increases. To obtain the accurate results shown in Table 5 it was necessary to represent the bending and twisting moment singularities in the reentrant corner correctly.

Accurate frequencies and corresponding nodal patterns have also been obtained for completely free triangular plates by the Ritz method. A representative

triangular configuration defining the dimensions a , b and c is shown in Figure 6. The first six frequency parameters $\omega a^2 \sqrt{\rho h/D}$ for $c/b = -0.5$ (scalene triangle), 0 (right triangle), and 0.5, and $a/b = 0.5$ and 1, are seen in Table 6. Corresponding nodal patterns are shown in Figure 6.

Complicating Effects

The plates described above may all have further complicating effects. An edge constraint may be discontinuous; for example, it may be clamped partly along an edge, and simply supported along the remainder. Then its frequencies fall between those of plates having the edge continuously clamped or continuously simply supported. Addition of a notch or crack decreases the frequencies – the mass of the system is virtually unchanged, but the plate stiffness is significantly decreased.

There are many complicating effects which result in a governing differential equation of motion being different than that of eqn [1]. Some of them relate to the material composition of the plate. The material may be anisotropic, or orthotropic (a special case of anisotropy), where the flexural rigidity (D) changes with direction. Or the material may be nonhomogeneous (i.e., having properties which vary with location in the plate). Examples of this would be: (1) a styrofoam plate with varying density and resulting variation of the modulus of elasticity (E), and (2) a

layered plate. There is ever-increasing utilization of laminated composite plates, that is, plates made of layers (lamina), the layers being orthotropic. A great deal of free vibration frequency and mode shape data has been published for these kinds of plates, especially laminated composites.

If a plate is subjected to inplane tensile stresses along its edges, frequencies are increased. Conversely, inplane compressive stresses cause the frequencies to decrease. For example, consider an SS-SS-SS-SS rectangular plate subjected to uniform tensile stresses σ_x and σ_y in the x and y directions, respectively, acting along its edges. For this case the free vibration mode shapes remain those of eqn [4], whereas the frequencies may be determined from:

$$\frac{\omega^2 a^4 \rho h}{D} = \left[(m\pi)^2 + (n\pi)^2 \left(\frac{a}{b} \right)^2 \right]^2 + \frac{\sigma_x h a^2}{D} (m\pi)^2 + \frac{\sigma_y h a^2}{D} (n\pi)^2 \left(\frac{a}{b} \right)^2 \quad [9]$$

Eqn [9] shows clearly that compressive stresses (negative σ_x and/or σ_y) cause all frequencies to decrease. Sufficiently large compressive stresses can decrease the frequencies to zero. Such an event corresponds to bifurcation buckling, with the first frequency to approach zero identifying the critical buckling stresses – when the destabilizing effects of compressive stress approach the magnitude of the stabilizing plate stiffness, the plate loses its ability to return to the flat, static equilibrium position, as required in a vibratory motion. These general statements apply to all plate configurations and edge constraints, as well as to other structural elements having bending stiffnesses (e.g., straight and curved beams, shells) or complete structures. One can determine buckling loads by plotting frequency versus loading. Shear stresses are also destabilizing (frequency-decreasing).

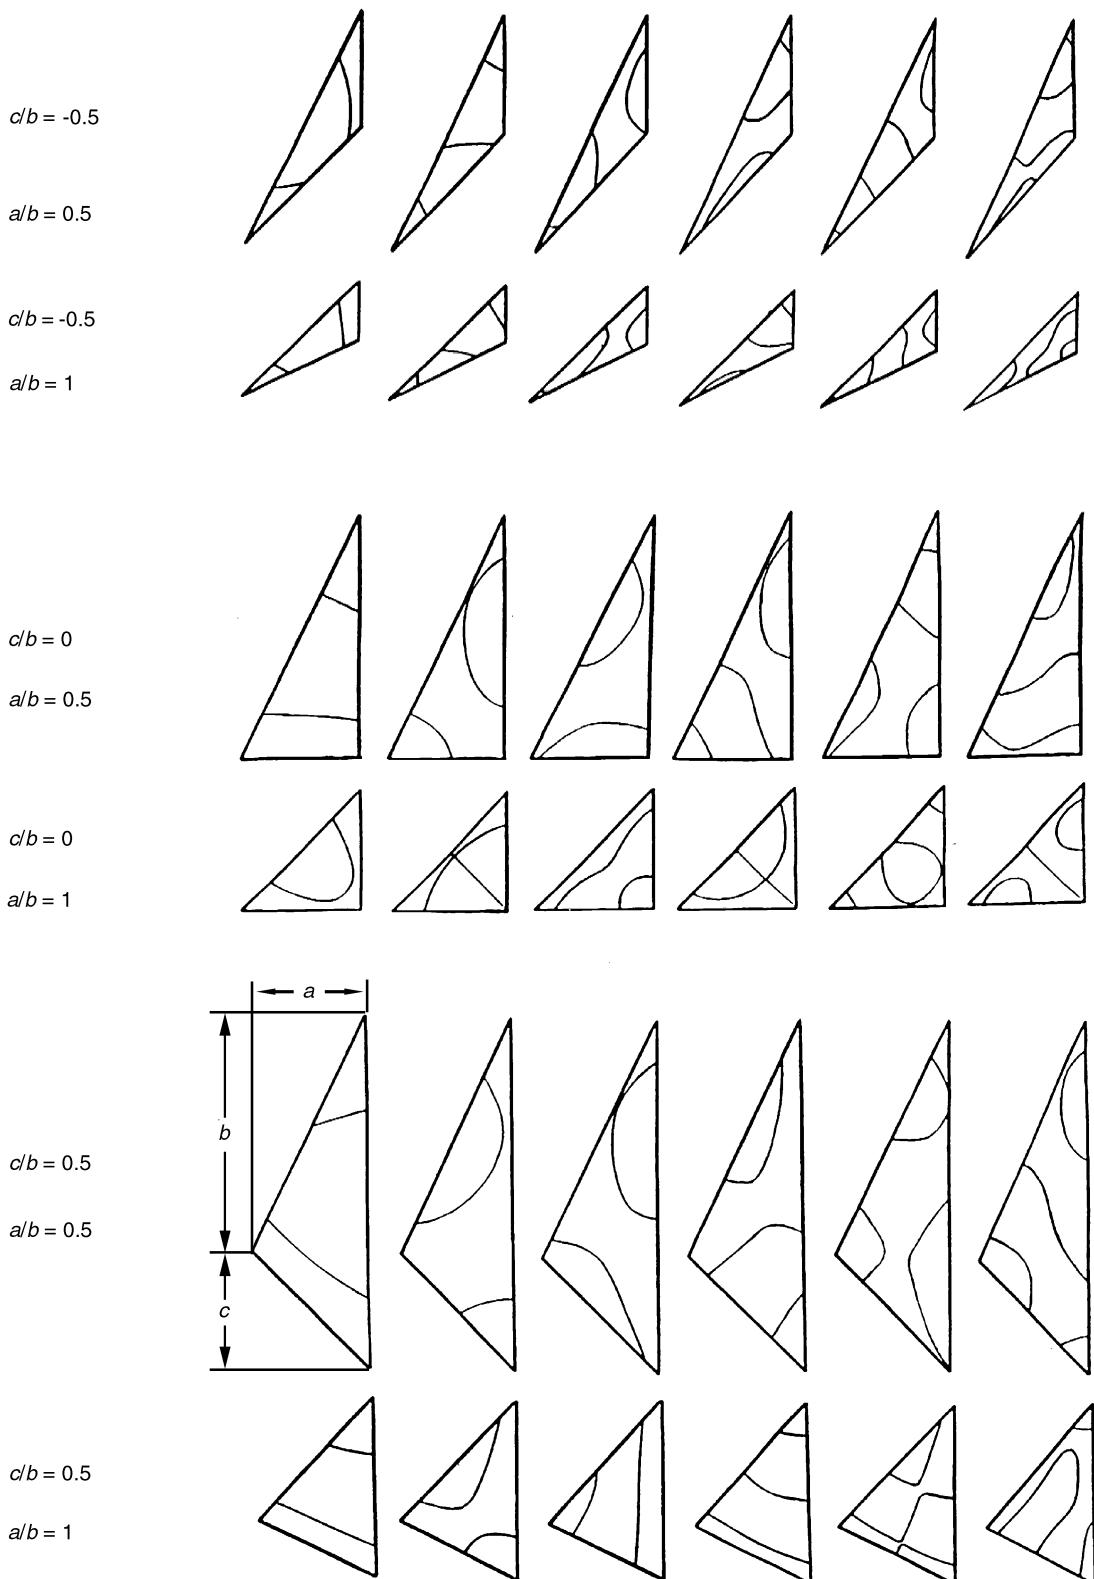

Figure 6 Triangular plates with dimensions a , b , and c .

If a plate has variable thickness, say $h = h(x, y)$, then not only is h a variable in eqn [1], but the first term ($D\nabla^4\omega$) becomes considerably generalized. The resulting problem is much more difficult to solve, and approximate methods are usually used.

A plate vibrating in a fluid medium, either compressible (e.g., air), or incompressible (e.g., water), has its frequencies decreased because the vibratory plate motion requires movement of the additional mass in the surrounding medium. Liquids typically reduce the frequencies considerably because of their relatively large mass density. But a plate vibrating even in a gas may also have a significant decrease ($\sim 5\%$) in some of its frequencies. Thus, experimental frequencies (typically obtained in air) can be expected to be somewhat less than theoretical frequencies (based upon vibration in a vacuum).

Eqn [1] includes the bending flexibility of a plate, but does not include its transverse shear flexibility. Also, it considers the translational inertia, but not the rotary inertia of the plate. The theory may be generalized to include both shear deformation and rotary inertia, and both effects are found to decrease the frequencies. A widely used sixth-order theory (three boundary conditions to be satisfied along each edge) was developed by Mindlin. Both effects become more significant as the relative thickness (say, h/a , for a rectangular plate) increases, and for the higher-frequency vibration modes. Because of their relatively large shear flexibility, laminated composite plate frequencies are affected greatly.

If a plate is constrained in its plane along its edges, then frequencies will increase if the amplitude of the transverse, vibratory motion is increased. Quite a significant frequency increase ($\sim 30\%$) may be expected as the magnitude of the amplitude

approaches that of the plate thickness. The increase is due to the additional stretching stiffness of the plate, which increases with amplitude (i.e., hard spring response). Generalization of eqn [1] to include this effect results in its character changing from being a linear equation to a nonlinear one.

Nomenclature

D	flexural rigidity
E	modulus of elasticity
v	Poisson's ratio
ϕ	phase angle
ρ	density
σ	tensile stress

R

RANDOM PROCESSES

doi:10.1006/rwvb.2001.0122

The probabilistic approach provides perhaps the most important method of treating uncertainty in dynamic loads and material properties for engineering analyses. In particular, the theory of probability and the theory of random processes provide a description for excitation forces, that cannot be adequately described by specified deterministic functions (wind loads on buildings, wave loads on ships and offshore structures, ground motions during earthquakes). The resulting structural response is certainly random, and should be treated accordingly.

This article provides a brief outline of the fundamentals of the theory of probability and the theory of random processes. Models for random dynamic loads and excitations are described.

A complete description of a continuous random variable (RV) X is provided by its probability density function (pdf) $p_X(x) = dF_X(x)/dx$, $F_X(x) = \text{Prob}\{X \leq x\}$ or set of moments $\langle X^n \rangle = \int_{-\infty}^{\infty} x^n p_X(x) dx$, with n being positive integers (angular brackets denote probabilistic averaging). Two lowest-order moments have special names: the mean or expected value and variance of X : $m_X = \langle X \rangle$, $D_X = \langle (X - m_X)^2 \rangle = \langle X^2 \rangle - m_X^2 = \sigma_X^2$ where σ_X is a root mean square (RMS) value of X . The normal or Gaussian RV, with pdf:

$$p_X(x) = \left(\sigma_X \sqrt{2\pi}\right)^{-1} \exp \left[-(x - m_X)^2 / (2\sigma_X^2) \right] \quad [1]$$

is completely described by these two moments. The constant cofactor with the exponential function provides the normalization condition. Namely, the integral of the pdf within a relevant domain, the whole axis x in this case, should be equal to unity as the probability of a certain event.

Alternatively, the Fourier transform of the pdf can be used, and this is called a characteristic function of the RV:

$$\begin{aligned} f_X(u) &= \int_{-\infty}^{\infty} \exp(iux) p_X(x) dx \\ &= \sum_m ((iu)^m / m!) \langle X^m \rangle \end{aligned} \quad [2]$$

For the pdf (eqn [1]) with $m_X = 0$:

$$f_X(u) = (\sigma_X \sqrt{2\pi})^{-1} \exp(-\sigma_X^2 u^2 / 2) \quad [3]$$

If two RVs are related deterministically as $Y = f(X)$, the pdf of Y can be expressed in terms of the pdf of X , using the condition for the same probability of events $Y \leq y$ and $X \leq g(y)$ or $Y \leq y$ and $X \geq g(y)$, within ranges with monotonously increasing or decreasing f , respectively, where $g(y)$ is the inverse function to $f(x)$. In the case of a monotonous and single-valued $f(x)$, the relation between the pdf functions is:

$$p_Y(y) = p_X(g(y)) |dg/dy| \quad [4]$$

In particular, if X is normal RV and f is linear, then Y is also normal. Eqn [4] can simply be extended to nonmonotonous $f(x)$ using summation in the RHS over the corresponding branches of the multivalued g .

A vector RV \mathbf{X} is described by joint pdf of its components X_j . The normal joint pdf is described completely by its mean vector with components m_j and covariance matrix \mathbf{K}_{XX} with elements:

$$\langle (X_j - m_j)(X_k - m_k) \rangle = \langle X_j X_k \rangle - m_j m_k$$

This matrix is nonsingular, provided that there is no deterministic relation(s) between any pair of components, otherwise the selected extraneous components may be excluded by reduction to the vector of a lower dimension. The normal joint pdf of an n -dimensional vector is:

$$p_X(\mathbf{x}) = C \exp \left[-(1/2)(\mathbf{x} - \mathbf{m}_X)^T \mathbf{K}_{XX}^{-1} (\mathbf{x} - \mathbf{m}_X) \right]$$

$$C = (2\pi)^{-n/2} |\mathbf{K}_{XX}|^{-1/2}$$

In the case of a diagonal covariance matrix this expression reduces to a product of exponents, corresponding to the independent normal RVs. The possibility of diagonalization of a given covariance matrix implies that a set of linear combinations may be introduced for given correlated RVs, which are uncorrelated, and therefore independent in case of their normality.

The normality is preserved if linear transformations are applied to a vector RV. This fact makes this property particularly important, together with the notorious central limit theorem (CLT). Thus, the pdf of a sum of two independent RVs $Z = X + Y$ may be written as a convolution integral of their individual pdfs. Applying the Fourier transform to the pdfs, one can express the characteristic function of Z as a product:

$$f_Z(u) = f_X(u)f_Y(u)$$

Thus, a characteristic function of the sum:

$$S_N = N^{-1/2} \sum_{k=1}^N X_k$$

where X_k are independent RVs, which have an arbitrary identical pdf $p_X(x)$ with zero mean and unit standard deviation, may be reduced, using the two-term expansion in eqn [2], to the N th power of the $f_{X/\sqrt{N}}(u)$. In the limit with $N \rightarrow \infty$ the exponent of the form (eqn [3]) is obtained for $f_{S_N}(u)$, which corresponds to the normal, or Gaussian pdf of S_N .

In its general formulation, the CLT states, that the pdf of a sum of independent RVs approaches the normal one with an increasing number of components, irrespective of the pdfs of the components, provided that none of these components is dominant.

This property provides a rationale for detecting defects in a roller bearing from its vibrational signal X . Thus, the nonsmall value of a properly scaled fourth-order moment, the so-called coefficient of excess

$$\gamma = \left\langle (X - m_X)^4 \right\rangle / \sigma_X^4 - 3 \quad [5]$$

which should be zero for the Gaussian pdf (eqn [1]), may imply the appearance of a dominating, and therefore abnormal source of vibration (defect).

In the case of a general relation between two vector RVs, their joint pdfs are related via the relevant

Jacobian of the transformation (extension of eqn [4] to a multidimensional case). In particular, if a two-dimensional vector \mathbf{X} has normal zero-mean independent components with the same RMS value σ , its amplitude $A = \sqrt{(X_1^2 + X_2^2)}$ and phase $\Theta = \tan^{-1}(X_1/X_2)$ have a Rayleigh pdf and uniform pdf, respectively:

$$p_A(a) = (a/\sigma^2) \exp(-a/2\sigma^2) \quad [6]$$

$$p_\Theta(\theta) = 1/2\pi \quad \text{for } 0 \leq \theta < 2\pi \quad [7]$$

A time-dependent RV $X(t)$ is called a random process. For its complete description a joint pdf of values at different time instants may be required in general. To make such a description practical some model of temporal variations for excitation force(s) is usually needed. The commonest one is that of a continuous normal $X(t)$, which is described completely by the (deterministic) mean value and autocorrelation function:

$$m_X(t) = \langle X(t) \rangle$$

$$R_{XX}(t_1, t_2) = \langle X(t_1)X(t_2) \rangle \quad [8]$$

The first-order pdf of a Gaussian $X(t)$ is of the same form (eqn [1]) as for the RV, with $\sigma_X^2 = R_{XX}(t, t)$. The second-order joint pdf of $X_1 = X(t_1)$ and $X_2 = X(t_2)$ is a negative exponent of a positively definite quadratic form of x_1, x_2 , with coefficients being defined by first-order and second-order moments (eqn [8]). Higher-order pdfs are uniquely related to the first-order and second-order ones.

Eqn [4] can be applied to a periodic signal $X(t)$, provided the time argument is selected in a random fashion, or a random phase Θ is added to it, which has a uniform pdf (eqn [7]). Thus, if:

$$X(t) = \lambda \sin(\omega t + \Theta)$$

then:

$$p_X(x) = (1/\pi)(\lambda^2 - x^2)^{-1/2} \quad \text{for } |x| \leq \lambda \quad [9]$$

and zero otherwise. The singularities, which can be seen in **Figure 1A** are typical for any periodic signal $X(t)$ with smooth peaks. Whilst these singularities may become ‘smeared’ for real signals due to the presence of other (nonperiodic) signals and/or noises, the observed bimodal pattern in the pdf of a vibrational signal (**Figure 1B**) may imply the presence of a certain periodicity in the signal, which usually has unimodal pdfs (**Figure 1C**). This method of detecting periodicity has an important advantage: it is relatively

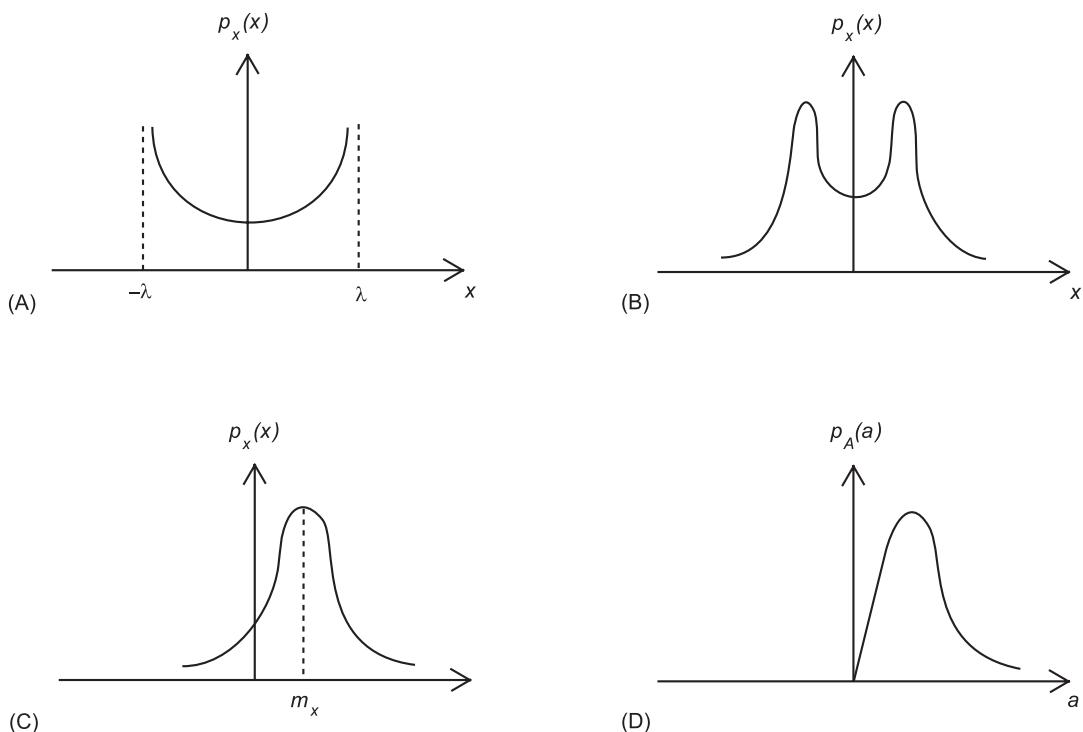

Figure 1 Specific pdfs. (A) Sinusoid with random phase; (B) bimodal; (C) unimodal; (D) Rayleigh pdf.

insensitive to temporal variations of phase. Thus, it is particularly appropriate for online detection of inherent ‘mild’ dynamic instability, which does not lead to an immediate failure but may still be undesirable. Such instability implies limited growth of the response with time, which is eventually restricted by some nonlinearity(ies). This results in limit-cycle vibrations, that would not be strictly periodic in the presence of external random excitation. Thus, online discrimination between subcritical and postcritical states of operation may be of interest, based on processing measured response signal(s) (heat exchanger tubes in a fluid flow and machine tool chatter).

A pair of normal processes $X(t)$, $Y(t)$ can be described by their mean values and cross-correlation function:

$$R_{XY}(t_1, t_2) = \langle X(t_1)Y(t_2) \rangle$$

Other useful models of excitation include:

- Poisson process: pulses, appearing at random instants, with an important parameter being their arrival rate.
- Periodic process with random-phase modulation, or random temporal variations of frequency. Each sinusoidal component of such a process has the strongly non-Gaussian pdf of the form given in eqn [9].

A random process is called stationary if its properties are invariant with respect to shift of time origin, and in particular, weakly stationary if only the first-order and second-order moments are considered. A weakly stationary process has a constant mean value, whereas its autocorrelation function only depends on a time shift $\tau = t_2 - t_1$. A random process may very often be regarded as a stationary one if it is generated under constant conditions, such as in the case of turbulent pressure oscillations in a steady flow.

Nonstationary excitation forces (such as those due to ground motions during earthquakes) are very often modeled by introducing deterministic temporal variations of parameters. If a random process is governed by a linear differential equation with a random RHS (as for random vibrations of systems with lumped parameters), it may be stationary provided that three following conditions are satisfied:

1. The process in the RHS, or excitation, is stationary.
2. Only the particular solution which corresponds to the steady-state response is considered. The initial conditions are ‘forgotten’ due to the decay of the initial transients in the (asymptotically stable) system.
3. The coefficients of the equation of motion are constant (time-invariant system).

A stationary process may also be ergodic, in which case probabilistic, or ensemble, averaging is equivalent to averaging over a single sample of sufficient length:

$$\langle * \rangle = \lim_{T \rightarrow \infty} T^{-1} \int_0^T (*) dt$$

The additional necessary conditions for ergodicity in various moments are those of a sufficiently rapid decay of the autocorrelation function, or finite correlation time. Such conditions insure that the initial state of the process may be ‘forgotten’ and all its properties are reflected in a single sample. The ergodic property is particularly important for processing measured random signals.

The autocorrelation function of a stationary random process $X(t)$ has the following important properties, which are obvious from its definition: it is an even function, that is, $R_{XX}(-\tau) = R_{XX}(\tau)$, and $R_{XX}(0) \geq R_{XX}(\tau)$ for any nonzero value of τ . Yet another property, the so-called positive definiteness, guarantees (together with the two above-mentioned ones), the properties of the power spectral density (PSD) of $X(t)$, which will be introduced later.

The basic properties of the autocorrelation function are used for online evaluation of the properties of structures with traveling random waves. Thus, consider nondispersive one-dimensional waves, say, longitudinal waves in elastic rods, with a propagation speed c . Let the response signals be measured at two points, the distance between points being L . The signals may then be related by a simple delay equation: $Y(t) = X(t - \Delta)$, where $\Delta = L/c$ is the transit time of the wave between the points. The autocorrelation functions of the signals are clearly the same in this case, whereas their cross-correlation function reproduces the autocorrelation function with a time shift, equal to the transit time L/c . Thus, the sign of the shift of the absolute maximum of $R_{XY}(\tau)$ indicates the direction of propagation (from X towards Y if it is positive), whereas its magnitude may provide an estimate for the propagation speed c . Energy losses may also be estimated, from the measured reduction of the absolute peak of $R_{XY}(\tau)$ compared with that of $R_{XX}(\tau)$.

The approach may also be extended to cases of media with dispersion of waves, such as bending waves in beams, which do not have a universal propagation speed. The apparent propagation speed of a sinusoidal signal depends in this case on its frequency ω , that is $c = c(\omega)$. The above approach may then be applied separately within various frequency bands, such that c is approximately constant

within each band, by band-pass filtering both signals X and Y . The procedure provides the so-called group velocity of waves, defined as:

$$c_g(\omega) = \frac{c}{1 - (\omega/c)(dc/d\omega)}$$

An interesting example of an actual application is online *in vivo* measurement of the pulse wave propagation speed in the human artery, which can be used to estimate the elasticity of its wall.

An important characteristic of a stationary random process is its PSD defined as a Fourier transform (FT) of the autocorrelation function:

$$\begin{aligned} S_{XX}(\omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{XX}(\tau) e^{-i\omega\tau} d\tau \\ &= \lim_{T \rightarrow \infty} (\pi/T) \langle \tilde{X}(\omega, T) \tilde{X}^*(\omega, T) \rangle \\ \tilde{X}(\omega, T) &= \frac{1}{2\pi} \int_{-T}^T X(t) e^{-i\omega t} dt \\ R_{XX}(\tau) &= \int_{-\infty}^{\infty} S_{XX}(\omega) e^{i\omega\tau} d\omega \end{aligned} \quad [10]$$

($*$ denotes the complex conjugate). In view of the properties of the autocorrelation function, the PSD is found to be a real, positive, and even function. It describes the continuous distribution of energy between different frequency components of the stationary random process, which is sustained but not periodic. This can be seen from the second, alternative expression for the PSD in terms of the ‘direct’ FT of the sample of $X(t)$. (The limit for this direct FT does not exist by itself, since its variance does not vanish with increasing sample length T .) A special case of eqn [10] for zero time shift illustrates how the mean square value of the random process, the integral of its PSD, is compiled from contributions due to different frequency components of $X(t)$.

Relations, similar to eqn [10], with the subscript XX replaced by XY , are used for a pair of processes $X(t)$ and $Y(t)$. Thus, the cross-correlation function of a pair of processes forms a FT pair with their cross-spectral density (the name autospectral density is used for a single process). The latter is complex in general, and its magnitude indicates a degree of coupling between the components of $X(t)$ and $Y(t)$ with a given frequency ω ; thus its normalized version is called the coherence function.

An exponentially correlated process (with zero mean), considered as an example, has:

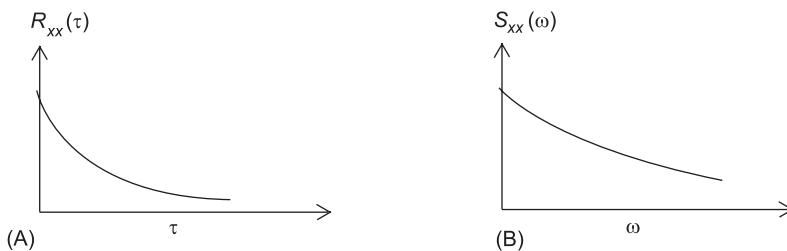

Figure 2 (A) Exponential autocorrelation function; (B) corresponding PSD.

$$\begin{aligned} R_{XX}(\tau) &= \sigma_X^2 \exp(-\gamma|\tau|) \\ S_{XX}(\omega) &= (\sigma_X^2 \gamma / \pi) / (\gamma^2 + \omega^2) \end{aligned} \quad [11]$$

Here σ_X is the RMS value of $X(t)$, and γ is seen to be a bandwidth parameter of S and also a reciprocal of the correlation time of $X(t)$, or of a characteristic decay time of R . (The autocorrelation function and PSD (eqn [11]) are illustrated in Figure 2 within positive semiaxes of the corresponding arguments of these even functions.) The Uncertainty Principle is thereby illustrated for the correlation/spectral properties of a stationary random process.

In the limiting case: $\gamma \rightarrow \infty$, $\sigma_X^2/\pi\gamma = S_0 = \text{const.}$, $R_{XX}(\tau) = D\delta(\tau)$ with $D = 2\pi S_0$ and δ is the Dirac delta-function; the process $X(t)$ is called the white noise of intensity D . Its PSD is constant everywhere, implying infinite variance. Whilst such a process seems to be physically impossible, a white-noise model of excitation is used very often and is found to be very convenient for random vibration studies. The reason is that any causal system only responds to a limited range of excitation frequencies, so components of the excitation which have frequencies that are too high become irrelevant for predicting the system's response.

PSDs of a derivative and an integral of a stationary random process can be expressed in terms of the PSD of the process itself. The relevant relations are actually special cases of a general input-output relation in statistical dynamics. Namely, if $H(i\omega)$ is a transfer function, or complex frequency response from the input, or excitation $X(t)$ to output, or response $Y(t)$, then:

$$S_{YY}(\omega) = |H^2(i\omega)|S_{XX}(\omega) \quad [12]$$

provided that both $X(t)$ and $Y(t)$ are stationary. Thus, say, $S_{\dot{X}\dot{X}}(\omega) = \omega^2 S_{XX}(\omega)$. Eqn [12] is used, in particular, to generate the process $Y(t)$ with a given PSD from an available process $X(t)$ (e.g., white noise)

by passing the latter through a specially designed system with the transfer function H . Such a system is called a shaping filter.

Whilst the PSD (eqn [11]) has a peak at zero frequency, a stationary random process may also, in general, have a nonzero predominant frequency. A process with a small spread of its power around the predominant, or center frequency, is called narrow-band; the half-power bandwidth is often used as an indicator of this spread, at the level where S equals half of its maximal value. Thus, the response of a lightly damped single-degree-of-freedom system to a white-noise excitation is usually narrow-band (see Figure 3, which has been obtained for the system with bandwidth ratio 0.02). Such a process has slowly varying amplitude and phase, which may be convenient state variables for analysis in a 'slow time', as well as the in-phase and quadrature components of the process, by using the stochastic averaging method.

For a normal, or Gaussian, random process information on its first-order and second-order moments is sufficient to establish its pdf. Thus, the probability for staying above a given level can be predicted, which in the case of a stationary process may be interpreted as a relative stay time above the level. However, in many cases of randomly vibrating structures this probability may not be sufficient by itself for an adequate description of the reliability of the structures. More complex functionals of the random structural response (e.g., stress, displacement, etc.) should be considered, depending on the possible failure mode of the structure and/or component. Three such modes are usually considered as:

- First-passage failures, such as those due to exceeding limiting stress in a brittle material or exceeding potential barrier for transition into the nondesigned state of the system ('snap-through' of a shallow arch or panel, ship capsizing).
- Failure due to damage accumulation, such as fatigue, wear.
- Failure due to stochastic (dynamic) instability.

Characteristics of the random processes, related to probabilistic analysis for the first two of the above

failure modes, are sometimes called ‘excursions’. One of these, an expected crossing rate (per unit time) with positive slope of a given threshold x by a process $X(t)$ is:

$$\begin{aligned} n_+(x) &= \int_0^\infty v p_{X\dot{X}}(x, v) dv \\ &= (2\pi)^{-1} (\sigma_V^2 / \sigma_X^2) \exp(-x^2 / 2\sigma_X^2), \quad v = \dot{x} \end{aligned} \quad [13]$$

Here $p_{X\dot{X}}(x, v)$ is a joint pdf of a random process $X(t)$ and its time derivative, which is denoted by $V(t)$. The second expression in eqn [13] corresponds to the case of a stationary normal zero-mean $X(t)$, with σ_X , σ_V being the RMS values of $X(t)$ and $V(t)$, respectively (the stationary process and its time derivative are uncorrelated).

This characteristic of a random process can also be used to evaluate the pdf of local peaks, or the amplitude of stress cycles. This pdf is used in certain simple models of fatigue failure, such as that of a linear damage rule. A simplified version of such an analysis only involves moments of stress peaks, which can be obtained from the joint pdf of the process and its first two derivatives. In particular, the amplitude of a Gaussian process has a Rayleigh pdf (eqn [6]). This approach is straightforward, at least for narrow-band temporal variations of stress, with only positive peaks and negative troughs (Figure 3). It may also be rather accurate for relatively broad-band stress variations at high levels, where the ‘irregular’ peaks/troughs of stress have a very small probability, roughly speaking, for $IF > 0.5$. Here IF is a so-called irregularity factor, which is used as a quantitative measure of the PSD bandwidth for excursion calculation: $IF = \sigma_{\dot{X}}^2 / (\sigma_X \sigma_{\ddot{X}})$. It can be clearly seen from the general expression (eqn [13]) and its obvious application to $V(t)$ and its derivative, that IF is the ratio of the expected number of zeros to that of peaks of $X(t)$ per unit time, and $IF = 1$ for a ‘truly narrow-band’ $X(t)$. For highly broadband stress variations other, more sophisticated models may be appropriate, such as the ‘rainflow model’.

Consider an example of a prismatic bar in a cross-flow of fluid, which may lead to an aeroelastic instability, or divergence of the bar at a certain critical speed. In the presence of a small ‘softening’ nonlinearity in the lift force as a function of the twist angle, the postcritical torsion is restricted, and is governed by:

$$Y = \sqrt{(X^2 - 1)} \text{ for } X \geq 1, \quad Y = 0 \text{ for } X < 1 \quad [14]$$

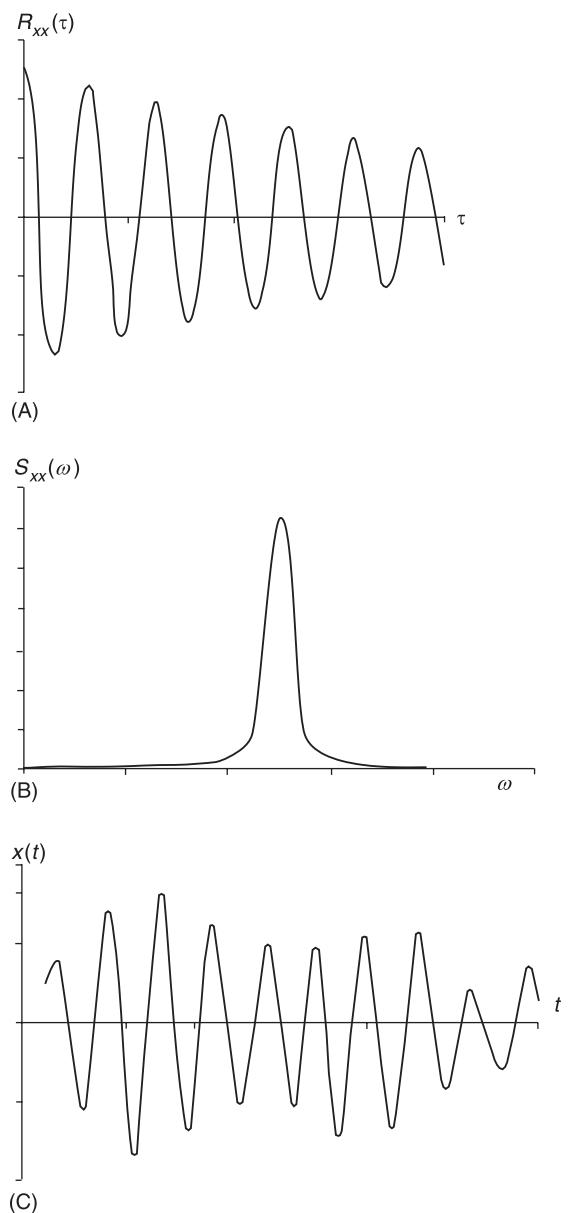

Figure 3 (A) Autocorrelation function and (B) PSD of a narrow-band process $x(t)$ (C) computer-generated with the use of a second-order shaping filter.

Here X is the ratio of the flow speed to its critical value and Y is the nondimensional stress due to aeroelastic torsion. The low-cycle fatigue due to occasional upcrossings of the flow speed $X(t)$ beyond the level $X = 1$ can be studied by direct application of eqn [4], provided that these temporal variations are slow enough to warrant use of the quasistatic relation (eqn [14]) (thereby ignoring inertia terms in the equation of the bar). In particular, if $X(t)$ is a zero-mean Gaussian process, then its amplitude, or peak

value $X_p = A$ has the Rayleigh pdf (eqn [5]). Eqn [4] is applied for this case to eqn [14], with subscript ‘ p ’ added to both X and Y in order to indicate their peak values. It results in the same but ‘nonnormalized’ Rayleigh pdf for peaks of nondimensional stress as:

$$p_{Y_p}(y_p) = P_D(y_p/\sigma_X^2) \exp\left(-y_p^2/2\sigma_X^2\right)$$

$$P_D = \exp\left(-1/2\sigma_X^2\right)$$

The ‘denormalizing’ factor P_D is a total probability for exceeding the critical flow speed $X = 1$ by a local peak of $X(t)$. Thus, the peak value of the stress is a combined discrete-continuous *RV*, with the finite probability $1 - P_D$ of a zero value, which corresponds to the subcritical state of the structure.

As for the first-passage failures, the (mean time before failure) (MTBF) $T(\mathbf{X})$ may be regarded as an important reliability characteristic for a given vector process $\mathbf{X}(t)$. This is a conditional expectation, the condition being that the crossing of the barrier should be the very first crossing. The argument \mathbf{X} is the initial value of $\mathbf{X}(t)$, which is assumed to be within the safe domain. However, particularly for high threshold levels, $T(\mathbf{X})$ is frequently found to be almost independent of \mathbf{X} , as long as the initial value is not too close to the threshold. (This is the case, where T is very large compared with the characteristic time for reaching the stationary pdf by $\mathbf{X}(t)$ when this pdf exists.) For so-called Markov processes the function $T(\mathbf{X})$ satisfies certain deterministic partial differential equations. More general partial differential equations are also introduced in this theory for the probability of staying within the safe domain during a given time interval, as well as for higher-order moments for the time before failure (see **Stochastic systems**).

An approximate approach for predicting reliability is based on using eqn [6] for the upcrossing rate (as well as its multidimensional extensions) together with the assumption of independent upcrossings (in this case x is a threshold level). The assumption may be adequate for systems with high reliability. As long as the upcrossings are rare for large X , they may be regarded as being independent, so that the MTBF may be related directly to $n_+(x)$. For narrowband (scalar) $X(t)$ this approach may have somewhat poor convergence rate with increasing barrier height because of the high correlation time (upcrossings appear in clusters); the accuracy may be improved by applying eqn [13] to the slowly varying amplitude of $X(t)$. The PDE for T can also be studied for the amplitude of X , and it may be of the reduced dimension, even an ODE in the case of a single-degree-of-

freedom system with a white-noise excitation, which can easily be integrated numerically.

Nomenclature

A	amplitude
c	propagation speed
IF	irregularity factor
K_{XX}	covariance matrix
L	distance between points
δ	Dirac delta function
σ_X	RMS value of X
τ	time shift

Whenever a vibrating system is excited by random force(s), the response is also random. Two methods are described in the following for predicting first- and second-order response moments for a given system from available data on the random excitation. Systems with lumped parameters are considered as governed by ordinary differential equations (ODEs), with random processes in their RHSs. (It goes without saying, that systems with distributed parameters may also be analyzed by the same methods, as long as they are reduced to ones with finite number of degrees-of-freedom (DOF)).

The method of moments, as described in the following, is applicable to any linear system subjected to an external random excitation. The latter may be nonstationary, whereas deterministic temporal variations of the system's parameters can also be included in the analysis (extension to the systems with randomly varying parameters is also possible, to some extent, based on another version of the method).

The other approach relies on a direct use of the basic excitation/response relation for power spectral densities (PSDs). Therefore it is only applicable to the steady-state responses of time-invariant systems to stationary excitations. (Certain extensions of the approach to nonstationary processes, based on evolutionary spectra, are known). However, it is important for qualitative insight into phenomena, particularly for interpreting measured random vibration data.

To apply the method of moments one should reduce the system's equations to the form where all excitations are white noises. This is done by introducing shaping filters for all given nonwhite excitations and adding the equations of the shaping filter(s) to

those of the system itself. As long as the PSD of the white noise is constant, one should just approximate the given PSD of any excitation by the ratio of two polynomials of squared frequency, with the degree of the numerator being less than that of the denominator. This results in a squared magnitude of the filter's transfer function H , so that the shaping filter's parameters become known. For example, let the excitation $z(t)$ have a PSD with a single peak at frequency v with half-power bandwidth β . A simple possible approximation for such a PSD with a single peak is:

$$S_{zz}(\omega) = \frac{S_0}{(\omega^2 - v^2) + 4\beta^2\omega^2} \quad [1]$$

It implies, that $z(t)$ satisfies the stochastic differential equation (SDE) $\ddot{z} + 2\beta\dot{z} + v^2z = \zeta(t)$, where $\zeta(t)$ is a white noise with intensity $2\pi S_0$. This requires the introduction of one additional DOF. Thus, for example, the study of a two-degrees-of-freedom (TDOF) tuned vibration absorber for offshore applications requires a model with at least three DOFs, as long as ocean waves usually have a nonzero predominant excitation frequency, which may require the use of an additional DOF for the shaping filter.

Thus, consider the n -dimensional state vector \mathbf{u} as compiled of the displacements and velocities x, v and possibly shaping filter variables z with some of their time derivatives. The basic matrix equation in the canonic form is written as:

$$\dot{\mathbf{u}} = \mathbf{A}(t)\mathbf{u} + \mathbf{F}(t) + \mathbf{B}(t)\zeta(t) \quad [2]$$

where $\mathbf{A}(t)$ and $\mathbf{B}(t)$ are deterministic $n \times n$ matrices, $\mathbf{F}(t)$ is an n -dimensional vector of deterministic forcing functions and $\zeta(t)$ is an n -dimensional vector of zero-mean white noises. The latter are defined with intensity matrix $\mathbf{W}(t)$, so that $\langle \zeta_i(t)\zeta_j(t) \rangle = W_{ij}(t)\delta(t - \theta)$. Temporal variations of the excitation

intensity may be used to describe nonstationary random dynamic loads.

The response vector $\mathbf{u}(t)$ is decomposed into its mean or expected value $\mathbf{m}(t) = \langle \mathbf{u}(t) \rangle$ and zero-mean part $\mathbf{u}^0(t) = \mathbf{u}(t) - \mathbf{m}(t)$. The mean response is analyzed separately by solving the deterministic equation $\dot{\mathbf{m}} = \mathbf{A}(t)\mathbf{m} + \mathbf{F}(t)$. The correlation matrix of the zero-mean part of the response is analyzed then, namely $\mathbf{R}_{uu}(t, \theta) = \langle \mathbf{u}^0(t)\mathbf{u}^{0T}(\theta) \rangle$. A two-step procedure is used, as based on the following pair of deterministic matrix ODEs:

$$\begin{aligned}\dot{\mathbf{D}} &= \mathbf{AD} + \mathbf{DA}^T + \mathbf{BWB}^T \\ (\mathrm{d}/\mathrm{dt})\mathbf{R}_{uu}(\theta, t) &= \mathbf{R}_{uu}(\theta, t)\mathbf{A}^T(t) \\ \mathbf{R}_{uu}(\theta, \theta) &= \mathbf{D}(\theta)\end{aligned}\quad [3]$$

Here \mathbf{D} is clearly seen to be the variance matrix, i.e., a special version of the correlation matrix, which corresponds to a zero time shift. It is obtained by integrating the first equation (eqn [3]) for any given initial conditions at $t = 0$, uncorrelated with the excitation if they are random (whereas $\mathbf{D}(0) = 0$ if they are deterministic). Integration of the second equation (eqn [3]) can be performed then, whereas the last relation (eqn [3]) is imposed as the initial condition, which specifies a relation between \mathbf{D} and \mathbf{R} .

As an example, consider a SDOF system with a white-noise excitation:

$$\ddot{X} + 2\alpha\dot{X} + \Omega^2 X = \zeta(t) \quad [4]$$

for a zero-mean white noise $\zeta(t)$ with intensity D_ζ . Rewriting eqn [4] in the form of eqn [2] with $u_1 = X$, $u_2 = \dot{X}$, the following set of three equations for variances is obtained as a scalar version of the matrix equation (eqn [3]):

$$\begin{aligned}\dot{D}_{11} &= 2D_{12}, \quad \dot{D}_{12} = D_{22} - 2\alpha D_{12} - \Omega^2 D_{11} \\ \dot{D}_{22} &= -4\alpha D_{22} - 2\Omega^2 D_{12} + D_\zeta\end{aligned}\quad [5]$$

This set has a simple (constant) steady-state solution, as obtained by equating the RHSs to zero:

$$D_{11} = D_\zeta/4\alpha\Omega^2, \quad D_{12} = 0, \quad D_{22} = D_\zeta/4\alpha \quad [6]$$

This steady-state solution, which is clearly also stationary in this case, exists only in the presence of damping. The transient solution to eqns [5] for the undamped case ($\alpha = 0$) for zero initial conditions indicates linear growth of the mean square displacement and velocity with time:

$$D_{11}(t) = (D_\zeta/2\Omega^2) t, \quad D_{22}(t) = D_\zeta t/2$$

This growth may be regarded as being ‘mild’ compared with the case of a perfectly resonant sinusoidal excitation for an undamped SDOF system (where the linear growth is observed for the response amplitude). However, it may be regarded as unavoidable, as long as detuning from a white noise is impossible.

Applying the second matrix equation (eqn [4]), we may derive three ODEs for the autocorrelation functions, R . For the stationary response their single argument will be $\tau = t - \theta$. Denoting derivatives over this argument by primes, we obtain, in particular, the following ODE for the autocorrelation function of the displacement response $R''_{11} + 2\alpha R'_{11} + \Omega^2 R_{11} = 0$ which coincides with the equation for free vibrations. Its solution, satisfying the initial condition $R_{11}(0) = D_{11}$ is:

$$\begin{aligned}R_{11}(\tau) &= D_{11} \exp(-\alpha\tau)[\cos \omega_d\tau + (\alpha/\omega_d) \sin \omega_d\tau] \\ \omega_d &= \sqrt{(\Omega^2 - \alpha^2)}, \quad \tau > 0\end{aligned}$$

(The other initial condition, satisfied by this expression, is also correct, since $R'_{11} = R_{12}$, and $D_{12} = 0$ according to the solution (eqn [6]).

The correlational analysis of the measured response to random excitation may be used, therefore, for an online evaluation of the system’s natural frequency and damping, when free vibration testing is not possible. Measurements of excitation are not needed, as long as it can be reasonably assumed, that its PSD is broadband with respect to the system. (This may be the case, e.g., with measured flow-induced vibrations in unconfined unseparated flows.) Damping can be conveniently estimated by plotting the (supposedly exponential) envelope of the autocorrelation function in semilog coordinates and using only that range of τ where the actual plot is indeed found to be linear. (Ranges with too large and too small values of τ are very often discarded – the former because of large scatter of statistical errors, the latter because of the influence of a band-pass filter, which may be used for MDOF systems to separate a specific modal response; in view of the Uncertainty Principle, the influence of such a filter decays earlier than the autocorrelation function, provided that the filter is broadband with respect to the given mode).

Whenever the response is stationary, its PSD can be predicted in terms of the excitation PSD and relevant complex frequency response H , using the basic relation:

$$S_{XX}(\omega) = |H^2(i\omega)|S_{FF}(\omega) \quad [7]$$

with appropriately assigned subscripts. (Excitation and response are denoted here by $F(t)$ and $X(t)$, respectively). The mean square response is then obtained by a simple integration. Very often one of the cofactors in the RHS of eqn [7] has a sharp peak at a certain frequency, which provides the dominating contribution to the mean square response (Figure 1). The latter may be calculated approximately by assuming the other cofactor to be constant in the vicinity of the peak. Thus, for a SDOF system (eqn [4]) with undamped natural frequency and damping factor, Ω and α , respectively (and with excitation $F(t)$ in the RHS), the mean square value of the (stationary) response $X(t)$ is found to be:

$$\begin{aligned}\langle X^2 \rangle &= \int_{-\infty}^{\infty} \frac{S_{FF}(\omega) d\omega}{(\omega^2 - \Omega^2)^2 + 4\alpha^2\omega^2} \\ &\cong \frac{\pi S_{FF}(\Omega)}{2\alpha\Omega^2} = \frac{D_\zeta}{4\alpha\Omega^2}\end{aligned}\quad [8]$$

if $\alpha/\Omega \ll 1$. This formula clearly illustrates filtering property of a lightly damped system. Namely, the system responds to a single frequency component of the excitation only, one with the system's natural frequency. And as long as excitation components with other frequencies become irrelevant, the response is found to be the same as in the case of a white-noise excitation $\zeta(t)$ with intensity $D_\zeta = 2\pi S_{FF}(\Omega)$ (compare with the first expression (eqn [5])). The condition for white-noise approximation for the excitation for a SDOF system is clearly seen to be that of a large excitation/system bandwidth ratio. (In the time domain it may be formulated as that of the short correlation time of the excitation compared with the system's time constant as defined by the reciprocal of its half-power bandwidth). The white-noise approximation is also seen to be adequate for predicting the mean square of velocity,

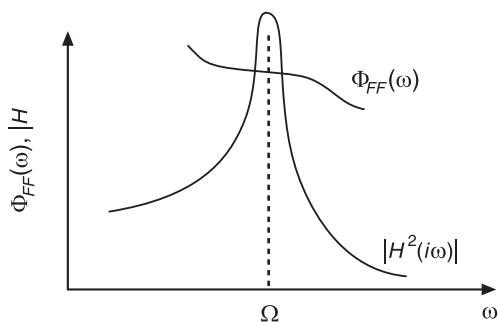

Figure 1 Broadband excitation of a lightly damped SDOF system.

but not that of the response acceleration, as long as $S_{\ddot{X}\dot{X}}(\omega) = \omega^4 S_{XX}(\omega) \rightarrow S_{FF}(\omega)$, with $\omega \rightarrow \infty$.

The approximation (eqn [8]), which only filters a single frequency component from the excitation PSD, can be easily extended to the MDOF systems, where the excitation may be regarded as 'locally broadband' in the frequency domain, that is, broadband with respect to each modal bandwidth. Values of this PSD at the natural frequencies of various systems will then be involved.

A similar approximation, based on an asymptotic evaluation of the integral for the mean square response, can also be used in the opposite case, where the excitation $F(t)$ is narrowband with mean frequency v , whereas $|H^2(i\omega)|$ is slowly varying in the vicinity of this frequency. The approximate expression for the contribution of this excitation into the overall response is then $\langle X^2 \rangle \cong |H^2(iv)| / \langle F^2 \rangle$.

Eqn [8] clearly indicates the inadequacy of undamped models of the systems for predicting steady-state random vibration. This should be expected, as long as the continuous excitation spectrum always contains a frequency component, which would be the resonant one.

Another general property of random vibrations of a SDOF system is related to the influence of the bandwidth of the excitation with fixed overall level. If the mean, or center frequency of the narrowband excitation is tuned to the system's natural frequency, the spread of the excitation energy in the frequency domain leads to reduction of its resonant component and thus of the response. On the other hand, in the case of large detuning of the center excitation frequency, this spread may increase the resonant component of the excitation, thereby increasing the response level. The critical value of the detuning between these two extreme cases is of the order of the system's half-power bandwidth.

Evaluation of the response correlation function(s) is also found to be rather simple by the spectral approach, since it just requires calculating the Fourier transform of the corresponding PSDs. Thus, applying the procedure to the integrand of eqn [8] (with approximately constant PSD of $F(t)$) yields the auto-correlation function of the SDOF system's response displacement to a white-noise excitation, which is the same expression as was obtained before.

The case of systems with periodic system matrix $A(t)$ deserves some special attention, as long as some important analytical solutions can be obtained by asymptotic methods. The methods may be applied either to the deterministic ODE (eqn [3]) for the variance matrix, or directly to the original stochastic equation of motion. Thus, averaging over the period can be applied to a SDOF system with periodic

parametric and external random excitation, as governed by:

$$\ddot{x} + 2\alpha\dot{x} + \Omega^2x(1 + \lambda \sin 2vt) = \zeta(t) \quad [9]$$

By introducing slowly varying in-phase and quadrature response components $x_c(t)$, $x_s(t)$ for small α , λ , $|v - \Omega|$, where $x(t) = x_c(t) \cos vt + x_s(t) \sin vt$, eqn [9] may be reduced approximately to a set of two SDEs with constant parameters. Steady-state analytical solution for the second-order moments $D_{cc,ss} = \langle x_{c,s}^2 \rangle D_{cs} = \langle x_c x_s \rangle$ can be obtained then, provided that $\mu < 1$, $\mu = (\lambda\Omega/4)/\sqrt{(x^2 + (v - \Omega)^2)}$. The latter inequality is the parametric stability condition for the system (eqn [9]). The solution yields, in particular:

$$\mu = \frac{[(D_{cc} - D_{ss})^2 + D_{cs}^2]^{1/2}}{(D_{cc} + D_{ss})}$$

(thereby relating the stability margin of the system (eqn [9]) to the second-order moments of its subcritical response, which can be estimated when $x(t)$ is measured on-line. The probability density function (pdf) of the response $x(t)$ is normal if $\zeta(t)$ has a normal pdf. Transforming in-phase and quadrature components of $x(t)$, which are also normal, to amplitude and phase, one can derive the pdfs of the latter state variables, in the same way as the pdfs (eqns [5] and [6]) were obtained in **Random processes**. The pdf of phase is found to be nonuniform, with the magnitude of its variations within $[0, 2\pi]$ equal to μ .

The method of moments may sometimes also be applied to systems with state-dependent random excitation(s), such as stochastic parametric excitations, provided that the linear deterministic ODEs for moments are still obtained. This generalization is based on the SDE calculus, as considered in more detail in **Stochastic systems**. Here we may just refer to the following relation for a set of SDEs for components an n -dimensional state space vector \mathbf{X} , with Gaussian white-noise excitations:

if $\dot{X}_i = g_i(\mathbf{X})\zeta_i(t)$; $\langle \zeta_i(t)\zeta_j(t+\tau) \rangle = D_{\zeta,ij}$
 $i, j = 1, 2, \dots, n$, then

$$\langle g_i(\mathbf{X})\zeta_i(t) \rangle = (1/2) \sum_{k=1}^n \left\langle g_k(\mathbf{X}) \frac{\partial g_i(\mathbf{X})}{\partial X_k} \right\rangle D_{\zeta,ik} \quad [10]$$

The expected values, which appear in the RHSs of the deterministic equations for expectations of the components of state vector \mathbf{X} , are seen to be linear in the

case of linear functions g . This provides a possibility of applying the method of moments to linear systems with white-noise parametric excitation(s). Thus, consider the SDOF system (eqn [4]) with an additional stochastic parametric excitation term $\Omega^2\xi(t)$ added to its LHS. Here $\xi(t)$ is a zero-mean Gaussian white noise with intensity D_ξ , uncorrelated with the external white noise in the RHS of eqn [4]. The corresponding additional terms in the RHSs of the second and third expressions in eqn [6] would be $\langle -\Omega^2 u_{11}\xi(t) \rangle$ and $\langle -2\Omega^2 u_{12}\xi(t) \rangle$, respectively, where $u_{ij} = X_i X_j$; $i, j = 1, 2$ (double subscripts for state variables are convenient here). According to the basic relation (eqn [10]), the second of these two expected values is found to be $\Omega^4 D_{11} D_\xi$ (the first one is zero). This results in the following modified solution for mean square displacement responses:

$$D_{11} = \frac{(D_\xi/4\alpha\Omega^2)}{1 - (\Omega^2 D_\xi)/4\alpha}, \quad D_{22} = \Omega^2 D_{11} \quad [11]$$

The numerator in eqn [11] for the mean square displacement coincides with the previously obtained expression (eqn [6]) for the case of a purely external excitation. The reciprocal of the denominator may then be called a parametric amplification factor of the mean square response to external excitation. It increases monotonously with the intensity level of the parametric excitation and becomes infinite at critical value of the latter, when:

$$D_\xi = D_{\zeta^{**}} = 4\alpha/\Omega^2 \quad [12]$$

This value corresponds to a threshold for stochastic stability in the mean square of the SDOF system. Study of stochastic stability is presented in **Stochastic systems**, whereas in this article only subcritical cases are considered, i.e., those where $D_\xi < 4\alpha/\Omega^2$. It should be noted that exceeding the stability threshold (eqn [12]) does not necessarily imply infinite growth of the response itself; the stationary response pdf may exist, which would, however, have infinite variance. Of course, such a situation is impossible in the case of a purely external Gaussian excitation, where the response is also Gaussian.

A generalized version of the method of moments, based on the relations, given in eqn [10], may also be used to incorporate another model of random excitation into random vibration analyses. This is a model of periodic excitation with random temporal variations of instantaneous frequency, or random phase modulation. In its simplest version of sinusoidal

periodic excitation with white-noise phase modulation, it can be described as follows:

$$F(t) = \lambda \cos z(t), \quad \dot{z} = v + \xi(t) \quad [13]$$

where $\xi(t)$ is a zero-mean stationary Gaussian white noise with intensity D_ξ . The PSD of the random process (eqn [13]) is:

$$S_{FF}(\omega) = \frac{(\lambda^2 D_\xi / 2) (\omega^2 + v^2 + D_\xi^2 / 4)}{\left(v^2 + D_\xi^2 / 4 - \omega^2 \right)^2 \omega^2 D_\xi^2} \quad [14]$$

The parameter D_ξ describes a ‘spread’ of the excitation energy in the frequency domain around the expected excitation frequency v . The PSD (eqn [14]) is seen to be similar to the PSD of a filtered white noise (eqn [1]). In the case of narrow-band excitations $z(t)$ and $F(t)$ these PSDs can be made identical by equating the intensity of frequency variations to the doubled bandwidth of the shaping filter: $D_\xi = 2\beta$ for $\beta \ll v$. On the other hand, the pdf of the excitation $F(t)$ is strongly non-Gaussian (see eqn [9] of **Random processes**).

To incorporate the model (eqn [13]) into a random vibration analysis one can use the following ‘autonomous’ representation of the trigonometric functions:

$$F(t) = \lambda z_1, \quad \dot{z}_1 = -(v + \xi(t)) z_2, \quad \dot{z}_2 = (v + \xi(t)) z_1 \quad [15]$$

The equations for second-order moments of the introduced ‘trigonometric’ state variables $D_{ij} = \langle u_{ij} \rangle = \langle z_i z_j \rangle$; $i, j = 1, 2$ are:

$$\begin{aligned} \dot{D}_{11} &= -2vD_{12} - 2v\langle u_{12}\xi(t) \rangle \\ &= -2vD_{12} - D_\xi(D_{11} - D_{22}), \\ \dot{D}_{12} &= v(D_{11} - D_{22}) + \langle (u_{11} - u_{22})\xi(t) \rangle \\ &= v(D_{11} - D_{22}) - 2D_\xi D_{12} \\ \dot{D}_{22} &= 2v\dot{D}_{12} + 2v\langle u_{12}\xi(t) \rangle \\ &= 2vD_{12} + D_\xi(D_{11} - D_{22}) \end{aligned}$$

These equations for second-order moments should be supplemented with an obvious relation $\langle z_1^2 \rangle + \langle z_2^2 \rangle = 1$, and then the unique steady-state solution is $D_{11} = D_{22} = 1/2$, $D_{12} = 0$ (the last equality is a clear result of random temporal phase variations, represented by the ‘damping’ term with D_ξ in the second equation).

Thus, the equation of motion with a forcing function $F(t)$ is supplemented by two equations [15] and a second-order trigonometric relation. The method of moment can then be applied, based on eqn [10]. Similar (multiple) relations between trigonometric functions would be required when higher-order moments of the response are calculated; such predictions may be relevant for reliability studies as long as the response may be non-Gaussian.

Eqn [13] seems particularly relevant for describing excitations due to traveling loads and/or traveling structures in case of an imperfect spatial periodicity of the loading pattern (and constant travel speed). It may also be appropriate in general for random excitations with relatively small variations of amplitude. The second-order moments of the response to such an excitation would be certainly the same as in case of a filtered Gaussian white-noise excitation with the same PSD. The higher-order moments may be different however, or they may not be if the normalization effect according to the central limit theorem (CLT) is present. **Figure 2** illustrates results for fourth-order response moments for a SDOF system with natural frequency and damping factor Ω and α respectively, excited by the external force (eqn [15]).

The excess factor γ of the response displacement (with negative sign) is defined in eqn [5] of **Random processes** together with expression [7] for the pdf of the sinusoid with random phase; the latter implies that the excitation $F(t)$ should have $\gamma = -1.5$. Curves of $-\gamma$ vs excitation/system bandwidth ratio D_ξ/α are presented for three different values of detuning between mean excitation frequency and system’s natural frequency (and fixed α/Ω). All three curves start at the value 1.5 for the extreme case of a perfectly sinusoidal excitation (zero excitation bandwidth), and all three approach zero value for high excitation/system bandwidth ratios, which

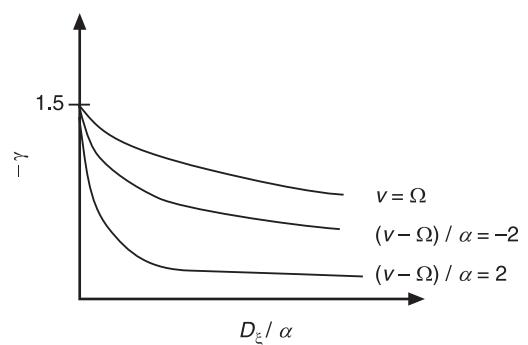

Figure 2 Excess factor of the response vs excitation/system bandwidth ratio.

correspond to the other extreme of an asymptotically normal, or Gaussian response. The convergence rate is not particularly high, with values of γ of the order 0.5 at $D_\xi/\alpha = 20$, however, all values were found to be zero up to four significant digits at $D_\xi/\alpha = 50$. The dependence of the convergence rate on detuning can also be seen. It is lowest at the exact resonance and lower for a subresonant excitation than for the post-resonant one with the same detuning.

Thus, application of the method of moments for systems with purely external narrowband excitation seems to be straightforward. It leads to some expansion of the vector of state variables. This is not the case with systems, which are subject to a narrowband parametric excitation. If the latter is described as a filtered white noise, the expanded system (with added shaping filter) will contain a (product-type) nonlinearity in the parametric excitation term. In the case of the parametric excitation of the type shown in eqn [13] a limited analytical study is possible, based on reduction of the original SDOF system by the method of stochastic averaging.

Results of the analysis of the first- and second-order moments of the response provide a complete description of the response pdf, provided that it is normal. Basically, there are two cases where the response to an external random excitation may be normal indeed (random parametric excitation can bring significant deviations from normality; this topic is studied in **Stochastic systems**:

- The excitation is normal.
- The excitation/system bandwidth ratio is large, so that the CLT may be relied upon (actual convergence rate to normality is case-dependent, of course).

If neither of these conditions is satisfied, another approach may be adopted based on the theory of Markov processes (see **Stochastic systems**).

An attempt can also be made to apply the method of moments to nonlinear systems with nonlinearities of a polynomial type. This attempt faces a basic difficulty with obtaining closed systems of equations for moments of various orders. For example, if the original SDE for $X(t)$ contains a term with X^3 , the equation for $\langle X \rangle$ would contain a term with $\langle X^3 \rangle$, the equation for $\langle X^2 \rangle$ would contain a term with $\langle X^4 \rangle$, etc. The difficulty is usually resolved by adopting a certain approximate closure scheme, whereby some relation(s) are enforced between response moments of various orders. The Gaussian closure scheme is the most common one, whereby, say, relation $\langle X^4 \rangle = 3(\langle X^2 \rangle)^2$ is imposed for the case of a single variable X , which corresponds to the relation between second- and fourth-order moments of the normal pdf. General

relations of this form can be used similarly for the case of a vector \mathbf{X} . The reasoning is that in the case of a small nonlinearity the pdf of the nonlinear system's response should not deviate much from that of a linear system. The resulting eqn [9] for variance matrix \mathbf{D} is found to be nonlinear in this case.

The approach can be extended to more general nonlinearities, including those of non-smooth type, by using method of statistical linearization. The original nonlinear system is replaced approximately by the 'equivalent' linear one. The condition for equivalence is that of a minimal mean square error of such a replacement. Being applied together with some closure scheme, it leads to an 'equivalent' linear system, with parameters of the latter being functions of the (unknown) first- and second-order moments of the response. This system may be analyzed either by the method of moments, or by the spectral approach if the stationary response is studied.

Thus, a system with nonlinear stiffness and a zero-mean Gaussian white-noise excitation

$$\ddot{X} + 2\alpha\dot{X} + f(X) = \zeta(t) \quad [16]$$

is approximated by an 'equivalent' linear one with the same white noise $\zeta(t)$ with intensity D_ζ :

$$\ddot{X} + 2\alpha\dot{X} + \Lambda^2 X = \zeta(t) \quad [17]$$

(in the case of a nonlinear damping in the original system (eqn [16]) the equivalent linear damping should also be introduced). The steady-state displacement response variance of the equivalent system is:

$$\sigma^2 = \langle X^2 \rangle = D_\zeta / 4\alpha\Lambda^2 \quad [18]$$

Now, the condition for equivalence is found to be $\Lambda^2 = \langle Xf(X) \rangle / \langle X^2 \rangle$. Using the Gaussian closure scheme, these expected values can be obtained by averaging over the normal pdf with zero mean and a (yet unknown) variance σ^2 . The resulting expression for the (response dependent) natural frequency of the equivalent linear system is then substituted into the solution (eqn [18]). An algebraic equation for the mean square response of the equivalent system (eqn [17]) is obtained in this way, which may provide a reasonable approximation to that of the original system (eqn [16]). Thus, for a system with cubic nonlinearity, where $f(X) = \Omega^2(X + \mu X^3)$, the equation is:

$$3\mu(\sigma^2)^2 + \sigma^2 - D_\zeta / 4\alpha\Omega^2 = 0$$

and can even be solved explicitly. For a system with a set-up spring, where $f(X) = \Omega^2(X + \mu \text{sgn}X)$, the corresponding equation is found to be:

$$\sigma^2 = (D_\zeta / (4\alpha\Omega^2)) [1 + (\mu/\sigma)\sqrt{(2\pi)}]$$

For both these examples the exact solutions by the method of Markov processes are available (see **Stochastic systems**). They show the above results to be of a reasonable accuracy even for values of the corresponding nonlinearity parameter μ which are not very small.

This success of the statistical linearization is not universal. Predictions of the response PSD are usually less accurate, as well as those of the excursions, especially at high levels, which are needed for reliability analyses. The presence of a stochastic parametric excitation also may lead to a poor accuracy of the approach, as long as significant deviations from the Gaussian response pdf may appear. A certain improvement in the resulting estimates is found to be possible sometimes through the use of other closure schemes. For example, whenever the response may be expected to be narrowband and with relatively small random variations of amplitude, another pdf would be more appropriate for establishing the desired relation between response moments of various orders – the pdf of a sinusoid with random phase. In any case, however, the accuracy of the method cannot be predicted in advance and should rely upon comparisons with benchmark results, obtained by other approaches – direct Monte-Carlo simulations or (if available) the method of Markov processes. The latter approach is considered in **Stochastic systems**. On the other hand, statistical linearization is perhaps the most general method for (nonlocal) analysis of nonlinear random vibration problems for MDOF systems.

Nomenclature

$A(t), B(t)$	deterministic $n \times n$ matrices
D	variance matrix

$F(t)$	deterministic forcing functions
$m(t)$	mean or expected value
R	response matrix
$u(t)$	response vector
$W(t)$	intensity matrix
β	half-power bandwidth
ν	frequency
ζ	white noise

Resonance vs Antiresonance

In a lightly-damped linear system, resonance occurs when the frequency of the applied harmonic excitation coincides with (or is close to) one of the natural

frequencies of the system. Resonance is a state of forced vibration. It takes place at the resonance frequency, i.e., at the frequency of excitation, which is close to one of the natural frequencies of the system.

Periodic excitation can produce resonance when the frequency of one of its harmonic components becomes equal (or close) to a natural frequency of the system. Random and frequency sweep excitations give rise to resonance when the frequency spectrum of the excitation encompasses any of a system's natural frequencies.

A swing pushed at the right time intervals exhibits resonant oscillations. Operation of soil compactors, concrete tampers, vibration conveyers, road drills, vibrating screens, and some fatigue-testing machines is often based on resonant vibrations. Resonance is produced in multiple-reed gauges and in piezoelectric accelerometers used for the detection of defects in rolling element bearings.

However, the main concern with resonance relates to its adverse effects. During operation at resonance, excessive motion (and stress) amplitudes are generated, causing structural fatigue and failure, harmful effects or discomfort to humans, and a decrease in product accuracy. The nuisance of a noisy component vibrating at resonance can be an obstacle to the sale of a car or a household appliance.

Sometimes resonance is a loosely used term. In the general acceptance, resonance is a condition whereby a minimum of excitation is required to produce a maximum of dynamic response. Resonance relates to the condition where either a maximum motion is produced by a force of constant magnitude, or a minimum force is required to maintain a given motion. The frequencies where the peak value of the forced vibration appears are referred to as resonance frequencies.

A resonance is defined by a frequency, a response (or excitation) level, and a bandwidth. Avoidance of large resonant vibration levels can be accomplished by:

1. changing the excitation frequency;
2. making stiffness and/or mass modifications to change the natural frequency;
3. increasing (or adding) damping;
4. adding a dynamic vibration absorber.

Antiresonances is a local state, in contrast to resonance, whereby a vibrating system most strongly resists being made to vibrate. It takes place at a frequency at which a maximum of force magnitude produces a minimum of motion, and is confined to specific frequencies at specific points.

Resonances occur at natural frequencies that are global properties of a vibrating system, independent of the driving point. Antiresonances are local (subsystem) properties, dependent on the driving location.

There is a clear distinction between the nodal points (or lines), that are characteristics of mode shapes, and the driving point of an antiresonance deflection shape, which is a local property of the system. Vibration nodes can be created by the mutual cancellation of a pole (natural frequency) with a zero (antiresonance).

The Grounded Mass-Spring-Damper System

Consider a mass-spring-damper grounded system subjected to a harmonic force applied to the mass (**Figure 1**). The steady-state response of the viscously-damped single-degree-of-freedom (SDOF) system is a harmonic motion of the same frequency as the excitation force, with a phase shift due to damping. The motion is describable in terms of displacement, velocity, or acceleration. The displacement amplitude, X , and the phase angle between displacement and force, φ , are functions of the forcing frequency, ω . For subcritical damping, as the excitation frequency approaches the undamped natural frequency, $\omega_r = \sqrt{k/m}$, the displacement amplitude approaches a peak value and the phase shift passes through 90° (see **Theory of vibration, Fundamentals**).

The frequency response diagram, displaying the motion amplitude versus forcing frequency for a given value of damping and constant force amplitude, exhibits a resonance peak (**Figure 1**). For viscous damping, the peak of the displacement resonance curve occurs at $\omega = \omega_r(1 - 2\zeta^2)^{1/2}$, while the phase shift is 90° at $\omega = \omega_r$. The first condition is often referred to as an amplitude resonance, while the second one is termed phase resonance. The difference in frequencies is small for lightly-damped systems.

For viscously-damped systems with a critical damping ratio $\zeta > 0.707$, the resonance peak is completely smooth. Over-critically damped systems do not exhibit resonances.

At the natural frequency $\omega = \omega_r$, the spring force balances the inertia force of the mass, and the excitation force overcomes the damping force only (**Figure 2**). There is a continuous interchange of potential and kinetic energy between the spring and the mass. The only external force that has to be applied to maintain the system vibrating is that needed to supply the energy dissipated in the damper.

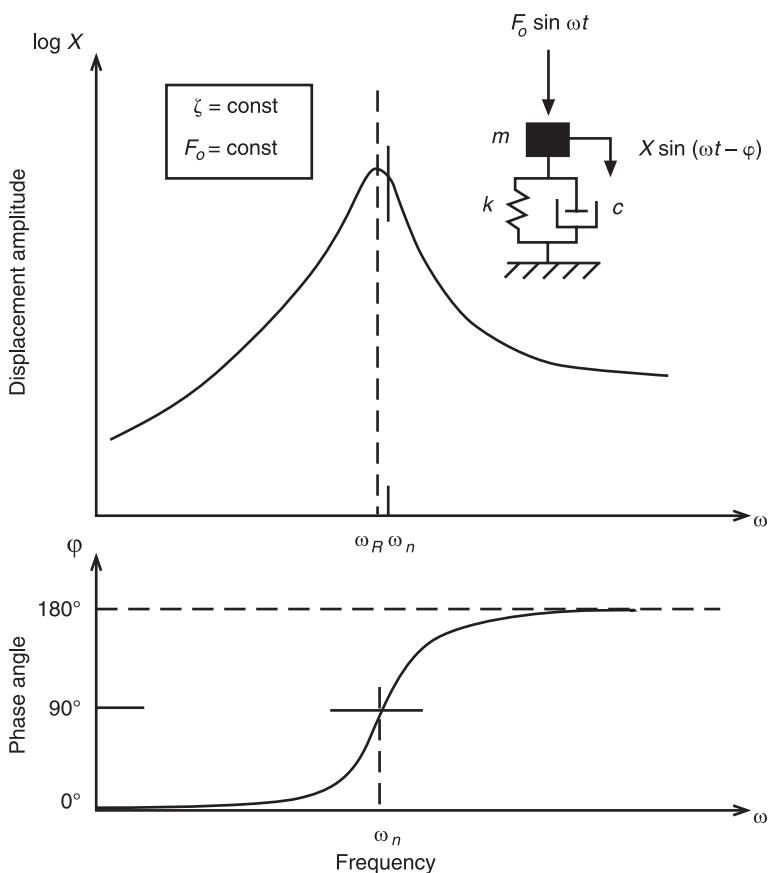

Figure 1 Resonant response of grounded single-degree-of-freedom (SDOF) system.

At resonance, the reactive energy (in spring and mass) is zero and the active energy (actually dissipated) is maximum. That is why a minimum of force is required to maintain a given displacement amplitude.

On a plot of the dynamic stiffness (force required to produce unit displacement at the driving point) versus frequency, the resonance appears as a trough.

The Ungrounded Mass-Spring-Damper System

One of the simplest systems exhibiting antiresonance is the mass-spring-damper ungrounded system, subjected to a harmonic force applied to the base. For constant force amplitude, the driving point displacement amplitude has a minimum value at antiresonance (Figure 3).

In the absence of damping, the antiresonance frequency of the base-excited sprung-mass system is the same as the resonance frequency of the mass-excited system grounded at the other end of the spring. The

presence of light damping has a small effect upon the equality of these frequencies. The sprung-mass system can be replaced by an equivalent, frequency-dependent mass that is infinitely large for the excitation at the antiresonance frequency.

The motion transmissibility, i.e., the ratio of the mass displacement to the base displacement, is maximum at the antiresonance.

If the sprung mass is attached to a free mass at the driving point, the resulting mass-spring-mass system exhibits both a resonance and an antiresonance in the driving-point response (Figure 4). At resonance, a node of vibration occurs at a point somewhere along the spring. If the system is divided into two parts at this location, then each subsystem is antiresonant at this frequency, because the large force acting across the spring is producing a negligible displacement at that point.

If the sprung-mass system is attached to the mass-excited mass-spring grounded system, the former acts as a dynamic vibration absorber. When it is tuned to the driving frequency of the grounded system (i.e., its parameters are chosen so that its antiresonance

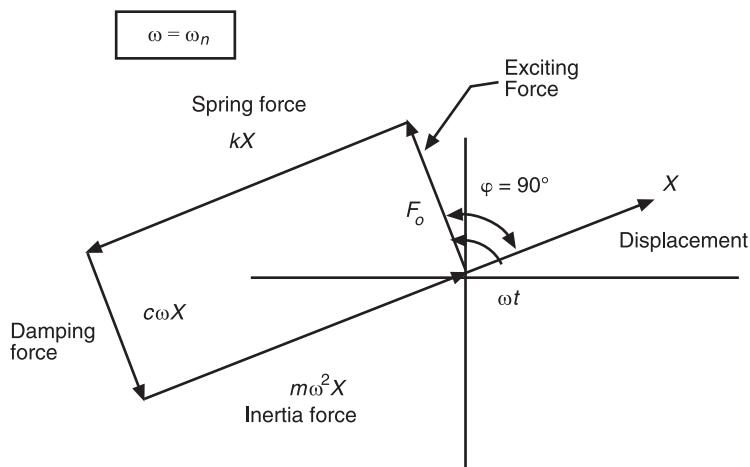

Figure 2 Force balance diagram at resonance for single-degree-of-freedom system.

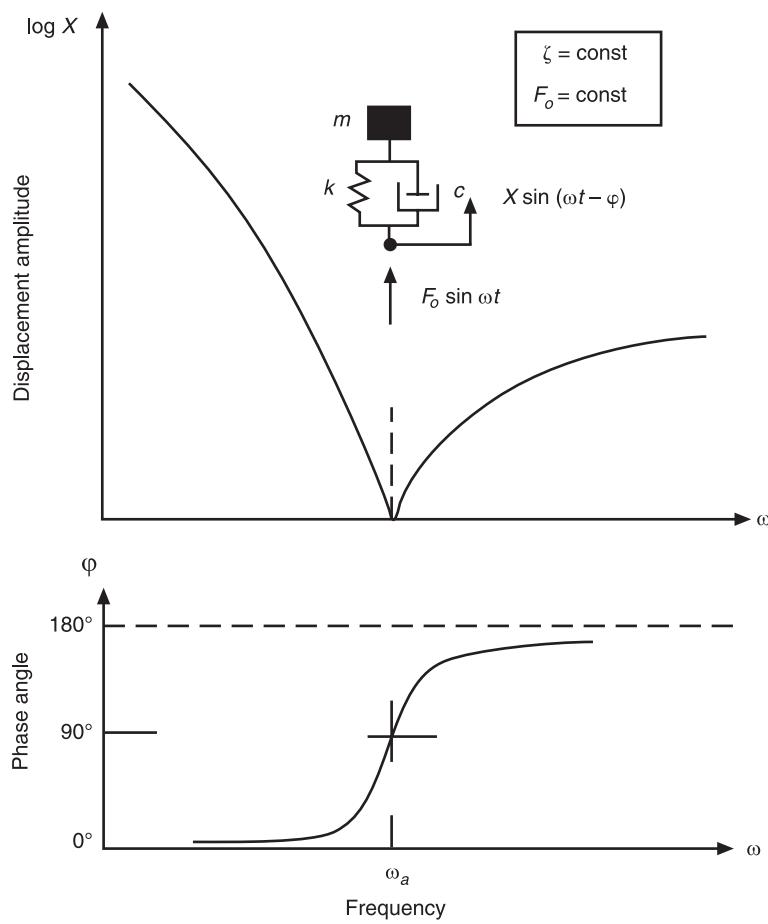

Figure 3 Antiresonant response of single-degree-of-freedom system.

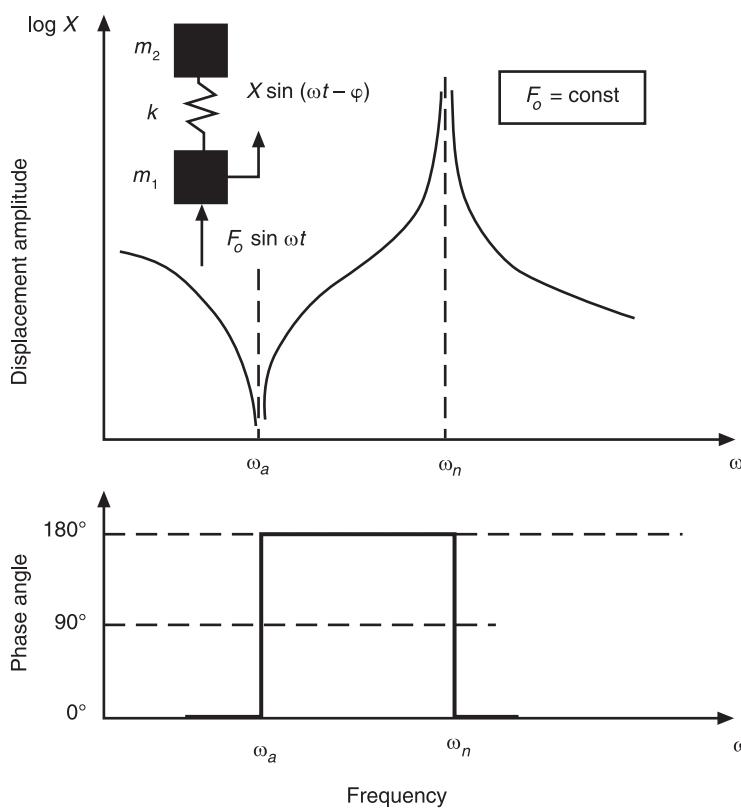

Figure 4 Frequency response of mass-spring-mass system.

frequency is equal to the frequency of the excitation force), the mass of the latter does not vibrate. The sprung mass vibrates in such a way that the spring force is equal and opposite to the excitation force. There is no net force acting on the mass of the grounded system at the antiresonance frequency of the sprung-mass subsystem.

Resonance in SDOF Systems

In the neighborhood of resonance, the response of a vibrating system can be analyzed from different points of view: the manner in which the system is made to vibrate, the physical quantities that are measured, the graphs that are plotted, and the model of damping considered.

Harmonic vs Swept-Sine Excitation

Resonance is basically defined as a forced vibration under steady-state conditions, i.e., for constant forcing frequency. In practice, the frequency of the harmonic excitation is varied, either continuously or stepwise, to determine the resonances. When the excitation frequency becomes equal to (and dwells on) a natural frequency of the system, it takes time until the steady-state response is attained. This time

depends upon the damping level. The lighter the damping, the longer is the time to reach the steady-state level of vibration.

When the forcing frequency is swept through a range of frequencies in the neighborhood of the resonance frequency, the system is said to pass through the resonance. The response exhibits a resonance-like peak, sometimes followed by a beating-like response. The maximum response amplitude does not necessarily occur at the steady-state peak frequency and an additional apparent bandwidth is created.

If the sweep is upwards in frequency, the peak frequency is higher than that obtained for steady-state conditions, the peak amplitude is lower, and the bandwidth is larger. If the sweep is downwards in frequency, the peak frequency is lower, and the peak amplitude is also lower than the dwell values. The effect of sweep rate is dependent on both the system damping and the dynamic range of the instrumentation.

Viscous vs Hysteretic Damping

The peak values of the dynamic flexibility acceptance, mobility and accelerance (displacement, velocity, and acceleration per unit force amplitude) diagrams occur

at slightly different forcing frequencies (Table 1). While some authors call these displacement resonance frequency, velocity resonance frequency, and acceleration resonance frequency, respectively, with the tacit assumption of constant excitation level, it seems more appropriate to term them peak frequencies. For damping levels usually encountered in engineering applications, the difference between the above three resonance frequencies is negligible. The frequency corresponding to the peak is often taken as being equal to the undamped system natural frequency.

Resonance Location

For harmonic force excitation, the complex displacement amplitude can be written:

$$\bar{X} = X e^{-i\varphi} = X_R + iX_I$$

where X is the modulus, φ the phase shift, X_R the coincident component, and X_I the quadrature component.

In plots of these quantities versus the driving frequency, resonance is located at peaks in X and X_I , and by points of maximum slope in φ and X_R . Also, at resonance, $\varphi = 90^\circ$ and $X_R = 0$.

In a Nyquist plot (X_I vs X_R), resonance occurs at the crossing of the circle with the imaginary axis (for hysteretic damping) or where the rate of change of the arc length with respect to frequency attains a local maximum.

These criteria are valid for receptances of SDOF systems with hysteretic damping. Provided that the natural frequencies are not close to each other, and that the damping is light, some of these resonance location criteria can be used to analyze single modes of multiple-degree-of-freedom (MDOF) systems during resonance testing (see **Modal analysis, experimental, Parameter extraction methods**).

If signals proportional to the force and displacement are applied to the X and Y plates of an oscilloscope, then an elliptical Lissajous figure is obtained. When the driving frequency is swept, the size and inclination of the ellipse change. At the phase resonance, when the phase shift is 90° the ellipse has vertical and horizontal minor and major axes.

Sharpness of Resonance

The sharpness or width of the magnitude frequency response diagram in the neighborhood of a resonance can be used as a measure of the amount of damping in the respective mode of vibration.

For a viscously damped SDOF system, at $\omega = \omega_r$, the dimensionless displacement amplitude (magnification factor) is $kX_{\text{res}}/F_o = 1/(2\zeta)$, where F_o is the amplitude of the harmonic driving force (see **Viscous damping**).

The quality factor, Q (borrowed from electrical engineering), is defined as $Q = 1/(2\zeta)$. It is related to the width $\Delta\omega$ of the resonance diagram at the half-power points (where the power dissipated by damping is half of that dissipated at resonance) by the approximate relationship:

Table 1 Peak and trough frequencies and frequency response function magnitudes for linear single-degree-of-freedom systems

Frequency response function	Viscous damping		Hysteretic damping	
	$\zeta = \frac{c}{2\sqrt{km}}$		$\eta = \frac{h}{k}$	
	Peak frequency	Peak magnitude	Peak frequency	Peak magnitude
Dynamic flexibility	$\omega_n(1 - 2\zeta^2)^{1/2}$	$\frac{1}{k} \frac{1}{2\zeta(1 - \zeta^2)^{1/2}}$	$\omega_n = \sqrt{k/m}$	$\frac{1}{\eta k} = \frac{1}{h}$
Mobility	$\omega_n = \sqrt{k/m}$	$\frac{1}{\sqrt{km}} \frac{1}{2\zeta} = \frac{1}{c}$	$\omega_n(1 + \eta^2)^{1/4}$	$\frac{1}{\sqrt{km}} \frac{1}{\sqrt{2}(\sqrt{1 + \eta^2} + 1)}$
Accelerance	$\omega_n(1 - 2\zeta^2)^{-1/2}$	$\frac{1}{m} \frac{1}{2\zeta(1 - \zeta^2)^{1/2}}$	$\omega_n(1 + \eta^2)^{1/2}$	$\frac{1}{m} \left(\frac{1}{\eta^2} + 1 \right)^{1/2}$
	Trough frequency	Trough magnitude	Trough frequency	Trough magnitude
Dynamic stiffness	$\omega_n(1 - 2\zeta^2)^{1/2}$	$k2\zeta(1 - \zeta^2)^{1/2}$	$\omega_n = \sqrt{k/m}$	$k\eta = h$
Impedance	$\omega_n = \sqrt{k/m}$	$2\zeta\sqrt{km} = c$	$\omega_n(1 + \eta^2)^{1/4}$	$\sqrt{km}\sqrt{2}(\sqrt{1 + \eta^2} - 1)$
Apparent mass	$\omega_n(1 - 2\zeta^2)^{-1/2}$	$m2\zeta(1 - \zeta^2)^{1/2}$	$\omega_n(1 + \eta^2)^{1/2}$	$m\eta(1 + \eta^2)^{-1/2}$

$$\frac{\Delta\omega}{\omega_r} = \frac{1}{Q} = 2\zeta$$

For hysteretic damping, the quality factor $Q = 1/\eta$, where η is the hysteretic damping factor (see **Hysteretic damping**).

Resonance in MDOF Systems

Resonances occur in MDOF systems having underdamped modes of vibration. Heavily damped systems do not exhibit resonances because the overdamped modes of vibration are not distinguishable.

Resonances can be defined by the imaginary parts of the poles of transfer functions. They appear as peaks in frequency response modulus plots of receptance, mobility, or accelerance, and as troughs in plots of dynamic stiffness, impedance, and apparent mass.

Resonance Testing

Resonance frequencies, levels of damping, and close approximations to the normal modes of vibration are measured by resonance testing. By exciting the system with harmonic forces (or by imposed harmonic displacements), and adjusting the driving frequency, successive modes are brought to resonance.

Frequency response data are collected and presented as a set of frequency response function (FRF) diagrams (see **Displays of vibration properties**). For lightly-damped systems with low modal density, resonance is indicated in the FRF plots by peaks of the magnitude of either modulus or the quadrature component of receptance as a function of frequency. Location at zero in-phase component or 90° phase shift gives erroneous values due to the (contribution of) off-resonant modes of vibration. Better location on the latter plots is obtained at the points of inflection.

In systems with proportional damping and low modal density, resonance is located at the frequencies of local maxima of the quadrature component of receptance FRFs. These are different from the frequencies of maximum modulus magnitude.

For systems having moderate damping and/or close modes, best resonance location is achieved on Nyquist plots, at the points where the rate of change of phase angle (and the arc length) with respect to frequency has local maxima. The resonance diameter of the approximating circles is neither coincident nor parallel to the imaginary axis. If marks are made on the plot at equal frequency increments, resonance is located at maximum spacing between successive points.

For systems with proportional damping, if the contribution of the off-resonant modes can be considered to be constant, then the resonance diameter of the circle fitted to the points around a given resonance is parallel to the imaginary axis of the Nyquist plot. It means that the peaks of the quadrature component of response versus frequency give an accurate resonance location.

Resonance search is a simpler test aiming to determine resonance frequencies alone. It is used in the pretest phase, for instance in vibration test programs, to establish the complexity of the behavior of the test object, the levels of excitation during the main test, and the degree of nonlinearity of the tested item. In modal testing, once resonances are located, one can decide whether or not to use lower sweep rates (in sine sweep) and/or larger dwell periods of time (in sine dwell) in the resonance vicinity.

Phase Resonance Method

The phase resonance testing method uses multipoint harmonic excitation, adjusted to excite a best approximation to an undamped mode of vibration at a time, at the respective phase resonance frequency.

The complication comes from the fact that at resonance, a single harmonic force cannot excite a pure undamped mode of vibration. If the structure is not too large, and if the driving frequency is equal to an undamped natural frequency, the steady-state response due to a single force is an operating deflection shape or forced mode of vibration, made of a summation of contributions from several normal modes.

Theoretically, for a system with a finite number of DOFs, it is possible to find a set of monophase (in-phase with one another) forces applied at all DOFs, capable of driving the system at resonance in a pure natural mode of vibration.

A pure mode is excited when the response and the excitation are in quadrature at each DOF or when the real part of the response vector is zero.

Indeed, at resonance, the stiffness and inertia forces oppose one another (the reactive energy being zero) and the excitation forces must balance only the damping forces. They should have the same spatial distribution as the damping forces and their work must compensate the energy dissipated by damping. The result is that the real part of the response is zero, hence the determinant, or one of the eigenvalues of the real part of the FRF matrix, vanishes. The total response is equal to the quadrature component, so that at resonance the response is in quadrature with the excitation.

If the system is excited harmonically by an array of monophasic forces and the driving frequency is

adjusted, phase resonance is obtained when a monophase response is obtained with a phase shift of $\pm 90^\circ$ relative to the excitation.

However, in practice, in a test using a finite number of forces, it is impossible to achieve the pure phase resonance condition, because the damping forces are continuously distributed throughout the system. When the damping forces are in equilibrium with the applied forces at only the excitation points, a local pseudoresonance is obtained at a test natural frequency. If the number of forces is small in comparison with the total number of DOFs of a system, the quadrature condition cannot be fulfilled, and a residual phase lag occurs in the modal displacements.

In modal testing, resonances can be located using various mode indicator functions (MIFs). Because measured FRF matrices are rectangular, plots of singular values versus frequency are used to locate resonance frequencies at peaks, troughs, or zero crossings, depending on the particular type of MIF used.

Antiresonance in MDOF Systems

Antiresonances appear as deep troughs in FRF modulus plots of the type motion/force, and as peaks in FRF plots of the type force/motion.

For undamped systems, antiresonances are defined by zeros of receptance-like transfer functions. Writing the transfer function in the rational fraction form,

antiresonances are defined by zeros of the numerator polynomial, while resonances are located at the zeros of the denominator polynomial.

In a driving point FRF, resonances and antiresonances alternate (Foster's reactance theorem). Between any two resonance peaks there is a deep antiresonance trough. This pattern can be used as a preliminary check of the validity for a measured driving point FRF.

In a transfer FRF, some or all antiresonances are replaced by minima (shallow troughs). While the phase of the FRF changes at both resonance and antiresonance, it does not change at minima that are not antiresonances.

The number and location of antiresonances change in FRFs plotted for different response measurement points and directions. They are found from the eigenvalues of a reduced system, obtained by deleting, from the stiffness and mass matrices, the response point column and the driving point row. Because antiresonances characterize the local behavior of a system, they can be used for detecting and localizing damage, although they are selectively sensitive to changes in system parameters.

Figure 5 is an overlay of three receptance curves calculated for three different directions at the same point of a structure. It illustrates the coincidence of resonance peaks and the different number and location of antiresonance troughs. The upper curve, where resonances and antiresonances alternate, is a drive-point receptance.

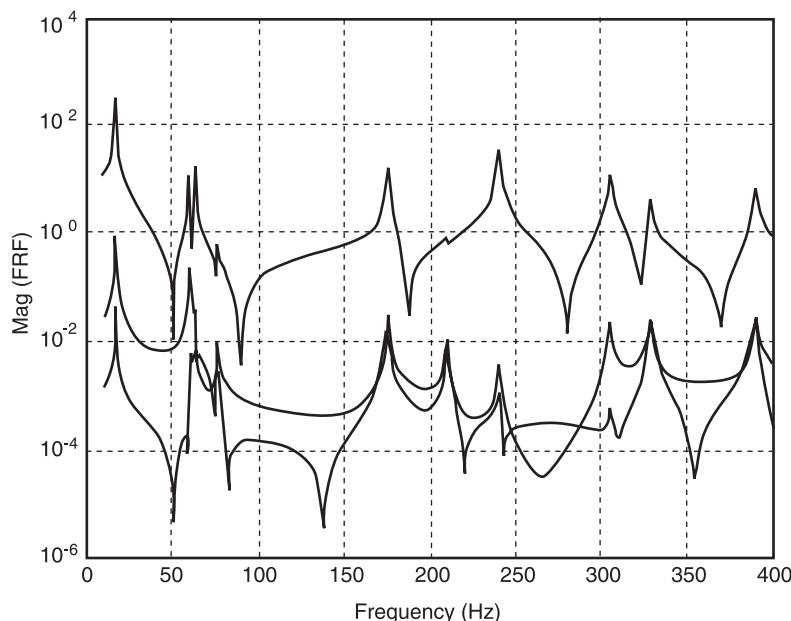

Figure 5 Receptance curves for the same location, in three different directions. FRF, frequency response functions.

Using the partial fraction expansion form of an FRF, it is seen that an antiresonance occurs between two consecutive resonances when the two resonant modes have the same sign for the modal constants. If the modal constants of the adjacent modes have opposite signs, there will be a minimum, not an antiresonance.

If a vibrating system is rigidly constrained in one DOF, the resonances of the constrained system occur at the antiresonances of the unconstrained system viewed at the location (or in the DOF) of constraint. When antiresonances of two subsystems coincide, a resonance of the combined system exists at that frequency and the respective mode has a node at the point of interconnection. As a result of a local, single-DOF, point modification, each resonance of the original system cannot be shifted farther than the adjacent antiresonance.

It is possible to create a vibration node at a given location by a so-called pole-zero cancellation, i.e., producing an antiresonance at a resonance frequency. The eigenvector of the pole (without the nodal coordinate) must be identical to the eigenvector of the zero. Also, the zero must show up in the point FRF and all the cross FRFs at the location of the node.

Isolation techniques based on the attachment of substructures at the nodal points are based on the same principle as the dynamic antiresonant vibration isolators, in which the motion of the excited body is accompanied by a reverse motion of some part of the isolating system. In the absence of damping, the internal transmitted force is zero at the antiresonance frequency, but it is small and finite when modest amounts of damping are present.

It should be remembered that absorbers, or dynamic neutralizers, are force-balancing devices attached to vibrating systems to bring the resonance peak down to its lowest possible value (see **Absorbers, vibration**). Usually, a resonance peak of the original system is transformed into an antiresonance of the modified system, by providing a reaction force that inhibits the vibration in the main system at that particular frequency. In a general treatment of dynamic neutralizers, the Frahm-type dynamic absorber can be replaced by a frequency-dependent equivalent mass (attached to the main system), which is infinitely large for the excitation at the absorber antiresonance frequency, plus a grounded damper.

Resonance in Parametric Vibrations

It was shown that, in linear systems, resonance occurs when the driving frequency and a natural

frequency coincide. The term resonance is used in a wider sense in parametric vibrations, sometimes instead of the term parametric instability (see **Parametric excitation**).

When the driving frequency is an integer multiple of the natural frequency of the associated linear system, nonlinear SDOF systems described by Mathieu equations exhibit parametric instabilities, referred to as parametric resonances.

The principal parametric resonance occurs when the excitation frequency is twice the natural frequency. Parametric resonances of fractional order also exist. MDOF systems can experience parametric resonance if the driving frequency and two or more natural frequencies satisfy a linear relation with integer coefficients.

Parametric resonance is a state of vibration in which energy flows into the system from an external source at resonance, increasing the amplitude of the system's response. This energy is dependent upon both the natural frequency of the system and the frequency of the parameter variation.

During resonant vibrations and self-excited vibrations, the system vibrates at its own natural frequency. But while the former are forced vibrations, whose frequency is equal to a whole-number ratio multiple of the external driving frequency, the latter is independent of the frequency of any external stimulus.

Resonance in Nonlinear Vibrations

Various types of resonance can also occur in nonlinear systems. Of primary interest is the synchronous resonant response. It occurs when the dominant frequency component is that of the driving frequency which is close to the natural frequency of the associated linear system (see **Nonlinear system resonance phenomena**).

The amplitude–frequency diagram of an SDOF system with nonlinear stiffness, calculated using the method of harmonic balance (see Figure 16 in **Displays of vibration properties**), is bent to higher frequencies (for a hardening spring) or to lower ones (for a softening spring). Resonance is located at the crossing of the frequency response curve with the backbone or skeleton curve, corresponding to the free vibration (frequency of the free vibration as a function of its amplitude).

When the excitation amplitude is increased, the nonlinear resonant response can exhibit a so-called jump phenomenon. As a result, the amplitude and frequency of the peak response depend on the manner in which the resonance is approached. If the excitation frequency is swept through the resonance,

transient motions occur due to sudden jumps between two steady states of different amplitudes at almost the same frequency.

Subharmonic resonance occurs when the system vibrates with a frequency equal to an integral submultiple of the driving frequency. Such a condition is possible because the free motion contains higher harmonics. The driving force can do work on one of them and, apparently, the peak amplitude is excited at a frequency lower than the forcing frequency. Superharmonic resonance occurs when the driving frequency is a submultiple of the frequency of the fundamental resonance. If the multiple is not an integer, the state is an ultrasuperharmonic resonance.

MDOF systems can exhibit autoparametric or internal resonances when there is a linear relationship between some of their natural frequencies. A transfer of energy between different modes of vibration takes place in these cases.

Nomenclature

F_o	amplitude of the harmonic driving force
Q	quality factor
X	modulus
\bar{X}	displacement complex amplitude
φ	phase angle
ω	frequency
ζ	damping ratio

ROBOT VIBRATIONS

W Book, Georgia Institute of Technology, Atlanta, GA, USA

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0070

The nature of robotic arms invites vibratory behavior while the function of robotic arms is heavily

penalized by that vibration. Consequently, understanding and compensating for the tendencies of a robot to vibrate are of great importance. Robotic vehicles have less tendency to vibrate, although mounting an arm on a vehicle introduces new sources of excitation and compliance and new penalties for the simple solution to vibration, that is, adding mass to rigidize the arm structure.

A key step to understanding is modeling. Modeling the vibration of a robot arm presents difficulties not found in many other mechanical systems. The arm is often called on to operate in multiple degrees-of-freedom. The vibrations are superimposed on rigid-body motions that excite the vibrations and alter the dynamic parameters of vibration. The compliance and mass elements often comprise a variety of phenomena. Bending, torsion, and compression of structural and drive components may be combined with fluid compliance of actuators, feedback control gains, and nonlinear linkage kinematics. The excitation may arise from the rigid-body motion, contact with work pieces or the surroundings, fluctuating torque of the actuators, and motion of the base or of the payload. In spite of these complexities it is important to model arm vibration to understand how it can be improved. It is useful to consider discrete or lumped models for some arm components and distributed models for others. When the nonlinear dynamics of the arm motion become important, the distributed models typically rely on modal coordinates to represent the flexible kinematics. Frequency domain models are also helpful since they accurately represent the linear distributed behavior, but must be augmented with time domain analysis if they are to represent the nonlinear behavior. Serial link arms are generally easier to model than closed chain designs that have algebraic constraints to represent the closure of a loop in the mechanism.

There are many ways to improve the vibration response of a robotic arm. Since a robot is usually computer-controlled with many sensors and actuators already in place, active options exist that might not otherwise be considered. The first step is to understand the significance of the compliance and mass of various components. If the performance requirements are not so severe, conventional approaches to rigidize the structure and drives may suffice. If the limits of performance are pushed, active controls are a viable alternative.

When should Flexibility be Considered?

To position a robotic arm according to a computer-generated command, some form of feedback control of a joint will usually be employed. The joint actuator (typically electric or hydraulic) is under closed-loop control. The great majority of closed-loop controllers employ PID control. The design of the PID control gains is commonly based on the assumption that the system consists of a rigid inertia. This assumption is acceptable as long as the damped natural frequency of

the closed-loop system ω_d (approximately its bandwidth), is less than about 10% of the natural frequency of the mechanical system with the joints clamped, ω_c . It is possible to push ω_d up to about 30% of ω_c , but with higher gains it is no longer possible to achieve adequate damping on the dominant mode of motion. A root locus diagram indicates the nature of this limitation as the position and velocity gains of the PID control are increased, as shown in Figure 1. The natural frequency, ω_c , is therefore a viable predictor of the importance of vibrational modes in the arm motion. In addition to natural frequency, compliance itself may be an important specification of the arm behavior. This is especially important if the placement accuracy is important with varying loads but without sensing or reprogramming of the motion that accounts for the different loads. If robot position is predicted by modeled rigid kinematic behavior as in offline programming, the rigidity may also be crucial.

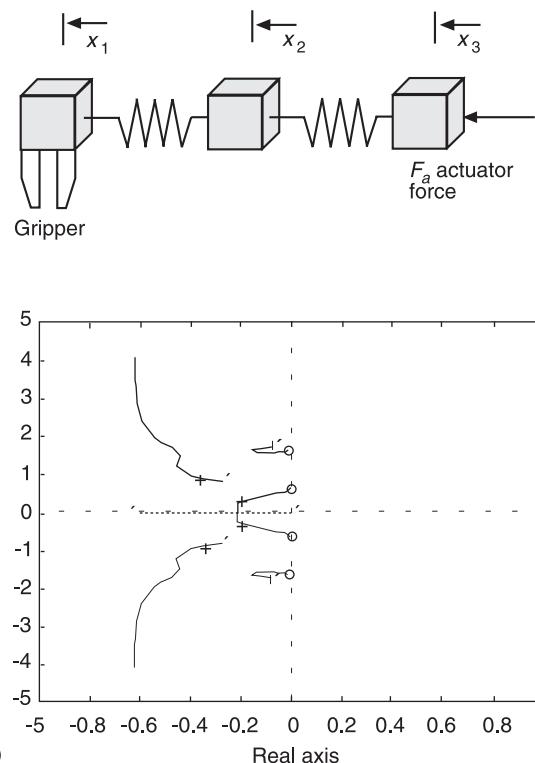

Figure 1 (A) Schematic of simple model of arm with flexibility. (B) Root locus for increasing feedback gain of position x_3 . Circles are limiting root positions for infinite gains at the system natural frequencies for x_3 fixed.

When is Vibration an Important Constraint?

Vibration is one of several constraints considered when sizing structural and drive components. Other constraints include buckling stability (in various modes) and strength. If strength considerations demand a structure size that exceeds the vibrational demands, vibration is not the active constraint on design and need not be considered. A detailed analysis of this issue requires a careful model of the relevant portions of the arm system. Analysis based on general models has indicated that flexibility is most important for systems with long reach and, high accuracy, and bandwidth requirements.

To Flex or Not to Flex

When deciding how rigid to make an arm, it is important to realize the tradeoffs that are being made. Improvements often come at some consequential cost: if the alternative being considered is to move to a more rigid material, the penalty is probably the cost; if the option is to add more material to rigidize the moving structure, the penalty to be paid is added inertia, which translates to either additional motor capacity or lower speed for large movements. Large movements will slow down because, if the motor is not increased in torque, then mechanical advantage of the drive must increase and the motor will reach its limiting velocity sooner. Ultimately, in a well-designed arm, one balances small motion speed (bandwidth) that is better for a heavy rigid system, with large motion speed that is better for a light flexible system.

How to Make an Arm Less Flexible

Wise investment of structural mass and wise location of nonstructural mass is the first priority in designing a robot arm without vibration problems. It is often the case that robot joints are the source of the most compliance and are the most difficult area to rigidize. Joint compliance comes from bearings, bearing housings, shafts, and gearboxes. Closely related is the compliance of drive shafts, belts, chains, cables, fluid lines, and other power transmission devices. The length of these transmission members is determined by placement of the other actuating components, such as electric motors, reducers, and hydraulic valves. Adding structural mass to connecting beams does nothing to reduce joint and drive compliance and in fact lowers the natural frequency by increasing mass carried by proximal

or inboard joints. If we observe a design where one component is effectively rigid through the investment of a substantial amount of mass, that mass would be better invested in rigidizing some other component if possible.

Vibration as a Result of Commanded Motion

Standard pick-and-place robot applications experience robot vibration most acutely when short cycle times lead to rapid deceleration and thus high jerk. The vibration may cause overshoot and thus a collision with surrounding objects or, in the desired stationary state, not following the commanded motion. The typical response is to program a delay between the completion of rapid motion and initiation of a precise motion. This increases cycle time and consequently productivity is limited.

With increasingly sophisticated control computers, improved motion profiles can be effectively generated. The simple and popular trapezoidal velocity profile which has limited acceleration but theoretically infinite jerk shown in Figure 2A can be replaced with a limited jerk profile, as shown in Figure 2B, jerk being the third derivative of position with respect to time. These profiles are compared in Figures 2A and 2B where the distance traveled is the same for motions with a factor of 10 difference in the permissible jerk. The travel time is also affected. This has a profound effect on excitation of vibration, but more improvement may be needed. The use of shaping filters can again reduce vibration and can be customized to the resonances of the arm. There is a further benefit that the user can generate the initial motion profile with minimal concern for vibration, simply leaving the job to the shaping filter to clean up the motion. Shaping filters based on time delay or finite impulse response filters (impulse response and vibratory response illustrated in Figure 3) have the added advantage over conventional notch or low-pass filters because their response is complete after a finite and relatively short time and yet they are simple to implement on a digital controller. Motion control companies have patented some aspects of these filters.

Modeling Robot Vibration

Some aspects of modeling robot vibration are not specific to modeling any other mechanical system. We will focus here on the aspects that are somewhat unusual. Some of these aspects are:

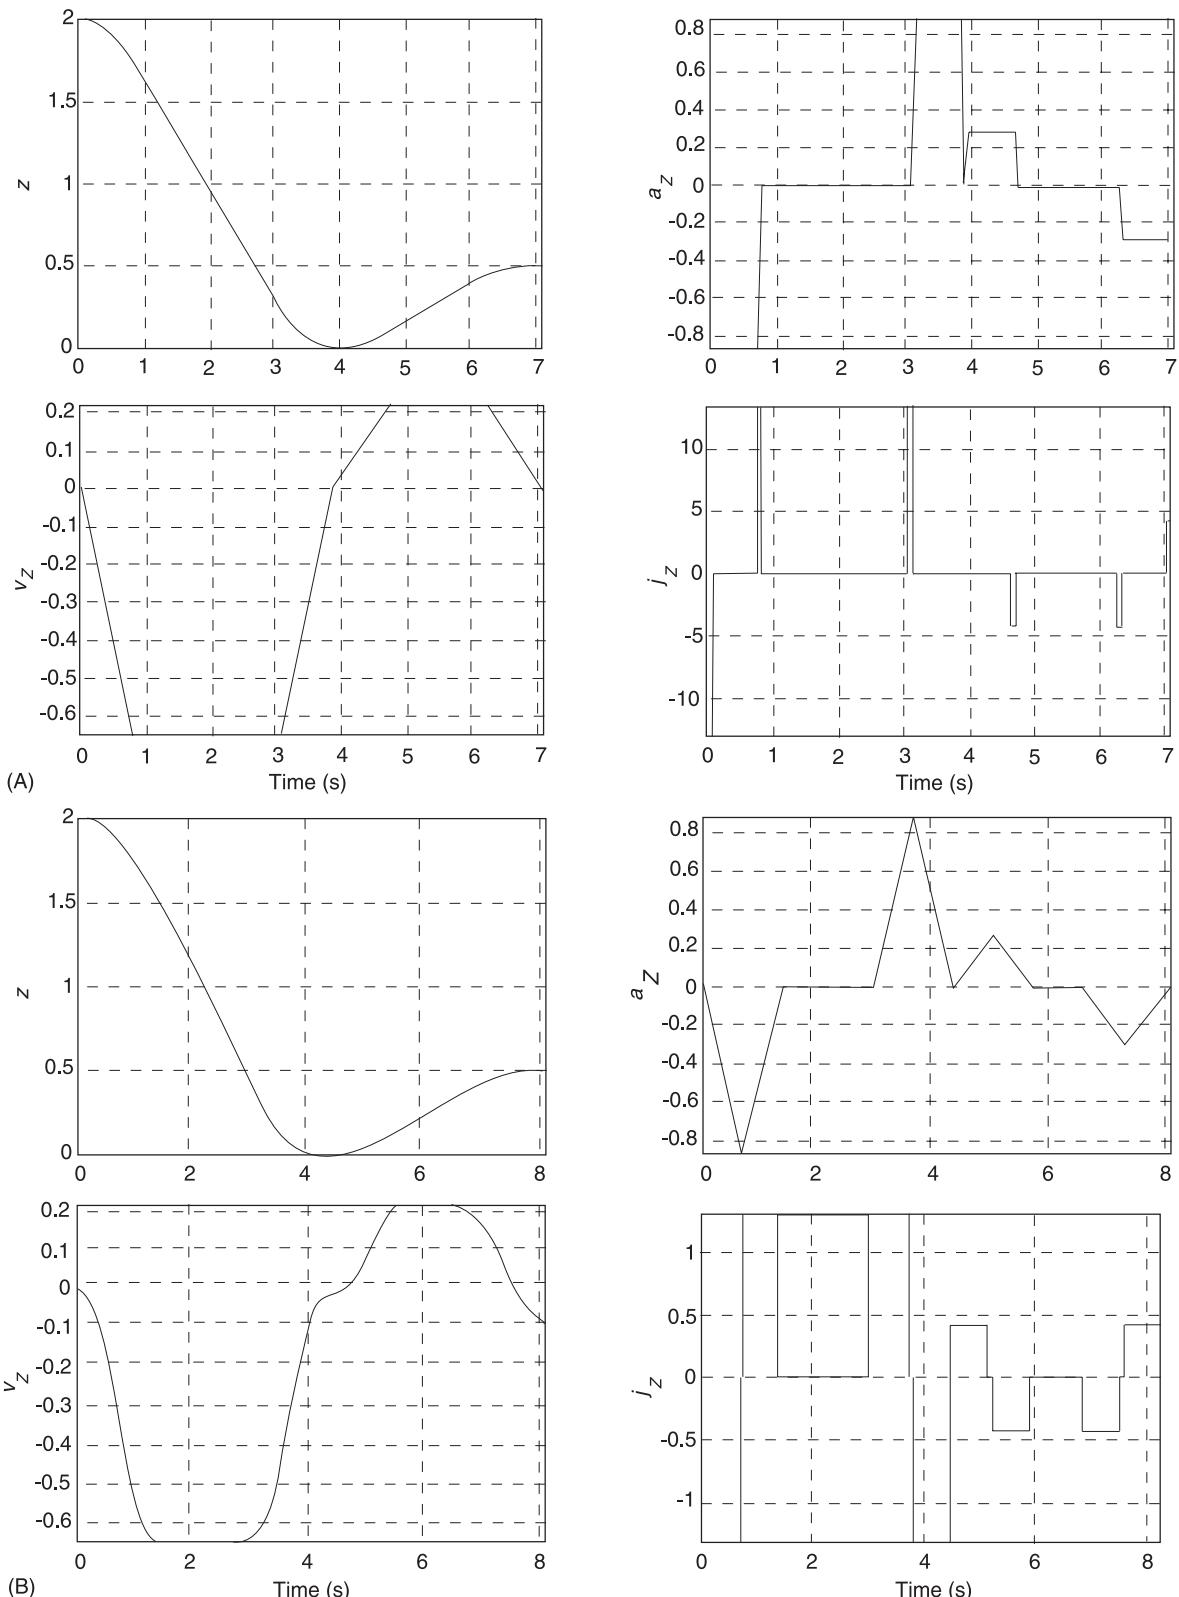

Figure 2 (A) Position (z), velocity (v_z), acceleration (a_z), and jerk (j_z) for a trajectory with limits on velocity and acceleration and very high limits on jerk. (B) As for (A) but the limits on jerk are reduced by a factor of 10. Courtesy of Ai Ping Hu, CAMotion, Inc., Atlanta, GA.

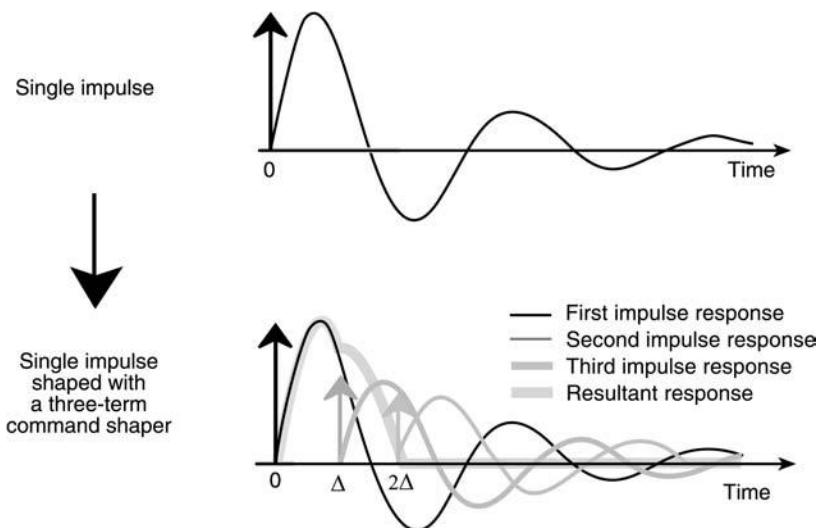

Figure 3 A time-delay command-shaper transforms a single impulse to three impulses. Optimal arbitrary time-delay filter shown. Courtesy of Sungsoo Rhim, CAMotion, Inc., Atlanta, GA.

- actuated joints
- variety of functional components (belts, shafts, bearings, motors, valves)
- variety of phenomena contributing to behavior (elastic, electromagnetic, hydraulic)
- kinematic linkages and resulting compliance and nonlinearities
- serial and/or in-parallel configuration
- the multidimensional ‘rigid-body’ motion

Actuated Joints

The joints are a major source of excitation when commanded to move. This leads to forced vibration. In free vibration due to initial conditions, joints pose a dilemma to the arm modeler. Is the joint free to translate or rotate when the actuators are unpowered? This is seldom the case, except possibly for direct drive arms. Direct drive joints, or joints with low friction reductions, may be back-driven to some extent, so forces imposed on the arm generate motion in the joint. The other extreme, a joint which cannot be back-driven, due to a large gear ratio and friction, is equally easy to examine since the joint is then simply a rigid connection between two links or possibly a connection with some gear compliance. The case in between the extremes is very difficult to examine. The joint motion impeded by dry or Coulomb friction behaves as a fixed connection for low-amplitude vibrations. For high-amplitude vibrations, one can treat the joint as damped by a linear viscous damping with fair accuracy. Non-linear analysis must be applied in the vast middle

ground if more precise analysis is needed. Unpowered joints are of interest primarily as a step in modeling the arm with powered joints. By modeling the free vibrations and determining the low-frequency modes, one can develop very efficient generalized coordinates for modeling a high-degree-of-freedom arm as a lower-degree-of-freedom system. This is discussed further below.

For the robot designer, the situation of greater interest is free vibration with joints powered and controlled to hold a fixed joint position. Joint friction is still an issue, much the same as for unpowered joints, discussed above. In addition, it is necessary to treat the feedback gains as if they were creating torques or forces like a physical spring (position gains) or dampers (velocity gains). The ideal equations are identical although actuator dynamics may alter the result in practice. Hydraulic actuators fed by electrohydraulic servo valves, for example, block flow from the back-driven actuator, leaving compressibility of the trapped fluid as the only compliance permitting the joint to move.

Variety of Phenomena and Components

The discussion above has already involved the reader in the variety of component types involved in robotic arm modeling. It is often possible to produce mechanical analogies of these components and phenomena. The spring analogy of position feedback control or fluid compressibility is an example.

Kinematic Linkages and Parallel/Serial Configuration

In an effort to achieve the greatest range of motion and minimize the moving mass, a combination of serial joints actuated by drive linkages is common in robot arms. Figure 4 illustrates a popular parallel linkage design that places two actuators at the base of a planar mechanism but allows a range of motion comparable to serial actuation. In other cases the actuator near the base is connected by cables, shafts, chains, or toothed belts. These also create parallel structural paths. Vibration analysts commonly deal with parallel structural paths such as trusses, since this is a very efficient design. Such models seldom articulate over large angles, however, during the operation being analyzed. The belt compliance is lower if the load is positioned near the driving pulley than if the load is far from the driving pulley.

Parallel linkages complicate the modeling of distributed components (e.g., beams) by adding algebraic constraints to the partial differential equations. There are exact treatments for this complexity, such as adjoining the algebraic constraints to the differen-

tial equations via Lagrange multipliers. There are approximate treatments also that may incorporate these constraints in acceptable ways, as shown in Figure 4. For example, a parallelogram with two sides deflecting (indicated by dashed lines) experiences negligible shortening of those sides. Consequently, the motion transmitted to an outboard link driven by the parallelogram is pure translation. Point A in Figure 4 translates to A'. This constraint simplifies the dynamic equations rather than complicates them.

Rigid-Body Motion in Multiple-Degrees-of-Freedom

Since the robot may have six or more joints to provide three positional and three rotational degrees-of-freedom, modeling the vibration as part of the full dynamic behavior is complex. Powerful numerical techniques based on finite element analysis are not usually oriented to this large motion analysis. The vibrational behavior of interest may be separately analyzed if it is sufficiently higher in frequency than the control behavior. A formal analysis based on this separation is the two time scale or singular perturbation approach. If performance of the arm is pushed higher, this separation is no longer sufficient, and the analyst must incorporate the vibrational degrees-of-freedom in the arm dynamic model. Each vibrational mode adds two system states, so the six-degree-of-freedom arm with 12 rigid states and nonlinear dynamics can easily become unmanageable for computer simulation or controller synthesis if too many modes of vibration are added.

To undertake the modeling of such a complex system is a daunting task, but it can be facilitated with symbolic manipulation software. Many analysts are familiar with Lagrange's equations and use of that method will be outlined here. A formulation known as Kane's method is also known to be suitable and may be more efficient. The technique described is suitable for chains of flexible bodies that are reasonably rigid. Because of effects known as foreshortening and centrifugal stiffening, these techniques are questionable for very large deflections and for very high rotational speeds. Lagrange's equation is given below and followed by a description of the major steps that must be followed when using that approach:

$$\frac{d}{dt} \left[\frac{\partial L}{\partial \dot{q}_i} \right] - \frac{\partial L}{\partial q_i} = Q_i \quad [1]$$

where:

- $L = T - V$

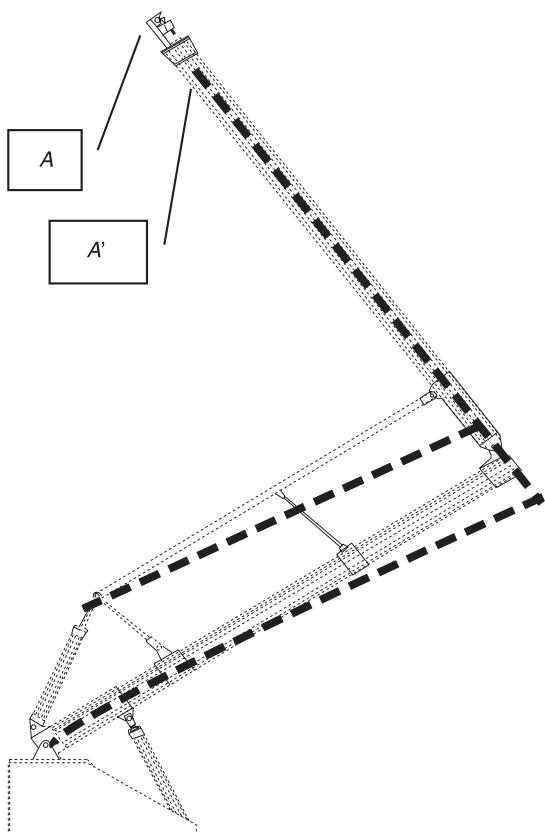

Figure 4 A flexible-link robot with parallel actuating linkage to drive outboard link. Deflection of link 1 produces no rotation on the outboard link.

- T = kinetic energy of the system
- V = potential energy of the system
- q_i = a generalized variable
- Q_i = the generalized force doing work through change in q_i

The steps in using Lagrange's equations are

1. Choose rigid-body coordinates and corresponding link boundary conditions. Two options are illustrated in Figure 5. The best choice depends

on your purpose. For tightly controlled joints, the tangent angle rigid-body coordinate and the clamped beam boundary condition is efficient (Figure 5A). To determine most easily the tip position based on rigid-body coordinates alone, rigid-body angles between lines that pass through the ends of beams that are assumed to be pinned may be preferred (Figure 5B). Figure 5 also shows the reference measurement consistent with a parallel linkage, as shown in Figure 4.

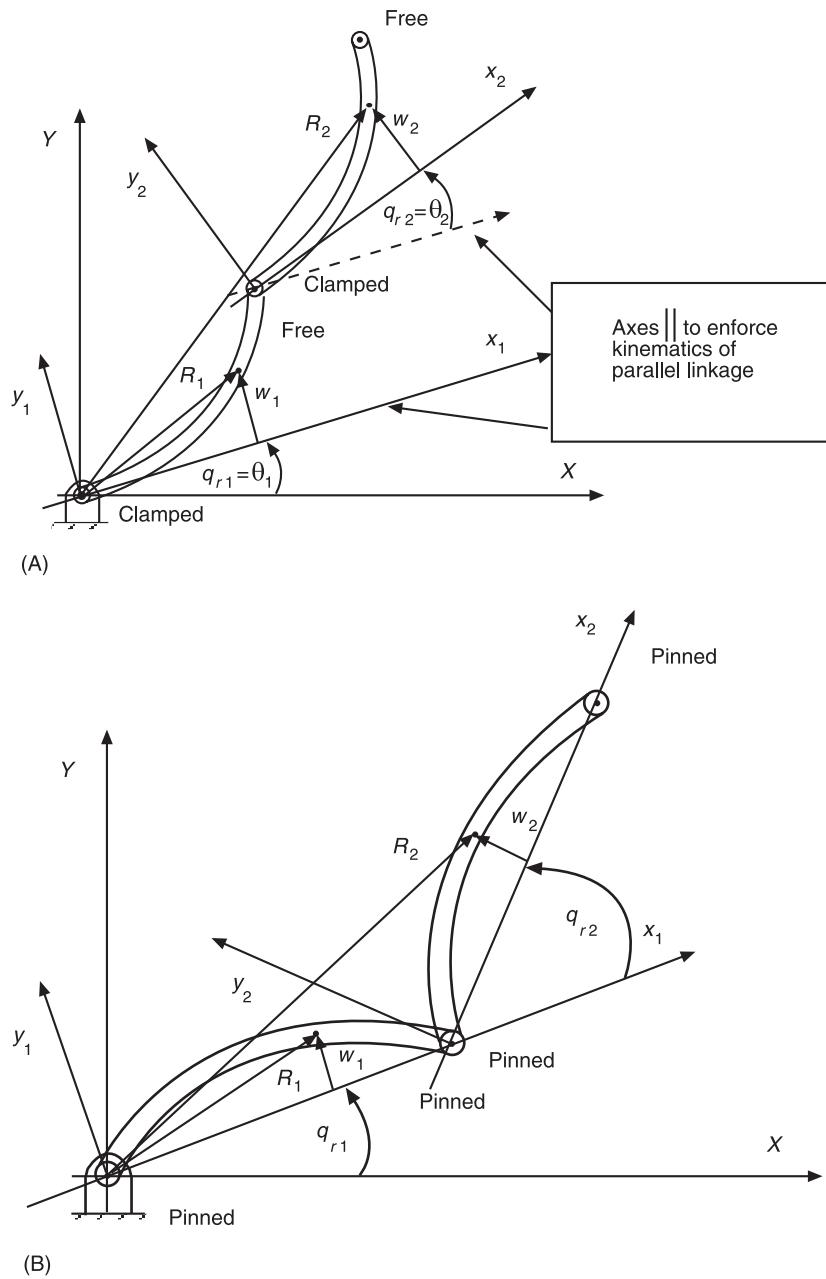

Figure 5 (A) Use of beam tangents to define 'rigid' coordinates and corresponding clamped-free boundary conditions. (B) Use of end-to-end connecting line to define 'rigid' coordinates and corresponding pinned-pinned boundary conditions.

2. Obtain basis functions (often mode shapes for assumed boundary conditions) for any components (e.g., beam-like links) that have distributed mass and compliance. As illustrated in **Figure 5**, the boundary conditions need to be consistent with the rigid-body coordinates. Finite element codes may be used for this purpose if the complex shape of the body must be incorporated.
3. Select a suitable number of basis functions for the accuracy needed
4. Combine rigid-body coordinates and basis functions into a description of the arm shape and change of shape with respect to time (velocity).
5. Formulate the kinetic energy of each component, which may involve an integral over a flexible body and hence an integral of the basis function describing shape. This ultimately leads to modal mass coefficients which reflect the choice of shape functions.
6. Formulate the potential energy consisting of gravitational, strain (of flexible bodies) and other terms (unusual). This may involve an integral over a flexible-body basis function leading to a modal stiffness coefficient.
7. Form the Lagrangian function and take appropriate derivatives.
8. Collect coefficients and simplify where possible. Identify terms that will be constant that can be replaced later with numerical values.
9. Compose the nonconservative terms consisting of joint friction, actuator forces, and torques and working forces due to contact with external objects. This term varies depending on the rigid and flexible coordinates used. It is the source of inaccuracies if complex actuator dynamics are poorly approximated.
10. Simplify if possible at each step and again at the end. Care in selecting basis functions can lead to orthogonal shapes and consequently to a large number of zero values in off-diagonal terms in the coefficients of acceleration.
11. Verify accuracy where possible with limiting cases of all types and by checking essential symmetry of mass and spring matrices. Supplement $D(q)$ with experimentally determined damping terms.

Systemization of the process listed above is crucial to accuracy. Symbolic manipulation programs are indispensable but their results should not be accepted without question either. The equations have a great deal of structure that can assist the analyst as has been noted by researchers. The final equations will have the form given in eqn [2]. The extension and use of

Jacobians, popular in robotic circles, for describing the velocity is one way to do this:

$$\begin{aligned} M(\mathbf{q})\ddot{\mathbf{q}} + D(\mathbf{q})\dot{\mathbf{q}} + K(\mathbf{q})\mathbf{q} + G(q) + H(q, \dot{q}) \\ = B(\mathbf{q})\mathbf{Q} \end{aligned} \quad [2]$$

where:

- $\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}$ and \mathbf{Q} are column vectors of the scalar with same symbol plus subscript
- $M(\mathbf{q})$ = the inertia matrix
- $D(\mathbf{q})$ = the linear damping matrix
- $K(\mathbf{q})$ = the linear stiffness matrix
- $G(q)$ = the effect of gravity
- $H(q, \dot{q})$ = the nonlinear terms due to centrifugal and Coriolis forces
- $B(\mathbf{q})$ = distribution matrix of generalized forces

The analyst may also consider commercial software products that are becoming increasingly powerful and accurate in approximating flexible behavior into multibody dynamic equations. Caution should be exercised in understanding that the approximations used by these products may not be suitable for an individual application.

Improving Behavior of Vibrating Robotic Arms

There exists a multitude of engineering approaches that can be used to attack a vibration problem. In many cases, a tradeoff exists and reduced vibration must be balanced against speed of operation, mass, complexity, and/or cost. This section discusses some of the strategies that have been studied and shown to be effective in practice, experiment or both.

Improved Allocation and Location of Mass

This may include adding structural material. As discussed early in this article, structural material also has mass that can harm more than help a given vibration problem. The shape of structural members is a key aspect of mass allocation. If it is possible to expand a link cross-section and place material in a beam or truss far from the bending axis of the component, the most favorable results can be obtained. Achieving the needed range of joint motion and obstacle avoidance becomes more difficult when the structure is expanded. If workspace needs are modest, a parallel-actuated design such as a ‘Stewart platform’ can be extremely stiff and light. Placing actuators and other massive components that do not contribute to stiffness near the base is part of this strategy, but requires compliant transmission shafts, cables, etc.

Select Improved Structural Materials

If the structure is a large part of the mass moved, as is typical, it is important to select materials with high stiffness-to-weight ratios. Many engineering materials that are lighter are also less stiff. Aluminum is one-third the weight of steel but also has one-third the elastic modulus of steel. Some composites are extremely stiff but are expensive to fabricate and join to drive structures. Do not overlook the improved damping that some materials have, particularly if there is concern for higher-frequency modes of vibration. Application of viscoelastic passive damping treatments is very effective if engineered appropriately. They should be installed with a stiff constraining layer and in appropriate segments. These treatments are similar to sound-deadening materials and may add substantial weight to a structure.

Change the Commanded Motion

The simplest version of this strategy is to slow down the motion or to wait after a move for vibration to decay. This is an unnecessary compromise of performance in most robots. Choose a velocity profile without sharp corners and filter the motion commands with shaping filters. This approach is often implemented with only minor compromise in complexity since the robot already has a computer-generated trajectory. Stability is not compromised if the command-shaping filter is outside the feedback loop. Adaptive command-shaping can be used in many cases if suitable parameters cannot be manually established.

Feedback Control and Active Vibration Damping

Even for simple feedback controllers, decisions substantially affect the vibration behavior. Very high position and velocity gains appear from a rigid analysis to give outstanding performance. However, the resulting stiff joints cannot remove vibrational energy (if the joint is back-drivable) and are more prone to excite vibrational modes (even if back-driving is not possible). This is probably the most frequent mistake relating to arm vibrational behavior. Many forms of control have been studied and shown to reduce the vibrational tendency of flexible robot arms. The need for sensors, the sensitivity to expected parameter changes and the complexity of design and implementation are all concerns to be considered before investing in one of these algorithms. With the reduced cost of sensors (e.g., accelerometers) and control computers and with the simplification possible by connect-

ing sensors and controllers via serial networks rather than massive wire harnesses, active control of vibration is the frontier of performance enhancement.

Altered Operational Strategies

The use of a robot can be modified to reduce the tendency to vibrate greatly. Since this requires collaboration between the designer and the user, it is difficult for anyone to make this happen except in extreme cases. If large motions requiring vibration-susceptible long arms can be effectively decoupled from the small motions requiring precision that is most jeopardized by the resulting vibration, both subsystems can be optimized for their essential tasks. Studies of a bracing action show this decoupling is possible using strategies similar to a human worker. Small motions of a human are carried out, after bracing the arm on a passive support for rigidity, by the fingers and wrist, which do not have the range of motion of the arm or legs but do have more precision. To mimick this requires robots with more degrees-of-freedom and potentially of greater cost. If compared with a design to the same specifications but without the motion specialization, the cost may still be lower. Additional degrees-of-freedom for small motion can also be used as inertial dampers similar to passive dynamic vibration absorbers found in more conventional forced-vibration solutions. Tuning the motion to the vibrational frequency is accomplished by sensing the vibration and commanding small motions that absorb the vibrational energy of multiple modes in multiple directions.

ROTATING MACHINERY, ESSENTIAL FEATURES

R Bigret, Drancy, France

Copyright © 2001 Academic Press

doi:10.1006/rwvb.2001.0090

Historical Background

Rotating machinery is essentially composed of a rotating part, the rotor, and a nonrotating part, the stator. Natural round forms were the inspiration for the wheel, then there followed a variety of rotating machinery. The following text reviews several developmental steps.

Two or three million years ago, the primate Australopithecus made the first tool from a sharpened stone. Left behind by glaciers, stones came hurtling down the mountainside, astounding people by their rounded form.

Some 7000 years ago the wheel and subsequently the wheelbarrow were invented. The wheel helped the Maltese people transport blocks of stone during the construction of their megaliths. The Egyptians knew about the wheel but didn't make significant use of it in building the pyramids.

The water wheel was first seen in Illyria a short time BC. In the first century AD the Chinese people were using bellows on the fires in their forges. These bellows were powered by water mills equipped with crank-connecting rod systems. The crank was introduced to the west in the 16th century, and nowadays it is used in car engines. Windmills were first turning on the plateaux of Iran in the seventh century.

In 1629 Giovanni Branca, an Italian, used a spray of steam to make a cog wheel turn, which in turn raised a power hammer, which would crush grain when released.

The Frenchman Blaise Pascal invented the Pascaline in 1642. This was a calculator using cog wheels.

Newcomen and Savary, who were English, invented an atmospheric girder-type machine to

drain mines, and the water drawn up was used to irrigate the fields. Steam would set in motion a piston which moved a lever to operate a piston and pump water. In 1712, Newcomen and Savary connected the lever to a steam tap: this was the first automatic closed loop which was the forerunner of industrial cybernetics.

The Englishman James Watt's steam machine was introduced in 1767. The machine was perfected with a double-acting piston, drawer distributor, and inertia wheel which reduced the fluctuations of rotation driven by the crank-connecting rod system.

Cugnot, a French engineer, made a self-propelling machine in 1776, comprising a steam generator, piston, crank, and three wheels. In 1923 Abner Doble presented the American Beauty in San Francisco. This traveled up to 150 km h^{-1} carrying five passengers.

The first steam boat was a paddle boat, driven by the Marquis de Jouffroy d'Albans, in 1776. It was 46 m long and went upstream on the Saône. The American company Fulton built the first propellor submarine in 1798 in France.

In England Richard Trevithick built the first locomotive in a coal mine (1804) and then another one in London in 1808, to entertain a dazzled public, with the slogan 'catch me who can'. The fight was on between the road and the railway. In 1837 the first train arrived in Paris.

Between 1784 and 1884, 195 patents for steam turbines were registered with the British Patent Office, among them one from James Watt. In 1843 the Swede Scheutz built a steam turbine to operate the 'mills' of the calculator of the Englishman Babbage. Tournaire, who was French, proposed a turbine in 1853 which in turn inspired other developments. The flow of steam was studied in 1883 by the Swede Carl Gustav De Laval, who experimented with centrifugal machines at 30 000 rpm, above the first critical speed, which some people said could not

be surpassed without causing a catastrophe. For public electricity in England, the District Electric Lighting Company used a turbo-alternator of 75 kW built by Parsons in 1890, followed by a prototype turbine operating at 4 kW and 18 000 rpm.

De Laval and Parsons were preoccupied with significant vibration. For rotor rotation, it was necessary to introduce oil to the bearings, this occurred in 1788. Between 1883 and 1891, Beauchamp Tower was interested in this process with relation to railway bearings, and Reynolds (1884–86) studied this in England. From 1867, Newton had been using oil to reduce friction.

Newkirk in England (1924) had concerns about the compressor vibration; he studied the situation in a laboratory and dealt with strange and violent phenomena due to the oil: this was diagnosed as oil whip in 1925. It took until the 1950s to understand and name this instability, following the work of the Russian Ljapounov in 1892.

In 1901 Edmond Rateau (1863–1930), a French engineer, built turbines with 30 disks. Ljunström adopted a flow of steam perpendicular to the axis of rotation and in 1910 built a 1000 kW turbine. Rateau invented the classification of high-speed supercharging to improve fighter performance during the First World War (1914–18). This is how gas was introduced to the turbine.

The turbomachinery built in Rateau's factory in La Courneuve, near Paris, was tested there. Rateau used dimensionless classifications of rotational speed, flow, pressure, and temperature. This classification made it possible to determine machine performance away from the testing area.

These classifications result from dimensional analysis initially explained in 1822 by the mathematician and physician Joseph Fourier (1768–1830), who was well known for his series concerning on periodic signals. The Scottish physician James Clerk Maxwell (1831–79) was also interested in dimensional analysis in 1870. A theory was proposed in 1914 by Vashy and Buckingham, of England; the Englishman Reynolds (1842–1912) constructed in 1883 a classification to create order in fluid flow. Mach, an Austrian (1838–1916) introduced in 1889 the ratio between the speed of a projectile and the speed of sound, and this generated interest in fluid compressibility. The German Sommerfeld (1868–1951) set out a classification which was useful to define stiffness and damping coefficients in bearings. Strouhal associated the vortex frequencies of the American Karman (1881–1963) to the velocity of a fluid in movement and to the dimension of the body inducing it.

Dimensionless classification opened the way to universalism founded on assumptions permitting the

inclusion of the unclassifiable. In Neufchâtel in Switzerland a group of gas turbines, compressors, and 4 MW electrical alternators for the chemical industry had a great success in 1940, one year after the declaration of war.

At the end of the 19th century, the power of the first turbo-alternator equipped with a watt regulator was 20 kW, and its productivity was about 2%. The steam turbine became the archetype for rotating machinery.

France set a new world record in 1996 for a turbo-alternator of 1500 MW at 1500 rpm. This rotating machine can supply 15 million homes, each using 100 W.

Space shuttles use pumps supplied by gas turbines which have two small wheels, at 55 MW.

A steam turbine connected to a gas turbine can drive an alternator creating power close to 500 MW. Productivity of one single gas turbine can reach 35% at 4000–6000 rpm. The output of a car engine is about 25% maximum.

Alternators supply a large variety of systems: electrical engines, including telesurgery motors using rotating machines – these are electrical engines of 300 µm diameter rotating at 30 000 rpm.

Inside a watch, alternator rotors work at 15 000 rpm, sustained by magnetic bearings supplied by capacitors. Electrical machines were developed quickly: Oersted, who was Danish, discovered magnetic forces in 1820; Faraday, who was English, formulated the law in 1831; the Scot Maxwell set out the theory in 1864–65 and in the USA the former blacksmith Thomas Davenport built the first electrical engines to drill and turn wood around 1840. Reciprocity brought about generators and alternators once a magneto had been realized by the Frenchman Piwii in 1832. In Paris the Place de la Concorde was first illuminated in 1844, the first embryo London Underground was installed in 1863, whilst the first Paris Métro was constructed in 1900.

And what about the forces of air and wind?

As regards aviation, in 1809 Sir George Cayley connected a propellor to a gas or internal combustion engine. Was the first flight in 1890 in France by Clement Ader, or in 1903 in America the Wright brothers' attempt, which lasted 3.5 s?

Then in the 1950s the turbo-reactor made the piston engine and the crank-connecting rod system redundant: if it weren't for turbos, there would not be space travel.

The idea of the helicopter started with Leonardo da Vinci in 1483; it was developed more fully by the Frenchman Louis Bréguet in 1907, using the internal combustion engine. It was marginalized for some time, and then was developed from 1942 in the

USA. The helicopter was used by the French during the war in Algeria (1954–62) and the Americans in Korea and Vietnam (1951, 1953). The helicopter was a clever evolution in a rotation festival.

The Englishman Hales (1677–1761) is responsible for the fan. Hales was interested in gas, and in the movement of these fluids. In 1736 a fan was renewing the air in London's Chamber of Commerce, as it was in 1845 in a Brussels jail, in 1850 in the Théâtre des Variétés in Paris, and in 1857 on a convict boat traveling from Toulon to Cayenne. In mines fans were also being used. In 1890 Rateau created a new high-output fan against firedamp, using ventilation to remove the nauseating smell, heat, and cool discreetly. In 1946, the electronic numerical integrator and calculator (ENIAC), the first computer, required about 120 kW for ventilation.

So what about water?

Some 3400 years ago, water was causing a problem in iron mines in Armenia, but it was useful in Andalusia because it could be raised by the noria. The Romans used wheels with pots, which were the first pumps. In the 16th century in German mines, Agricola used suction pumps and force pumps with a crank-connecting rod system and wheels with pots, carried by men similar to squirrels in a cage. Whole towns were supplied by pumps: Nuremberg, Toledo, Gloucester, Bremen, Ausburg, London, Paris. Today the wide range of turbo-pumps and motor pumps supply the many needs of industry and life.

Hydraulic turbines naturally arrived before pumps: these turbines used the flow of falling water to rotate and Renaissance scientists, connecting a turbine and a pump, tried to create perpetual motion. Alternator power created by hydraulic turbine reached 700 MW, and even greater.

Sea tides provide so-called blue coal to tidal power stations, like that on the river Rance in France, where 24 machines have created 240 MW power since 1966. The world's water is shared by structures and dams where turbo-alternators and motor pumps are installed.

Rotating Machines: Diverse Realizations

In the beginning there was the hydraulic machine and the steam machine. The need to manipulate and transform energy led to a multitude of machines varying with electricity, technology, and computer science. Essential categories can be distinguished.

Thermal machines use two sources of heat, one hot and one cold, a petrol or fuel engine, steam or gas turbine. Thermal machines supply cars, power gen-

erators, pumps, fans, and compressors. Thus the turbine creates a category of turbo-machines: turbo supercharging engines, turbo-compressors, and turbo-fans. A turbo-reactor aids propulsion by varying the degree of fluid movement. A turbo-fan is a turbo-reactor with two flows; turbo-propulsive force drives a propellor, while turbo-bellows empower huge forges. A turbo-statoreactor combines a turbo-reactor and statoreactor using compressed air at the speed of the plane. A turbo-motor comprising a gas turbine can supply coupling for a helicopter, train, or vehicle. A turbo-generator can supply an electrical machine, while turbo-drilling drives a trepan. Turbo-pumps and turbo-alternators provide electric energy in fuel oil and coal stations and nuclear power stations. Turbo-pumps operate in satellite launchers and space shuttles. Inverse thermal machines function between a cold and a hot source: between heat pumps and refrigeration systems.

- Hydraulic machines use the flow of water or air: for example, hydraulic turbines, alternators, and pumps.
- Electric machines use electricity: examples include motor-pumps, motor-compressors, ventilation motors, motor-blowers, motor bellows, converters, motors supplying vehicle engines and various systems, such as computer disks.
- Multipliers and speed reducers with gears.

This list is not exhaustive. For example, in Paris the pump manufacturers' trade union gives its members' list as 12 full pages: pumps were used for water conveyance, baling out, and fire extinguishing. In Quebec a pump dictionary was published for use in the chemical industry and refineries running hundreds of pumps.

Vibration Availability

Some components of a rotating machine may become defective, leading to failure, and even catastrophe. A catastrophe would be measured by rotor kinetic energy ε . For a cylindrical rotor of mass m and radius R , rotating at speed Ω : $\varepsilon = \frac{1}{4}mR^2\Omega^2$ for $m = 1000 \text{ kg}$, $R = 0.5 \text{ m}$, $\Omega = 618 \text{ rad s}^{-1}$ ($\rightarrow 6000 \text{ rpm}$), $\varepsilon = 2.465 \times 10^7 \text{ J}$. For a turbo-alternator rotor of 1500 MW at 1500 rpm $\varepsilon = 7.5 \times 10^9 \text{ J}$. The kinetic energy of an arrangement of 2400 trucks of 10 tonnes (10^4 kg) at 90 km h^{-1} (25 ms^{-1}) it is equal to $7.5 \times 10^9 \text{ J}$.

To avoid machine downtime, the machine must be stopped for causes which require maintenance, such as assembly corrections, replacing of components, cleaning, and balancing. Machine downtime is costly, especially since halting a machine may cause

production to be canceled: this would cost 1–2 million FFr per day for a refinery, and 2–4 million FFr for a nuclear center producing electricity, not to mention client inconvenience, in the face of competition. Failure to carry out unconditional maintenance is risking material and human chaos, which cannot merely be judged by financial effects.

An optimum level between availability and unavailability, by carrying out effective maintenance, can be achieved through monitoring, analyzing conditions, such as lubricants, waste, temperature, pressure, flow, and vibratory performance. Since unbalance on a rotor cannot be canceled out, vibration is always detectable and subject to limits. Numerous other situations can be identified by descriptors derived from an analysis; their numerical values may permit diagnostics, and therefore stopping the machine or maintaining it while in use. Before the introduction of captors and systems of measurement and analysis, users would listen to bearings with a stethoscope and would see vibration with a corner placed on the edge. For the corner to remain horizontal, and supposing an harmonic variation, it is required that $mA\omega^2 > mg$, or $A\omega^2 > g$ or $v > g/\omega$ where m = coin mass; A = displacement amplitude; ω = displacement; g = acceleration by gravity = 9.81 m s^{-2} ; v = amplitude of displacement speed. Where $\omega = 314 \text{ rad s}^{-1}$ ($\rightarrow 3000 \text{ rpm}$); $v > 31.2 \text{ mm s}^{-1}$ ($\rightarrow 99.36 \mu\text{m}$). Such a machine is not in good order. Today, in principle, it would be subject to maintenance, and in this case balancing.

Definitions

A rotating machine (Figure 1) is comprised of:

- A rotor, whether its structure has symmetrical axes or not, in rotation around a rotation line; it may be

formed by a shaft and added elements, such as disks, bladed disks, and cables

- A nonrotating structure comprising a stator, which also forms the envelope, bearings, whether connected or not to the stator; the stator contains elements connected to parts of the rotor, such as bladed diaphragms, diffusers, rectifiers, cables, sealing systems
- Links arranged between bearings, to insure guidance of the rotor in relation to the stator; the links use fluid, which is often oil, ball bearings and rollers, or a magnetic field; sealing systems can give rise to forces which place them in the sphere of links

A rotating machine is arranged on a receiving structure:

- connected to earth
- connected to a moving engine for transport, robotics, connected to manual use

The characteristics of the receiving structure and the elements placed between the structure and the rotating machine – the interfaces – can have a great influence on vibratory performance and on that of the supplier before use.

The Rotating Line

On the rotor radial section (Figure 2) the geometric center C is defined by the barycenter of the section profile. The arrangement of points C defines the rotation line (Figure 3) around which the rotor elements turn; the rotation line is in motion: each point describes a precession path; the rotation line is a result of flexural deformation; when the rotation line results from rotor forces, forces caused by unbalance, run outs, peaks, coaxiality faults, and performance is linear, the path is elliptical, even

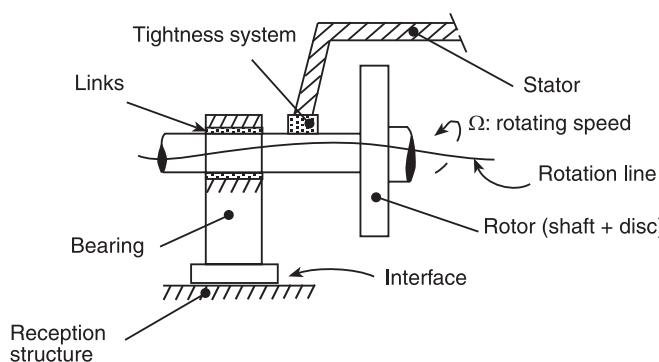

Figure 1 Rotating machine.

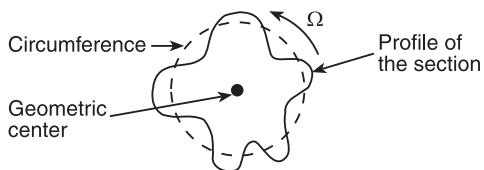

Figure 2 Radial section of a rotor.

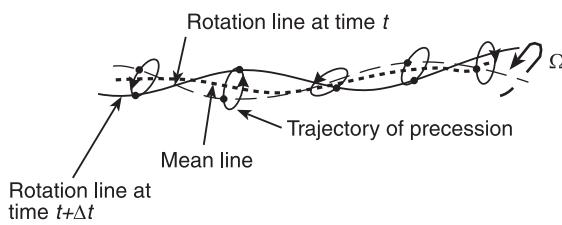

Figure 3 Rotation line.

circumferences or right-angles. On these ellipses the displacement direction of the point C may be that of speed Ω (direct precession) or inverse (inverse precession); on a rotation line the direction may be different, on either side on a rectilinear path; the direction may vary with rotation speed. When the path is not elliptical, their harmonic components are ellipses covered in the direction Ω , whether direct or inverse.

When the rotation speed is zero, the rotor is vertical, outside the force field, free, the rotation line is perpendicular; its axis is ideal for manufacturing. Such a model is classically used in theoretical studies.

The average line is fixed for a constant static condition; it is sensitive to radial forces which are

not connected to speed Ω , such as the force of gravity. In a normal situation the rotation line is a result of unbalance torsion, shown in Figure 4; vectors CG rotate around C. Run outs are neglected (see **Bearing vibrations**). Analysis of the form of the rotation line, of the average line, and the path dimensions is one of the bases of diagnostics which makes it possible to appreciate normal or abnormal conditions of rotating machinery.

Rotor elements may vibrate around the rotation line, around vectors parallel to its axis; the rotor is then in a state of torsion, which is very characteristic of piston machines, such as petrol motors, oil motors, and compressors.

Links and Couplings

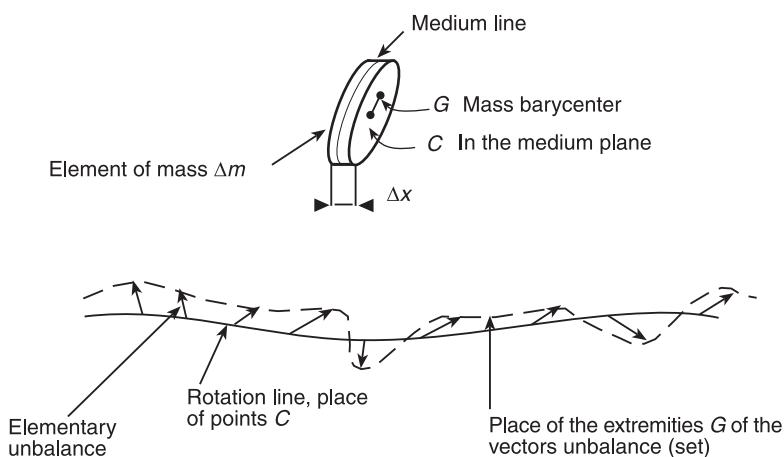

In principle, the number of links may not be less than two, in principle. In this case the static forces perpendicular to each of the two links, resulting from outside forces, are easy to determine by a classical mechanical theorem:

The sum of forces = 0

The sum of moments = 0

The rotor is in an isostatic state. When the number of links is greater than two, determining static forces perpendicular to the links involves taking into account global stiffness resulting from stiffness of the links and the receiving structure; this stiffness may be difficult to recognize. The rotor is in a hyperstatic condition.

When the rotor comprises several elements, for example, a turbine rotor and a compressor rotor, it

Figure 4 Elementary unbalance, $b = \Delta mCG$ and unbalance ensemble.

is possible to arrange each rotor isolated in an isostatic state, then to couple them rigidly without restraint using rigid couplings.

What is the result of forces when, for example, displacement modifies the position relative to bearings, leading to malalignment? The average rotation line is modified (see **Rotor stator interactions**).

During rotation the situation is more complex, since impedance resulting from stiffness and damping may be uncertain and variable. Such situations may lead to deterioration in the turbine caused by the compressor and, conversely, the delicate and dangerous passage of critical speed or onset of instability, defined in the article on the dynamics of rotating machinery (see **Rotor dynamics**), which may be difficult to manage when there are different manufacturers for different elements of the machine. Various types of coupling may be used, whether rigid or flexible (see **Balancing**). For rotors on ball bearings or rolling bearings, flexible couplings are useful when significant misalignment is possible in use.

ROTATING MACHINERY, MODAL CHARACTERISTICS

doi: 10.1006/rwvb.2001.0101

Introduction and Definitions

Dynamic characteristics of a rotating machine in planes perpendicular to the line of rotation are the result of forces, moments, and deformations caused

by excitation and its components (masses, stiffness, damping) and this is expressed by modal characteristics:

- Complex eigenvalues (natural frequencies)
- Natural modes associated with natural frequencies

Natural frequencies define the temporal behavior of free responses. Natural modes describe the spatial distribution of displacements, angles, and forces. Together with excitation, forced response is expressed by a sum of modal components.

Formulations

These formulas result from the Newton-d'Alembert principle and the critical moment theorem, expressed by linear relations which make up theoretical models.

Second-order Formulation

This formulation is explained in the article on dynamics of rotating machinery (see **Rotor dynamics**). A formulation is said to be second-order if first and second derivatives of the component vector \mathbf{u} are present. This formulation makes it possible to derive frequencies and natural modes, as does the study of forced response from matrix \mathbf{S} . It is appropriate for structures represented by symmetrical matrices. Matrices of rotating machinery, expressing gyroscopic couples, links, and sealing systems (see **Bearing vibrations**) may be asymmetric. It is then better to adapt a first-order formulation.

First-order Formulation

Dowson Duncan introduced the first-order formulation around 1960. This formulation uses second-order formulation matrices:

$$\mathbf{A}\dot{\mathbf{w}} + \mathbf{B}\mathbf{w} = \mathbf{Q} \quad [1]$$

where:

$$\begin{aligned} \mathbf{A} &= \begin{bmatrix} \mathbf{O} & \mathbf{M} \\ \mathbf{M} & \mathbf{A}_v \end{bmatrix} & \mathbf{B} &= \begin{bmatrix} -\mathbf{M} & \mathbf{O} \\ \mathbf{O} & \mathbf{K}_d \end{bmatrix} \\ \mathbf{w} &= \begin{bmatrix} \dot{\mathbf{u}} \\ \mathbf{u} \end{bmatrix} & \mathbf{Q}^T &= [\mathbf{O}^T \mathbf{S}^T] \end{aligned}$$

$$\mathbf{u}^T = \{ \dots y_l \psi_l z_l \theta_l \dots f_{yp} f_{zp} \dots \}^T$$

where T is the transposition; y_l, z_l are components of displacement from the geometric centre C_l of element l ; ψ_l, θ_l are components of rotation around C_l of element l , f_{yp}, f_{zp} are components of forces at right-angles to section p and to links, and to sealing systems and between the elements. \mathbf{M} is the mass matrix. $\mathbf{A}_v = \mathbf{A}_e + \mathbf{A}_i + \mathbf{G}$, where \mathbf{A}_e is the external damping matrix; \mathbf{A}_i is the internal damping matrix; \mathbf{G} is the gyroscopic effects matrix. $\mathbf{K}_d = \mathbf{K} + \mathbf{K}_i$ where \mathbf{K} is the rigidity matrix and \mathbf{K}_i is the rigidity matrix due to internal damping.

The matrix \mathbf{S} makes it possible to express forces of unbalance, moments caused by warp, forces caused by initial spurs, forces caused by coaxiality faults, harmonic forces, and spectral components of periodic forces.

Eqn [1] leads to:

$$\mathbf{M}\ddot{\mathbf{u}} - \mathbf{M}\dot{\mathbf{u}} = \mathbf{0} \quad [2]$$

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{A}_v\dot{\mathbf{u}} + \mathbf{K}_d\mathbf{u} = \mathbf{S} \quad [3]$$

Eqn [2] is always satisfied. Eqn [3] is presented in the article on the dynamics of rotating machinery (see **Rotor dynamics**). Eqn [1] is said to be self-attached to eqn [3].

Example: De Laval Model

Introducing components f_y and f_z of the forces which are at right-angles to the links, eqn [1] from the chapter on the dynamics of rotating machinery (see **Rotor dynamics**) is written as follows:

$$\begin{bmatrix} m & 0 & 0 & 0 & 0 & 0 \\ 0 & m & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \ddot{y}_c \\ \ddot{z}_c \\ \ddot{y}_i \\ \ddot{z}_i \\ \ddot{f}_y \\ \ddot{f}_z \end{bmatrix}$$

$$+ \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2f_{yy} & 2f_{yz} & 0 & 0 \\ 0 & 0 & 2f_{zy} & 2f_{zz} & 0 & 0 \end{bmatrix} \begin{bmatrix} \dot{y}_c \\ \dot{z}_c \\ \dot{y}_1 \\ \dot{z}_1 \\ \dot{f}_y \\ \dot{f}_z \end{bmatrix} \quad [4]$$

$$+ \begin{bmatrix} k_a & 0 & -k_a & 0 & 0 & 0 \\ 0 & k_a & 0 & -k_a & 0 & 0 \\ k_a & 0 & -k_a & 0 & 1 & 0 \\ 0 & k_a & 0 & -k_a & 0 & 1 \\ 0 & 0 & 2k_{yy} & 2k_{yz} & -1 & 0 \\ 0 & 0 & 2k_{zy} & 2k_{zz} & 0 & -1 \end{bmatrix} \begin{bmatrix} y_c \\ z_c \\ y_1 \\ z_1 \\ f_y \\ f_z \end{bmatrix}$$

$$= me\Omega^2 \mathfrak{R} \begin{bmatrix} \exp i\Omega t \\ -i \exp i\Omega t \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

Forces can be introduced in another way:

$$\begin{bmatrix} m & 0 & 0 & 0 & 0 & 0 \\ 0 & m & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \ddot{y}_c \\ \ddot{z}_c \\ \ddot{y}_1 \\ \ddot{z}_1 \\ \ddot{f}_y \\ \ddot{f}_z \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 & 0 & | & 0 & 0 \\ 0 & 0 & 0 & 0 & | & 0 & 0 \\ 0 & 0 & -2f_{yy} & -2f_{yz} & | & 0 & 0 \\ 0 & 0 & -2f_{zy} & -2f_{yy} & | & 0 & 0 \\ 0 & 0 & 0 & 0 & | & -2f_{yy} & -2f_{yz} \\ 0 & 0 & 0 & 0 & | & -2f_{zy} & -2f_{yy} \end{bmatrix} \mathbf{R}_f^{-1} \mathbf{R}_f \begin{bmatrix} \dot{y}_c \\ \dot{z}_c \\ \dot{y}_1 \\ \dot{z}_1 \\ \dot{f}_y \\ \dot{f}_z \end{bmatrix}$$

$$+ \begin{bmatrix} k_a & 0 & -k_a & 0 & | & 0 & 0 \\ 0 & k_a & 0 & -k_a & | & 0 & 0 \\ -k_a & 0 & k_a - 2k_{yy} & -2k_{yz} & | & 0 & 0 \\ 0 & -k_a & -2k_{zy}k_a & -2k_{zz} & | & 0 & 0 \\ -k_a & 0 & 0 & 0 & | & k_a - 2k_{yy} & -2k_{yz} \\ 0 & -k_a & 0 & 0 & | & -2k_{zy} & k_a - 2k_{zz} \end{bmatrix} \mathbf{R}_k^{-1} \mathbf{R}_k = me\Omega^2 \Re \begin{bmatrix} y_c \\ z_c \\ y_1 \\ z_1 \\ y_1 \\ z_1 \end{bmatrix}$$

[5]

where:

$$\mathbf{R}_f = \begin{bmatrix} I & | & 0 \\ - & - & - & - & - & - \\ 0 & | & 2f_{yy} & 2f_{yz} \\ - & - & - & - & - & - \\ 0 & | & 2f_{zy} & 2f_{zz} \end{bmatrix},$$

$$\mathbf{R}_k = \begin{bmatrix} I & | & 0 \\ - & - & - & - & - & - \\ 0 & | & 2k_{yy} & 2k_{yz} \\ - & - & - & - & - & - \\ 0 & | & 2k_{zy} & 2k_{zz} \end{bmatrix}$$

and \Re = operator of the real part.

The product of \mathbf{R}_f and \mathbf{R}_k by $[y_1 \ z_1]^T$ leads to $[\mathbf{f}_y \ \mathbf{f}_z]e^T$. These forces can also be calculated using the impedance matrix of links and $[y_1 \ z_1]^T$, $[y_1 \ z_1]^T$ determined by eqn [4] without $[\mathbf{f}_y \ \mathbf{f}_z]^T$. The form of eqns [4] and [5] is identical to that of eqn [3]. It can be shown in the form of eqn [1].

Natural Frequencies

Where $\mathbf{Q} = \mathbf{O}$ and $\mathbf{u} = \mathbf{U} \exp pt$ eqn [1] leads to:

$$\mathbf{A} \begin{bmatrix} p^2 \mathbf{U} \\ p \mathbf{U} \end{bmatrix} + \mathbf{B} \begin{bmatrix} p \mathbf{U} \\ \mathbf{U} \end{bmatrix} = \mathbf{O}$$

[6]

$$[\mathbf{M}p^2 + \mathbf{A}_v p + \mathbf{K}_d] \mathbf{U} = \mathbf{O}$$

Complex eigenvalues:

$$p_l = \delta_l + i\omega_l$$

where $l = 1, 2, 3 \dots$ and $i^2 = -1$ are the roots of the determinant of:

$$\mathbf{M}p^2 + \mathbf{A}_v p + \mathbf{K}_d$$

Thus:

$$\det[\mathbf{A}p + \mathbf{B}] = 0 \quad [7]$$

A complex eigenvalue $p_l^* = \delta_l - i\omega_l$ is always associated with p_l . For stability, $\delta_l < 0$.

Natural Modes

Natural Right and Left Modes

Right modes (associated with right eigenvectors) \mathbf{W}_l^d associated with p_l are defined by:

$$[p_l \mathbf{A} + \mathbf{B}] \mathbf{W}_l^d = \mathbf{O} \quad [8]$$

Natural left modes \mathbf{W}_l^g associated with p_l are defined by:

$$\mathbf{W}_l^{gT} [p_l \mathbf{A} + \mathbf{B}] = \mathbf{O}^T \quad [9]$$

so that:

$$[p_l \mathbf{A}^T + \mathbf{B}^T] \mathbf{W}_l^g = \mathbf{O}$$

Left modes are the right eigenvalues of a fictitious or virtual model, associated to the actual model and represented by matrices \mathbf{A}^T and \mathbf{B}^T . As the second members of eqns [8] and [9] are zero, when calculating \mathbf{W}_l^d and \mathbf{W}_l^g it is necessary to normalize.

When $\mathbf{M}^T = \mathbf{M}$, $\mathbf{A}_v^T = \mathbf{A}_v$, $\mathbf{K}_d^T = \mathbf{K}_d$; i.e., when the matrices \mathbf{M} , \mathbf{A}_v , and \mathbf{K}_d are symmetrical, natural left eigenvectors are the same as the natural right eigenvectors.

Example: De Laval Model

Excluding forces and canceling the second member, eqn [4] leads to:

$$\begin{aligned} & \begin{bmatrix} m & 0 & 0 & 0 \\ 0 & m & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \ddot{y}_c \\ \ddot{z}_c \\ \ddot{y}_i \\ \ddot{z}_i \end{bmatrix} \\ & + \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -2f_{yy} & -2f_{yz} \\ 0 & 0 & -2f_{zy} & -2f_{zz} \end{bmatrix} \begin{bmatrix} \dot{y}_c \\ \dot{z}_c \\ \dot{y}_i \\ \dot{z}_i \end{bmatrix} \\ & + \begin{bmatrix} k_a & 0 & -k_a & 0 \\ 0 & k_a & 0 & -k_a \\ -k_a & 0 & k_a - 2k_{yy} & -2k_{yz} \\ 0 & -k_a & -2k_{zy}k_a & -2k_{zz} \end{bmatrix} \begin{bmatrix} y_c \\ z_c \\ y_i \\ z_i \end{bmatrix} = \mathbf{O} \end{aligned} \quad [10]$$

If $f_{yz} = f_{zy}$ and $k_{yz} = k_{zy}$, matrices \mathbf{A}_v and \mathbf{K}_d are symmetrical, natural right eigenvectors are the same as those on the left. Symmetry is maintained when a different column-type of matrix is adopted, for example: $\{\mathbf{y}_c \mathbf{y}_1 \mathbf{z}_1 \mathbf{z}_c\}^T$. In general, nonsymmetries are due to impedance of the links and gyroscopic effects.

Free Responses

Initial Conditions

Free responses are defined by initial values, at time $t = 0$, components of \mathbf{u} and its speed $\dot{\mathbf{u}}$, which is connected to frequencies and natural modes by eqn [6]. The components of the natural modes are

affected by the characteristics of the machine (mass, stiffness, and damping).

Example

$$\begin{aligned} u_1 &= u_{11} \exp p_1 t + u_{11}^* \exp \bar{p}_1 t \\ &+ u_{12} \exp p_2 t + u_{12}^* \exp \bar{p}_2 t \\ u_2 &= u_{21} \exp p_1 t + u_{21}^* \exp \bar{p}_1 t \\ &+ u_{22} \exp p_2 t + u_{22}^* \exp \bar{p}_2 t \end{aligned} \quad [11]$$

For $t = 0$:

$$\begin{bmatrix} u_{10} \\ u_{20} \\ \dot{u}_{10} \\ \dot{u}_{20} \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ p_1 & p_1^* & p_2 & p_2^* \\ 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} u_{11} \\ u_{11}^* \\ u_{12} \\ u_{12}^* \end{bmatrix} \quad [12]$$

$$+ \begin{bmatrix} 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ p_1 & p_1^* & p_2 & p_2^* \end{bmatrix} \begin{bmatrix} u_{21} \\ u_{21}^* \\ u_{22} \\ u_{22}^* \end{bmatrix}$$

Relationships between natural modes are expressed by:

$$\begin{bmatrix} u_{21} \\ u_{21}^* \\ u_{22} \\ u_{22}^* \end{bmatrix} = \begin{bmatrix} \mathbf{M}_1 & | & \mathbf{O} \\ \mathbf{O} & | & \mathbf{M}_2 \end{bmatrix} \begin{bmatrix} u_{11} \\ u_{11}^* \\ u_{12} \\ u_{12}^* \end{bmatrix} \quad [13]$$

Using eqns [11] and [12]:

$$\begin{bmatrix} u_{10} \\ u_{20} \\ \dot{u}_{10} \\ \dot{u}_{20} \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ p_1 & p_1^* & p_2 & p_2^* \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad [14]$$

$$+ \begin{bmatrix} 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ p_1 & p_1^* & p_2 & p_2^* \end{bmatrix} \begin{bmatrix} \mathbf{M}_1 & \mathbf{O} \\ \mathbf{O} & \mathbf{M}_2 \end{bmatrix} \begin{bmatrix} u_{11} \\ u_{11}^* \\ u_{12} \\ u_{12}^* \end{bmatrix}$$

Once u_{10} , u_{20} , \dot{u}_{10} and \dot{u}_{20} have been imposed, eqn [14] makes it possible to calculate $[u_{11} u_{11}^* u_{12} u_{12}^*]^T$ and eqn [13] enables the calculation of $[u_{21} u_{21}^* u_{22} u_{22}^*]^T$.

In order for response to be carried out on $p_1 = \delta_1 + i\omega_1$, it is necessary for $U_{12} = u_{12}^* = u_{22} = u_{22}^* = 0$.

So then, according to eqn [14]:

$$\begin{bmatrix} u_{10} \\ u_{20} \\ \dot{u}_{10} \\ \dot{u}_{20} \end{bmatrix} = \mathbf{T}\mathbf{I} \begin{bmatrix} u_{11} \\ u_{11}^* \\ 0 \\ 0 \end{bmatrix}$$

and thus:

$$\begin{aligned} \begin{bmatrix} u_{10} \\ u_{20} \end{bmatrix} &= \mathbf{T}\mathbf{I}_1 \begin{bmatrix} u_{11} \\ u_{11}^* \end{bmatrix} \\ \begin{bmatrix} \dot{u}_{10} \\ \dot{u}_{20} \end{bmatrix} &= \mathbf{T}\mathbf{I}_2 \begin{bmatrix} u_{11} \\ u_{11}^* \end{bmatrix} \\ \begin{bmatrix} \dot{u}_{10} \\ \dot{u}_{20} \end{bmatrix} &= \mathbf{T}\mathbf{I}_2[\mathbf{T}\mathbf{I}_1]^{-1} \begin{bmatrix} u_{10} \\ u_{20} \end{bmatrix} \end{aligned} \quad [15]$$

thus:

Eqn [15] shows that relations must exist between displacement and critical speed for response on p_1 . Relations of the same force exist in order for free response on p_2 .

When u_1 and u_2 represent displacement from the center of a rotor vortex, in a plane perpendicular to the rotation line, this center can describe a spiral in the sense of rotation Ω of the rotor (direct precession) or inversely, according to initial conditions.

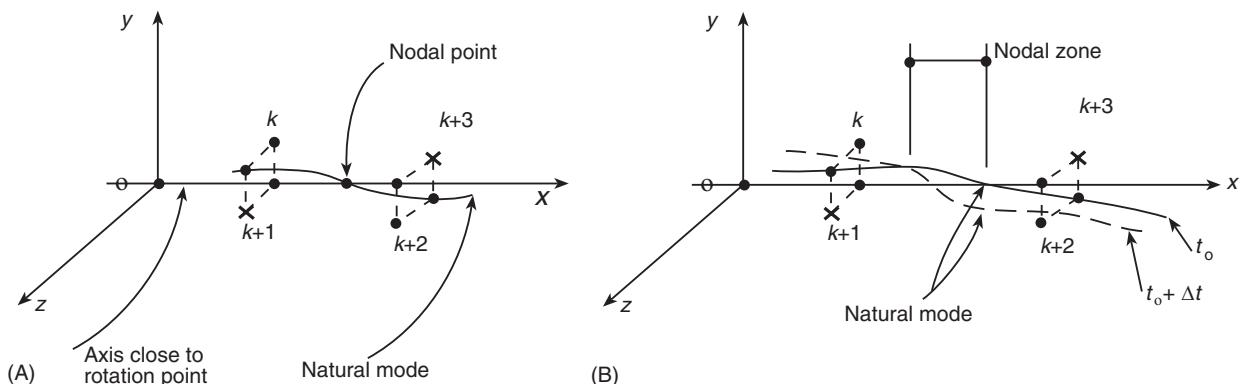

Figure 1 (A) Nodal point; (B) nodal zone.

$$U_k = A_k \sin \omega_l t$$

$$U_{k+1} = A_{k+1} \sin \omega_l t$$

$$U_{k+2} = A_{k+2} \sin (\omega_l t + \pi)$$

$$U_{k+3} = A_{k+3} \sin (\omega_l t + \pi)$$

$$U_k = A_k \exp \delta_l t \sin \omega_l t$$

$$U_{k+1} = A_{k+1} \exp \delta_l t \sin (\omega_l t + \vartheta_{k+1})$$

$$U_{k+2} = A_{k+2} \exp \delta_l t \sin (\omega_l t + \vartheta_{k+2})$$

$$U_{k+3} = A_{k+3} \exp \delta_l t \sin (\omega_l t + \vartheta_{k+3})$$

Nodal Points and Zones

In certain planes the amplitude of natural modes may be zero. When $\mathbf{A}_v = [0]$, displacement components from the geometric centers of the sections of a rotor perpendicular to the rotation line, at frequency ω_l , when initial conditions suitable are:

$$u_k = A_k \sin(\omega_l t + \varepsilon\pi)$$

where $l = 1, 2 \dots$ and $\varepsilon = \begin{cases} 0 \\ 1 \end{cases}$ and A_k depends on l .

Figure 1A shows a point of zero amplitude: a nodal point; components are canceled out simultaneously. This situation exists when $\mathbf{A}_v = a\mathbf{M} + b\mathbf{K}_d$, where a and b are constants. When $\mathbf{A}_v \neq 0$, around certain planes, a nodal zone may exist. Figure 1B shows components which do not cancel each other out simultaneously. The number of points, zones, and nodal zones increases with l .

Sensors which make it possible to measure rotor vibrations used for monitoring, protection, and diagnostics should not be installed near nodal zones which may move with rotation speed, and on which pulsations and natural modes depend.

Biorthogonality

General Relations

Natural frequencies, p , and their associated natural modes, \mathbf{W}_0^g and \mathbf{W}_0^d , enable to define relationships of biorthogonality:

$$\mathbf{W}_s^{gT} \mathbf{A} \mathbf{W}_l^d = \alpha_{sl} \delta_{sl} \quad [16]$$

$$\mathbf{W}_s^{gT} \mathbf{B} \mathbf{W}_l^d = -\alpha_{sl} p_l \delta_{sl} \quad [17]$$

where α_{sl} = a constant linked to the standard; δ_{sl} , the Kronecker symbol = 1 if $s = l$; $\delta_{sl} = 0$ if $s \neq l$.

Eqns [16] and [17] allow us to define p_l :

$$p_l = \frac{\mathbf{W}_s^{gT} \mathbf{B} \mathbf{W}_l^d}{\mathbf{W}_s^{gT} \mathbf{A} \mathbf{W}_l^d}$$

This expression permits us to verify the value of p_l , which is obtained using the determinant [7].

Biorthogonality can be expressed by the second-order formulation:

$$\mathbf{u}_s^{gT} [\mathbf{M}(p_s + p_l) + \mathbf{A}_v] \mathbf{u}_l^d = \alpha_{sl} \delta_{sl} \quad [18]$$

$$\mathbf{u}_s^{gT} [\mathbf{M}p_s p_l - \mathbf{K}_d] \mathbf{u}_l^d = \alpha_{sl} p_l \delta_{sl} \quad [19]$$

Biorthogonality for $\mathbf{A}_v = a\mathbf{M} + b\mathbf{K}_d$

Eqns [18] and [19] become:

$$\mathbf{u}_s^{gT} \mathbf{M} \mathbf{u}_l^d = \alpha_{sl} \frac{1 + bp_l}{a + bp_l^2 + 2p_l} \delta_{sl} \quad [20]$$

$$\mathbf{u}_s^{gT} \mathbf{K}_d \mathbf{u}_l^d = -\alpha_{sl} \frac{p_l^2 + ap_l}{a + bp_l^2 + 2p_l} \delta_{sl} \quad [21]$$

The biorthogonality can be expressed by \mathbf{A}_v .

Kinetic Energy and Biorthogonality

When $\mathbf{A}_v = 0$ and the rotation line is an axis (Figure 2), limiting the description to the plane Oxy , eqn [18] leads to:

$$[y_G + \theta l_1; \theta; \dots; y_G + \theta l_i; \dots]_l$$

$$\times \begin{bmatrix} m_1 & 0 & \dots \\ 0 & J_1 & & \\ & \ddots & \ddots & \\ & & m_i & \\ & & & J_i \\ & & & & \ddots \end{bmatrix} \begin{bmatrix} y_G & + & \theta l_1 \\ \theta & & \\ y_G & + & \theta l_i \\ \vdots & & \ddots \end{bmatrix}_l = \frac{\alpha_{ll}}{2p_l}$$

$$2\varepsilon_c = my_G^2 + J\theta^2 = \frac{\alpha_{ll}}{2p_l}$$

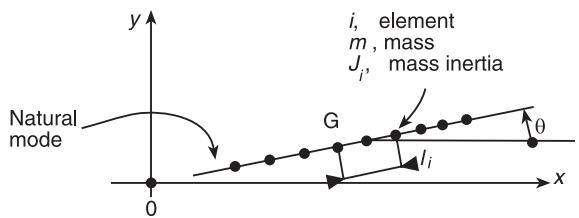

Figure 2 Rigid rotor: G , mass center of gravity.

where m is the rotor mass; J is the mass rotor inertia with relation to G ; G is the mass center of gravity; ε_c is the critical energy.

For a symmetrical rotor guided by two identical links, the first natural frequency ω_1 leads to:

$$\frac{m}{2} (y_G \omega_1)^2 = \frac{\alpha_{11} \omega_1}{4i}$$

where $i^2 = -1$.

The second natural frequency ω_2 leads to:

$$\frac{J}{2} (\theta \omega_2)^2 = \frac{\alpha_{22} \omega_2}{4i}$$

These relations show that the coefficient $\alpha_{..}$ is connected to the norms of y_G and θ .

Diagonalization

Eqns [16] and [17] lead to:

$$\mathbf{G}^T \mathbf{A} \mathbf{D} = \boldsymbol{\alpha}_{ll} \quad [22]$$

$$\mathbf{G}^T \mathbf{B} \mathbf{D} = -\boldsymbol{\alpha}_{ll} \mathbf{p}_l \quad [23]$$

where $\boldsymbol{\alpha}_{ll}$ and $\boldsymbol{\alpha}_{ll} \mathbf{p}_l$ are diagonal matrices.

$\mathbf{G} = [\mathbf{W}_1^g \dots \mathbf{W}_l^g \dots]$ is a modal matrix of natural left eigenvalues.

$\mathbf{D} = [\mathbf{W}_1^d \dots \mathbf{W}_l^d \dots]$ is a modal matrix of natural right eigenvalues.

Diagonalization of the matrices \mathbf{A} and \mathbf{B} is possible regardless of \mathbf{M} , \mathbf{A}_v , and \mathbf{K}_d , which in general cannot be directly diagonalized in the same way.

Forced Responses

Base Relation

Laplace transformations, denoted as L , applied to eqn [1] lead to:

$$[\mathbf{sA} + \mathbf{B}]L\mathbf{w} = L\mathbf{Q}$$

$$L\mathbf{w} = [\mathbf{sA} + \mathbf{B}]^{-1}L\mathbf{Q}$$

The transfer function $[\mathbf{sA} + \mathbf{B}]^{-1}$ is defined by:

$$[\mathbf{sA} + \mathbf{B}]^{-1} = \mathbf{D} \left[\frac{1}{\alpha_{ll}(s - p_l)} \right] \mathbf{G}^T$$

where $[1/\alpha_{ll}(s - p_l)]$ is a diagonal matrix.

When excitatory elements of \mathbf{Q} are in harmony with the frequency Ω which is equal to rotation speed, $s = i\Omega$:

$$\mathbf{W} = \mathbf{D} \left[\frac{1}{\alpha_{ll}(i\Omega - p_l)} \right] \mathbf{G}^T \mathbf{Q} \quad [24]$$

where:

$$\mathbf{W} = \sum_l \frac{\mathbf{W}_l^d}{\alpha_{ll}(i\Omega - p_l)} \mathbf{W}_l^{gT} \mathbf{Q}$$

This fundamental relation, once transposed, shows that excitatory elements are counterbalanced by the modal matrix of the left-hand modes.

Example

For a rotor which is affected by unbalance and an initial deflexion, defined in the article on the dynamics of rotating machinery (see **Rotor dynamics**):

$$\begin{aligned} \mathbf{Q}^T = & \{ \dots 0 \dots m\epsilon\Omega^2 + k_0 f_0 \exp i\theta_f, -i m\epsilon\Omega^2 \\ & -ik_a f_0 \exp i\theta_f, -k_a f_0 \exp i\theta_f, ik_a f_0 \exp i\theta_f, \dots 0 \}^T \end{aligned} \quad [25]$$

The complex number U_k , associated with displacement u_k ($u_k = |U_k| \cos(\Omega t + \varphi_k)$ where φ_k is an argument for U_k) of the geometric center of a radial section k of the rotor, is defined by eqns [24] and [25]:

$$\begin{aligned} U_k = & \sum_l \frac{U_{kl}^d}{\alpha_{ll}(i\Omega - p_l)} \\ & \times [U_{ql}(m\epsilon\Omega^2 + k_a f_0 \exp i\theta_f) \\ & + U_{(q+1)l}^g(-i m\epsilon\Omega^2 - ik_a f_0 \exp i\theta_p) \\ & + U_{(q+2)l}^g(-k_a f_0 \exp i\theta_f) \\ & + U_{(q+3)l}^g(ik_a f_0 \exp i\theta_f)] \end{aligned} \quad [26]$$

where U_{kl}^d = component of the natural right eigenvector of section k , associated to natural frequency p_l and U_{0l}^g = component of the natural left eigenvector of section 0, linked to natural frequency p_l . The term

between square brackets represents modal excitation. It contains all the excitatory terms of the rotor (unbalance, initial deflexion) considered here. Components referred to as q and $q + 1$, and $q + 2$ and $q + 3$ are in the same radial plane.

Modal Excitation

In a general way, U_{0l}^d , U_{0l}^g , and p_l and therefore α_{ll} depend on rotation speed Ω , and in particular on the gyroscopic effects and impedance of the links and sealing systems.

Modal excitation comprises terms formed by components from the left modes (see **Rotor dynamics**):

$$\begin{aligned} & [U_{.l}^g - iU_{(.+1)l}^g][(me) \cdot \exp i\Psi \cdot \Omega^2] && \text{Unbalance} \\ & [U_{xl}^g - iU_{(x+1)l}^g][(\alpha f_0)_x \exp i\theta_x] && \text{Initial spur} \\ & [U_{0l}^g - iU_{(0+1)l}^g] \\ & \times \left[\frac{mR^2}{4} \sqrt{V_y^2 + V_z^2} \exp i(\Psi_v + \pi) \right] \Omega^2 && \text{Thin disk} \end{aligned}$$

where m is the mass, R is the radius, and V_y and V_z are angles of shadow.

Modal excitation also includes terms comprising components of left modes conjugated as follows:

$$\left. \begin{aligned} & \bar{U}_{.l}^g(me) \cdot \exp i\Psi \cdot \Omega^2 \\ & -i\bar{U}_{(l+1)l}^g(me) \cdot \exp i\Psi \cdot \Omega^2 \end{aligned} \right\} \quad \text{Unbalance}$$

Other terms may be taken into account to express unbalance of the axis.

Critical Speed

Speed at which $|U_k|$ is maximal is the critical speed. It depends on k ; that is, the point and direction of observation and measurement.

Reduction to Two Terms

In certain conditions, in eqn [26] the number of sum terms can be reduced. Where there is unbalance (*me*) and $\delta_l \ll \omega_l$; $\omega_{l-1} \ll \omega_l \ll \omega_{l+1}$; $\omega_{l-1} \ll \Omega \ll \omega_{l+1}$; $\Omega \approx \omega_l$:

$$U_k \approx \left[\frac{U_{kl}^d (U_{ql}^g - iU_{(q+1)l}^g)}{\alpha_{ll}(i\Omega - \delta_l - i\omega_l)} + \frac{\bar{U}_{kl}^d (\bar{U}_{ql}^g - i\bar{U}_{(q+1)l}^g)}{\bar{\alpha}_{ll}(i\Omega - \delta_l + i\omega_l)} \right] m\epsilon\Omega^2 \quad [27]$$

For a De Laval motor (see **Rotor dynamics**) guided by links with high levels of impedance:

$$U_{(k+1)l}^g = 0 \quad (g \rightarrow k)$$

Where $U_{kl}^d = 1$, $U_{kl}^g = -i/2m\omega$, eqn [27] leads to:

$$U_k \approx \frac{me\Omega^2}{m(-\Omega^2 - 2i\Omega\delta + \omega^2 + \delta^2)} \quad [28]$$

Direct study of a De Laval rotor (of mass m , damping coefficient c , and stiffness k) leads to:

$$\begin{aligned} U &= \frac{me\Omega^2}{-m\Omega^2 + ic\Omega + k} = \frac{e\Omega^2}{-\Omega^2 - 2i\Omega\delta + \omega^2 + \delta^2} \\ \delta \pm i\omega &= -c/2m \pm i\sqrt{k/m - c^2/4m^2} \end{aligned} \quad [29]$$

are natural frequencies.

U_k obtained by modal decomposition is closely related to U which is obtained by direct study. In a general way, each term of eqn [26] represents modal participation, whose denominator is the same as that of the transfer function of a De Laval rotor.

Representation of Left Modes

Natural left modes are mathematical entities. An approximate representation results from eqn [27] where $\Omega = \omega_l$. The second neglected term and $U_{ql}^g = U_{(q+1)l}^g$.

$$U_k \approx \frac{U_{kl}^d U_{ql}^g m e \Omega^2}{-\alpha_{ll} \delta_l}$$

U_k , measured for unbalance me successively disposed in planes, q , $q+2$, $q+4 \dots$ leads to:

$$\frac{U_{k(q+4)}}{U_{kq}} = \frac{U_{(q+4)l}^g}{U_{ql}^g} = \frac{U_{k(q+2)}}{U_{kq}} = \frac{U_{(q+2)l}^g}{U_{ql}^g}$$

The measured relations $U_{k..}/U_{kq}$ represent relationships of left modes.

Example: Left and Right Modes

A steam turbine rotor of horizontal mass 46 244 kg is guided by two identical oiled links 6960 mm apart. The mass barycenter is at equal distance from the links (Table 1).

Table 1 shows the ratio between natural left and right modes. The anisotropy of bearings with three lobes is not as marked as that of cylindrical bearings; the ratio A^d/A_0 are closer to 1 and the differences between the phases are smaller.

Sensitivity for Resetting

The modal characteristics of the theoretical model of rotating machinery may be compared to the modal characteristics of the physical machine it claims to represent, determined by a theoretical-experimental procedure of modal analysis. Differences can appear between the frequencies and natural modes. Updating or adjustment can make it possible to reduce these differences by modifying the numerical value of certain factors characterizing the theoretical model. Structure modifications may be applied taking into account the limits of the machine.

Table 1 Turbine rotor: natural right and left modes

Bearing ϕ 400 mm	Natural frequencies (rad s ⁻¹)		Distance between natural right and left modes			
			A^d/A_0 (amplitude at 1500 rpm); $\theta_d - \theta_g$ (phases: degrees)			
	1116 rpm	1500 rpm	Link 1		Link 2	
			A^d/A_0	$\theta_d - \theta_g$	A^d/A_0	$\theta_d - \theta_g$
Cylindrical	$-11.75 \pm i107.7$	$-5.56 \pm i105.3$	0.98	11	0.99	11
clearance 0.2%	$-2.06 \pm i117.8$	$-2.38 \pm i115.6$	2.32	38	2.05	54
Three lobes	$-4.37 \pm i111.4$	$-1.89 \pm i109.8$	0.94	13	0.92	13
clearance 0.2%	$-1.37 \pm i119$	$-1.48 \pm i119.5$	1	8	0.91	15
Coefficient of precharge 0.5						

There are several possible methods, such as using the sensitivity coefficients S_{pq}

$$\begin{bmatrix} \Delta G_1 \\ \vdots \\ \Delta G_p \\ \vdots \end{bmatrix}$$

$$= \begin{bmatrix} S_{11} & \cdots & & \\ \vdots & & & \\ & S_{pq} & \cdots & \\ \vdots & & & \end{bmatrix} \begin{bmatrix} \Delta \lambda_1 \\ \vdots \\ \Delta \lambda_q \\ \vdots \end{bmatrix} \rightarrow \Delta \mathbf{G} = \mathbf{S} \Delta \boldsymbol{\lambda}$$

The matrix \mathbf{S} is linked to the sensitivity.

$\Delta G_p = G_{\text{measurement}} - G_{\text{model}}$ = modal size at $\Delta \lambda = \lambda_{\text{initial}} - \lambda_{\text{corrected}}$ = mass, stiffness, and damping of the theoretical model, and \mathbf{S} is used by an iterative procedure which must, if possible, lead to $\Delta G_p < \varepsilon_p$, where $p = 1, 2, \dots, n$. ε_p defines the model quality and it is important to fix this as a function of its application.

The sensitivity coefficient affected by natural frequency p_l is written as:

$$\frac{\delta p_l}{\delta \lambda} = \frac{-1}{\alpha_{ll}} \mathbf{W}_l^{gT} \left(p_l \frac{\delta \mathbf{A}}{\delta \lambda} + \frac{\delta \mathbf{B}}{\delta \lambda} \right) \mathbf{W}_l^d$$

λ may be the mass of an element of the theoretical model. If λ is stiffness, k_p , contained in \mathbf{B} :

$$\frac{\delta p_l}{\delta k_p} = \frac{-1}{\alpha_{ll}} \mathbf{W}_l^{gT} \frac{\delta \mathbf{B}}{\delta k_p} \mathbf{W}_l^d$$

The sensitivity coefficient affected by the natural right eigenvectors may be obtained by:

$$\frac{\delta \mathbf{W}_l^d}{\delta \lambda} = -[\mathbf{p}_l \mathbf{A} + \mathbf{B}]^{-1} \left[\frac{\delta p_l}{\delta \lambda} \mathbf{A} + p_l \frac{\delta \mathbf{A}}{\delta \lambda} + \frac{\delta \mathbf{B}}{\delta \lambda} \right]$$

$$\frac{\delta \mathbf{W}_l^d}{\delta \lambda} = \sum_j \beta_l \lambda_j \mathbf{W}_j^d$$

where:

$$\beta_l \lambda_j = \frac{\mathbf{W}_j^{gT} [\mathbf{A}] (\delta \mathbf{W}_l^d / \delta \lambda)}{\alpha_{ll}}$$

or:

$$\beta_l \lambda_j = \frac{p_l \mathbf{W}_j^g (\delta \mathbf{A} / \delta \lambda) \mathbf{W}_l^d + \mathbf{W}_l^{gT} (\delta \mathbf{B} / \delta \lambda) \mathbf{W}_l^d}{\alpha_{ll} (p_j - p_l)}$$

The sensitivity coefficient affected by the left natural modes can be obtained using these formulae, defined here for the right mode, by substituting g for d :

\mathbf{A}^T to \mathbf{A} and \mathbf{B}^T to \mathbf{B}

ROTATING MACHINERY, MONITORING

R Bigret, Drancy, France,

doi:10.1006/rwvb.2001.0096

Introduction

When rotating machinery is inoperative, this affects its associated systems and industrial complexes. In 1985, the Electric Power Research Institute estimated that 40% of stoppages at fossil-fuel stations in North America were due to rotating machinery problems, and in France the loss due to disruptions in 900-MW turboalternators was equivalent to the energy produced by a 750-MW machine. A study carried out in 1987 by the Centre Technique des Industries Mécaniques in France showed the following causes of machine failure:

1. steam turbines: rotors 50%
2. turbocompressors: rotors 30%; bearings and thrusts 26%
3. centrifugal pumps: sealing systems 44%; bearings and thrusts 24%
4. gas turbines: rotors 16%

Monitoring and protecting rotating machinery will help reduce downtime.

Monitoring, Protection, Diagnostics, and Maintenance

The noise and vibrations made by rotating machinery give a good indication of its mechanical state. Together with measurements of overall condition – temperature, pressure, flow, intensity – the indicators-features which can be drawn from an assessment of vibration will reveal degradation before there is complete failure.

Two types of feature are used:

1. Global, represented by levels within a large frequency band for monitoring and protection
2. Specific, in general within a diagnostic frequency domain

Specific features are required for diagnostics, when the value of the global features goes beyond the range fixed by the person setting the standard. The limits of this range may depend on the general condition of the machinery and knowledge acquired during operation.

It may be useful to know exact quantitative values of global features even when these are obviously below the limits.

Diagnostics may lead to a maintenance operation which will reduce deterioration and prevent breakdown, catastrophe, and physical injury. Carrying out maintenance means that maximum machine availability insures maximum profit such as guaranteeing electric supply to a site and enhance reputation an important aspect in marketing and business. Machine availability is defined by the relationship between time available and time required, with numerous slight variations.

Maintenance is set out in Figure 1, and this cannot establish the economy of cost (direct, indirect (materials, salary, charges)) because of the uncertainty of a breakdown. The profitability of an arrangement is insured if the cost system divided by variation in the cost of unavailability is less than one.

Abnormal Situations

Feature values may go beyond the acceptable range in abnormal situations. Examples are:

- Instability
- Critical speed, when vibrations are outside the limits
- Blades being lost or destroyed
- Jammed alternator rotor bars
- Misalignments between links (bearings, rolling bearings, sealing system), each of a particular type; loss of balance caused by rotation, stator slipping, thermal anisotropy
- Coaxiality faults caused by coupling and thermal effects (slippage)
- Violent variations in the degree and phase of vibration caused, for example, by relative displacements of the elements of a rotor, or a missile release
- Friction between rotor and stator
- Friction perpendicular to the sealing systems of turbomachines and alternators
- Shocks to the rotor caused by brief rotor-stator interaction
- Problems of lubrication in the coupled elements
- Cracks in the rotor
- Loosening of rotor and stator elements
- Random variations in vibration amplitude and phase as a result of the presence of a moving foreign body in the stator

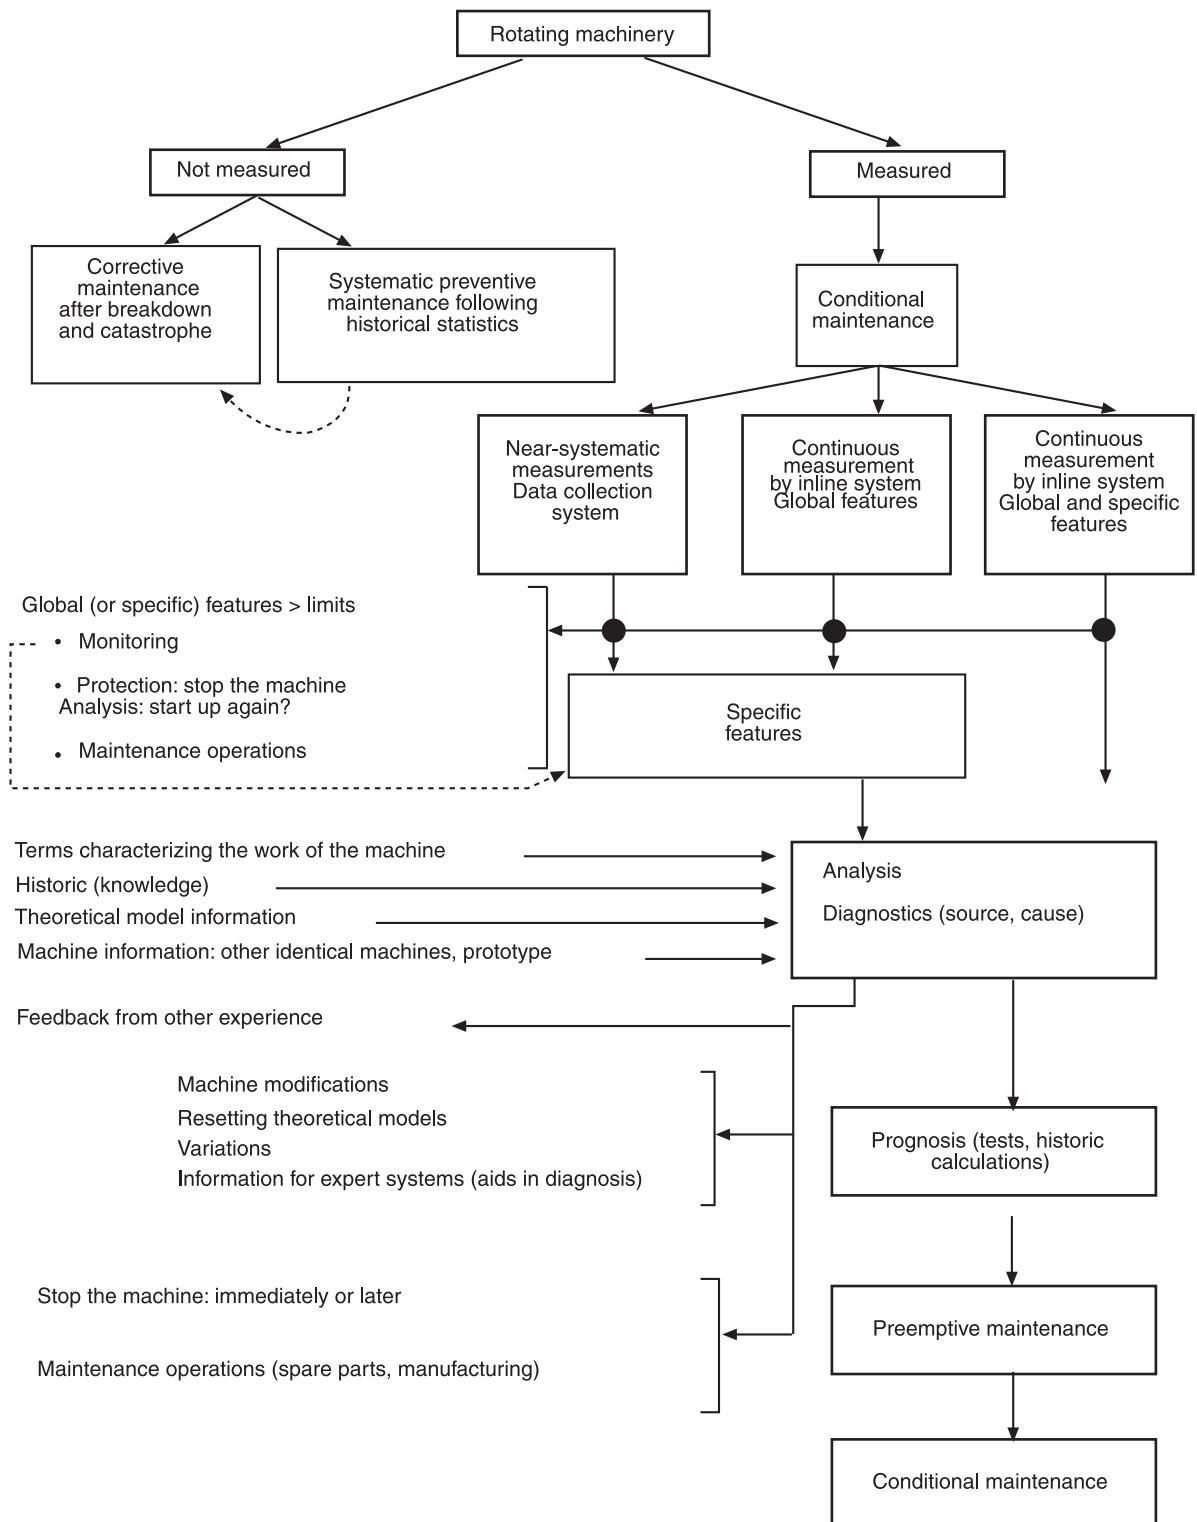

Figure 1 Maintenance.

- Blockage of ventilation circuit (alternator engine)
- Deterioration in the links, caused by fluid, bearings, magnetic field
- Deterioration in the gears
- Raised temperature in the bearings
- Unsteady torsion
- Specific states due to coupling, and deformation in the rotors

- Cavitation in the pumps
- Instability in the compressors (pumps)
- Deterioration of valves in alternating machines and variation in position of cycle phases
- Short circuits between rotor peaks in electric machines
- Electric shocks through the links generated by electrostatics resulting in pitting
- Measuring system errors

Analysis and diagnostics set in motion by abnormal situations require definitive knowledge of the technological management and maintenance policy. Theoretical models form part of this knowledge.

Measuring and Sensors

Classically, vibrations are measured using sensors which are perpendicular to the rotating elements.

- Magnetic sensors measure relative vibrations of the rotor and nonrotating structure
- Acceleration sensors measure absolute vibration of the nonrotating structure

Figure 2 shows a normal setup (see **Balancing**). Typical essential features of magnetic sensors are as follows:

- Measuring range: 0.15–2.15 to 0.9–12.9 mm
- Passband: 0–5000 Hz; 0–10 000 Hz
- Temperature range: –40°C to 220°C

The first natural frequency of the setup sensor-support-cable assembly must be more than four times the maximum frequency of interest. The sensor also measures the run-out which must be deducted from the measured value (see **Balancing**). The appropriate standard is International Standardization Organization (ISO) 7919.

Typical essential features of accelerometers are:

- With piezoelectric transducers: $5 < f < 2000$ Hz; $-200^\circ\text{C} < T < 650^\circ\text{C}$
- With piezoresistive transducers: $0.2 < f < 1000$ Hz; $-40^\circ\text{C} < T < 90^\circ\text{C}$

Different arrangements make it possible to reduce the minimum frequency and signal noise on displacement (μm) resulting from double integration of a signal. The first natural frequency of an accelerometer fixed on the structure must be four times greater than the maximum frequency of interest. Velocimeters may be used. The sensor C_r (Figure 2) which senses the passage of the indicator enables one to measure speed and phase difference between frequency components.

The standard ISO 10817.1 System for measuring vibrations of rotating shafts, part 1, transducers of relative and absolute signals of radial vibrations, is applied here.

The system shown in (Figure 2) makes it possible to make the following measurements of global vibrations: relative, and absolute for blade and rotor, in each direction, Δ and Δ' . The combination of vibrations using Δ and Δ' leads to a precession path

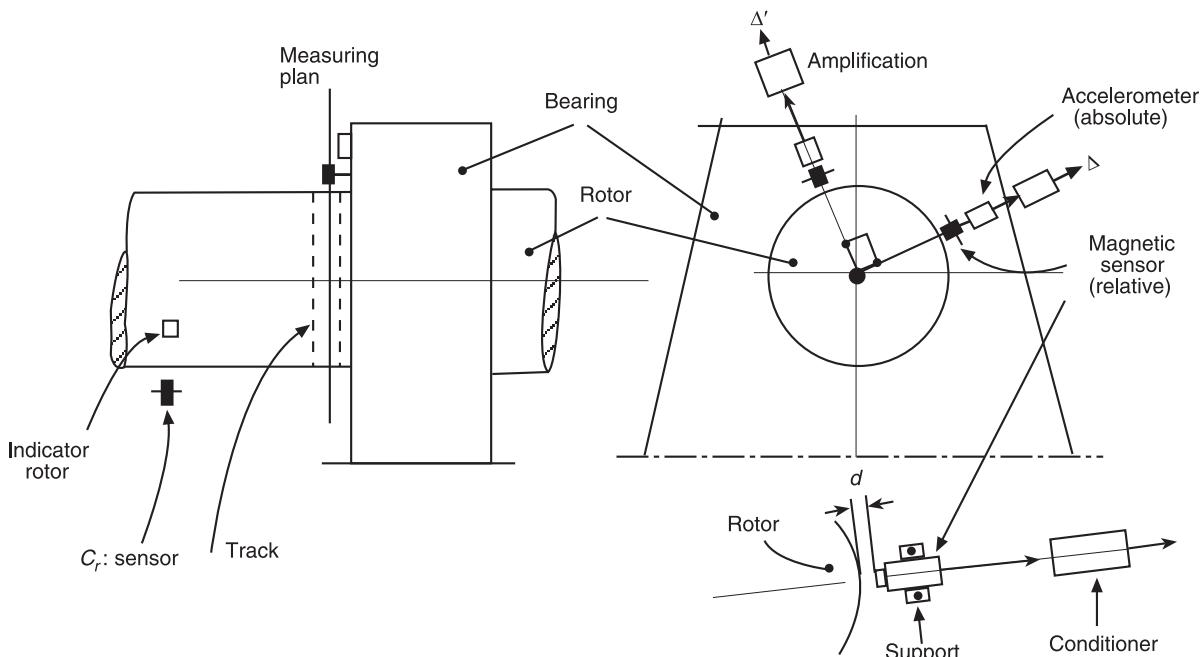

Figure 2 Normal layout of a sensor.

(Figure 3) called the orbit, which is relative when vibrations are relative, and absolute when rotor vibrations are absolute.

When frequency spectra contain only one component at frequency f the path is a conical ellipse, described at frequency f (for balancing $f = \Omega/2\pi$, where Ω = rotation speed). S_A (peak-to-peak) and S_B (peak-to-peak) depend on the direction of Δ and Δ' ; S_{\max} and S_{\max} (peak-to-peak) do not depend on this factor.

Absolute bearing vibrations are generally expressed by effective values in mm s^{-1} in one direction. Temperature measured for example with thermocouples, gives additional information. Vibration in the direction of the rotor axis may also be taken into account.

Limits

Limits are set by the manufacturers, who may be inspired by the standards established by the ISO and American Petroleum Institute (API), and these limits may be modified by the machine operator. For steam turbines and turbocompressors, the API limit (S_A (peak-to-peak) or S_B (peak-to-peak)) is defined by:

$$25.4\sqrt{12\,000/N(\text{rpm})}(\mu\text{m})$$

where $25.4\mu\text{m}$ is the peak-to-peak relative vibration for $N = 12\,000$ rpm.

In ISO standard 7919/1 (Mechanical vibrations of nonalternating machines: measurements on rotating shafts and evaluation criteria, part 1: general directives) defines four zones (Figure 4):

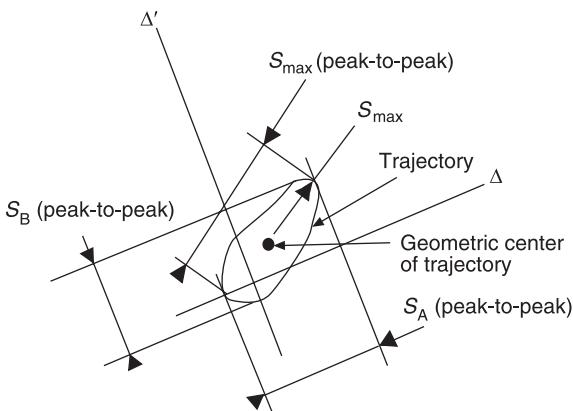

Figure 3 Precession path S measured in μm .

- Zone A: for machines which have recently been serviced (formula criterion)
- Zone B: normal operation
- Zone C: cannot be used for long periods (alarms go off, analytical investigations need to be made)
- Zone D: possible deterioration (possible shut down; need for protection)

Standards 7919/2-5 define the zone limits for different machine types. According to 7919/3 for industrial machines coupled at 12 000 rpm, S_{\max} (peak-to-peak) = $43.8\mu\text{m}$ as the limit of zone A for a suitable frequency band. This limit is often defined in accordance to the specific machines attached.

According to ISO7919/1, variations in levels around established values must be taken into account; standard 7919 defines the permitted range: ± 0.25 as the limit of zone B. Vibration levels may diminish when the unbalance caused by missile release is counteracted by initial unbalance.

Standard ISO 10816/1 (Mechanical vibrations: evaluation of machine vibration by measurement of nonrotating blades: part 1, general directives) defines four zones A-D for effective global levels, expressed as mm s^{-1} ; the limits of the zones, which are constant between frequency f_x and $f_y > f_x$, can be reduced for $f < f_x$ and $f > f_y$: f is related to rotation speed.

Standard 10816/2-5 defines the limits of the zones for different machine types. According to 10816/3, for industrial machines of nominal power greater than 15 kW and nominal speed between 120 and 15 000 rpm measured *in situ* on rigid support (natural frequency of the machine-support $> 1.25f_{ex}$, where $f_{ex} = f$ general rotation), the limit of zone A is equal to 2.3 mm s^{-1} RMS in a region of 10 and 1000 Hz at

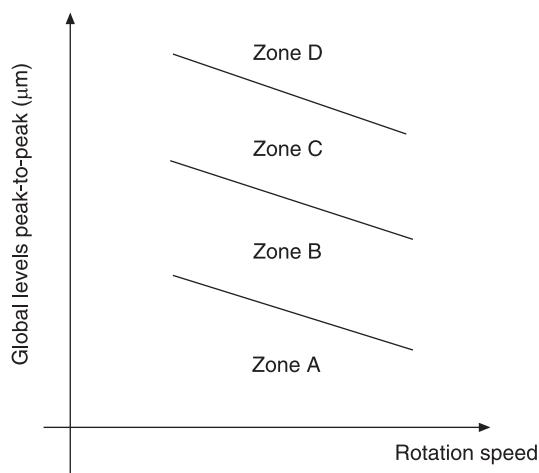

Figure 4 Zones according to ISO 7919/1. For global levels, see Figure 3.

speeds faster than 600 rpm. As with 7919/0, the variation in level is taken into account: ± 0.25 of the limit of zone B.

Only the standard 7919/5 (hydraulic turbine) uses S_{\max} and S_{peak} (peak-to-peak) (see Figure 3) within the limits defined by 7919/0 and 10816/0 for permanent normal rates of flow. For 7919/2 (turboalternators on a radial base), an amendment published in 1998, proposes taking into account variations in flow rate at constant rotation speed (limit approaching that of zone C) and critical speed (limit approaching 1.5 times the limit of zone C). Not well defined frequencies and technological setups permit exchanges between client/user and constructor/insurer so that they can determine the limits written in the specification agreement, and revise them under certain conditions.

Standards

- ISO 11342 Methods and criteria for mechanical balancing of flexible rotors (being revised)
- ISO 10814 Machine susceptibility and sensitivity to unbalance: Normal machine speed may be close to critical speed if damping is important

Online and Data Collecting Systems

Monitoring, protection, and diagnostics (Figure 1) can be carried out by:

- Online systems permanently connected to sensors: signals are analyzed continuously, in real time or soon after their occurrence
- Data collectors used by operators on a weekly basis: this permits immediate assessment of features and signal storage for later analysis

The two methods are comparable with regard to cause of malfunctions.

Examples of Abnormal Situations

Instability

Rotor instability may happen suddenly, in permanent or transient flow, as a result of increased rotation speed, or it may be a gradual progression. It is characterized by greater amplitude of the precession paths at frequencies which are often less than the rotation frequency.

- A permanent data-collecting system may make it possible to recognize the limit cycle by measuring the frequency. However, if a protective mechanism insures that the limit cycle automatically shuts the machine down, no information will be obtained.
- An online system receiving continuous signals (average values) and alternating signals from free-standing magnetic sensors, link fluid temperature, and other machine variables (speed, pressure, temperature, voltage) can, in both permanent and transient flow, determine the moment when the instability appeared and show average position of the rotor-stator and other variables at that precise point, to give a good diagnosis.

If the cycle limit automatically shuts the machine down because of the monitoring and protection system which is in place, such system will equally provide a great deal of information.

Variations in unbalance

Variation in unbalance is linked to an increase or decrease in vibration amplitude. Increases may cause deterioration, notably in the regions of critical speeds:

- A data-collecting system which is permanently in operation may show global variations in amplitude

as well as in amplitude component and phases. However, if a protective mechanism insures that the cycle limit automatically shuts the machine down, no information will be gained.

- An online system makes it possible to assess how vibrations have changed over time and, in particular, to detect significant changes which generally correspond to failure of rings and blades. Such a system also facilitates recognition of changes in misalignment. When an online system is in operation permanently, once the rotation speed has markedly slowed down, relative rotor movement variation in relation to the links permits the detection of coaxiality faults. When operated temporarily, recording while the machine is slowing down, when amplitude is measured, the risk of rotor-stator contact is evaluated. If the cycle limit automatically shuts the machine down because of the monitoring and protection system which is in place, this system will equally provide a great deal of information.

Faults of Ball Bearings

Uncertainty about the ball bearing lifespan may be an important factor, particularly if there is also uncertainty about the rotating forces. There are a number of software packages which provide features. Generally, ball bearings will initially deteriorate slowly, but as their condition worsens, they are quickly destroyed.

Using a data-collecting system which provides signals measured in conjunction with appropriate software, it is possible to follow the features with measurements made periodically every month or week. A suitable interval to stop and replace the parts can be established.

In this case, after measuring at time t_m , it is premature to stop the machine as long as the bearing permits it. If the machine is not stopped at time t_k , it may break down before the next measurement at time t_{k+1} , but this becomes less likely with the decrease in time between the two measurements. Availability can increase but at a higher cost of operation.

Using an online system, features are checked periodically. The frequency of checking may be small, large or even every minute. Service is then optimal and the history of deterioration is known.

Rotor Cracks

Under the effect of static and dynamic strain, a flaw will grow until it cracks apart completely. A crack causes a variety of amplitudes and phase

differences of the harmonic components of vibration. The rate of change is larger, and detection of crack possible.

Vibration monitoring may be done permanently or temporarily, once the machine has slowed down.

A permanently operating online or data-collecting system using particular software makes it possible to detect the appearance of a crack. Only an online system which is able to pick up vibrations when the machine slows down can provide effective descriptors on the state of any cracks.

Coaxiality Faults

Due to the effect of a thermal spatial gradient or relative element displacements, the average rotor rotation line may move away from the normal reference line. This movement, which represents a coaxiality fault, gives rise to rotating forces which must not be confused with rotating forces from other sources, in particular as a result of unbalance.

This displacement can be assessed when rotation speed is slow, such as when the machine is started up or stopped. An online system measuring average signal values measured by sensors of relative rotor-stator displacement may make it possible to recognize misalignments. A data-collecting system is not suitable for this purpose.

Transient State of Operations

- Measuring during transient state permits to improve monitoring and protection, in particular at critical speed. Analysis of recorded signals facilitates better diagnostics and provides additional information to update theoretical models.
- Measurement in transitory state often allows satisfactory balancing (see **Balancing**).
- The article on the essential features of rotating machinery (see **Rotating machinery, essential features**) covers acquisition in transitory state. As shown, we can calculate the influence on the amplitude and phases at critical speed of damping levels ξ and of:

$$\left| \frac{d\Omega}{dt} \right| \frac{1}{\omega_0^2} = \gamma \quad [1]$$

where $d\Omega/dt = \alpha$ = acceleration and deceleration, and ω_0 = natural radial frequency.

For large γ , the relation between the amplitude at critical speed in both permanent and transitory regimes is weak: ≈ 0.5 for $\gamma = 10^{-2}$. This property

is sometimes used to avoid contact between rotor and stator.

- The article on balancing (see **Balancing**) discusses the acquisition of fundamental components. Systems, which are generally digital, carry out the simultaneous acquisition of signals in increments of speed $\Delta\Omega$ ($\Delta\Omega \leq \Delta\Omega_{cr}/6$). The time T_a between two acquisitions may be utilized, and this enables the system to calculate features (discrete Fourier transformations), to transfer them, and to store them.

If it is accepted that $|\mathrm{d}\Omega/\mathrm{d}t|$ must be small in order that machine vibration may approximate the vibrations in steady state. Then errors of amplitude and component phase at rotation Ω are:

$$\varepsilon_A(\%) = 29.3 \frac{|\mathrm{d}\Omega/\mathrm{d}t|}{\Delta\Omega_{cr}/T_a} \quad [2]$$

$$\begin{aligned} Q_{3dB} &= 1/2\xi = \frac{\Omega_{cr}}{\Delta\Omega_{cr}} \\ \Delta\phi(^{\circ}) &= 57.5 \frac{|\mathrm{d}\Omega/\mathrm{d}t|}{\Delta\Omega_{cr}/T_a} \end{aligned} \quad [3]$$

The number of measurements between $\Omega_{cr} - \Delta\Omega_{cr}/2$ and $\Omega_{cr} + \Delta\Omega_{cr}/2$ is equal to $(57.5/\Delta\phi) + 1$.

Eqns [2] and [3] relate $|\mathrm{d}\Omega/\mathrm{d}t|$ and $\Delta\Omega_{cr}/T_a$ which are expressions of pressure gradients. If $|\mathrm{d}\Omega/\mathrm{d}t| = 0.1$, $\Delta\Omega_{cr}/T_a = 0.1 \times (80 \text{ rpm}/0.2 \text{ s}) = 40 \text{ rpm s}^{-1}$ from 4000 rpm to 0 in 100 s, $\varepsilon_A = 2.9\%$, and $\Delta\phi = 5.75^{\circ}$. The number of measurements equals 11.

When $\omega_0 = 314 \text{ rad s}^{-1} \approx \Omega_{cr}$ (3000 rpm), $|\mathrm{d}\Omega/\mathrm{d}t|/\omega_0^2 = 4.2 \times 10^{-5}$, let $|\mathrm{d}\Omega/\mathrm{d}t| = 4.14$, with $\xi \geq 0.02$ ($Q_{3dB} \leq 50$), the transitory machine state is close to steady state. When $\omega_0 = \Omega_{cr}$, eqns [1]–[3] lead to:

$$\varepsilon_A = 14.65 \frac{\gamma T_a \xi}{\Omega_{cr}}$$

$$\Delta\phi = 28.75 \frac{\gamma T_a \phi}{\Omega_{cr}}$$

where $T_a = \max(T_{a\varepsilon}, T_{a\phi}) > T_a$ the limit of the acquisition system. $|\mathrm{d}\Omega/\mathrm{d}t| \leq \gamma\Omega_{cr}^2$: γ is a function of ξ , and also the ratio of amplitude and phase shift between transitory and steady state region.

Eqns [1]–[4] address the component whose frequency is equal to rotation speed. *A priori*, Ω_{cr} and

ξ can be affected by significant uncertainties; the procedure leading to $|\mathrm{d}\Omega/\mathrm{d}t|$ must be initialized by tests (preferably at reduced or increased speed) at different values of $|\mathrm{d}\Omega/\mathrm{d}t|$ and minimum T_a . These tests enable to discover the best conditions in which to acquire all the components of the spectrum which are contained in the frequency range of interest and which are necessary for monitoring, protection, and diagnostics. The discrete signals are acquired simultaneously, either in free running or synchronous mode. The noise (runout) associated with magnetic sensor signals must be subtracted from the equation.

doi: 10.1006/rwvb.2001.0091

Introduction

Rotating machinery was defined in the article **Rotating machinery, essential features**. The study of the dynamic performance of rotating machinery, which is essentially vibratory, is the subject of this article. We will follow a simple mathematical model, based on De Laval's study of the rotor.

De Laval (1845–1913) was Swedish. In 1895 Föppl used a model to demonstrate the possibility of a rotation speed which was faster than natural frequency. In 1919 Jeffcot, who was Irish, published an interesting study of a simple model which aroused the interest of other researchers.

These studies shed light on the behavior which had been observed, while mathematics enabled to quantify the phenomena.

Before reading this article, we recommend that the reader refers to the principles of vibratory mechanics which are discussed in other chapters.

From Observation to Models

In 1883 Carl Gustav De Laval's centrifuge passed a critical flexion speed to reach 30 000 rpm: in 1924–25 Newkirk, who was English, encountered a strange phenomenon, which he called oil whip.

A description of the performance of a simple machine, which is the physical model of a whole class of simple machines, provides further information. The simple machine is shown in Figure 1; the disk vibrations, perpendicular to the line of rotation, are measured and analyzed by a single magnetic

sensor. Figures 2 and 3 show the amplitude and frequency of the component parts:

- Maximum amplitude is at 9000 rpm close to natural frequency of the stationary rotor placed on rigid supports: 8760 cycle min⁻¹
- When the speed is increased, the frequency suddenly changes from 200 to 106 Hz and the amplitude increases: hysteresis is noted when speed is reduced

Theoretical models enable us to relate these behaviors (critical speed $N = 9000$ rpm, instability at $N \geq 12\,000$ rpm) to the characteristics of the rotor and its links.

Theoretical mathematical models help in diagnostics. They must be complemented by physical information so that adjustments can be made if necessary. Models are the building blocks from which we can create:

- A clarification of the relations between hypotheses and performance
- A review of the hypotheses
- Ideas for the analysis and investigation of complex systems
- Personal communication

De Laval's model

Formulation

In 1686–87 Newton defined the law of inertia. D'Alembert formulated it as $\vec{F} = \vec{m}\vec{v}$ in 1743. Figure 4 shows De Laval's model of a rotor directed by two links. The equations of movement arise from the combined principle of Newton–d'Alembert. This can be simply expressed as a fixed Galilean referential, taking into account the isotropy of the shaft (the inflexibility which is independent of the azimuth):

$$\left. \begin{aligned} m \frac{d^2 y_c}{dt^2} + k_a(y_c - y_1) &= me\Omega^2 \cos \Omega t = me\Omega^2 \operatorname{Re}(\exp i\Omega t) \\ m \frac{d^2 z_c}{dt^2} + k_a(z_c - z_1) &= me\Omega^2 \sin \Omega t = me\Omega^2 \operatorname{Re}(-i \exp i\Omega t) \\ 2k_{yy}y_1 + 2k_{yz}z_1 + 2f_{yy} \frac{dy_1}{dt} + 2f_{yz} \frac{dz_1}{dt} + k_a(y_c - y_1) &= 0 \\ 2k_{zy}y_1 + 2k_{zz}z_1 + 2f_{zy} \frac{dy_1}{dt} + 2f_{zz} \frac{dz_1}{dt} + k_a(z_c - z_1) &= 0 \end{aligned} \right\} [1]$$

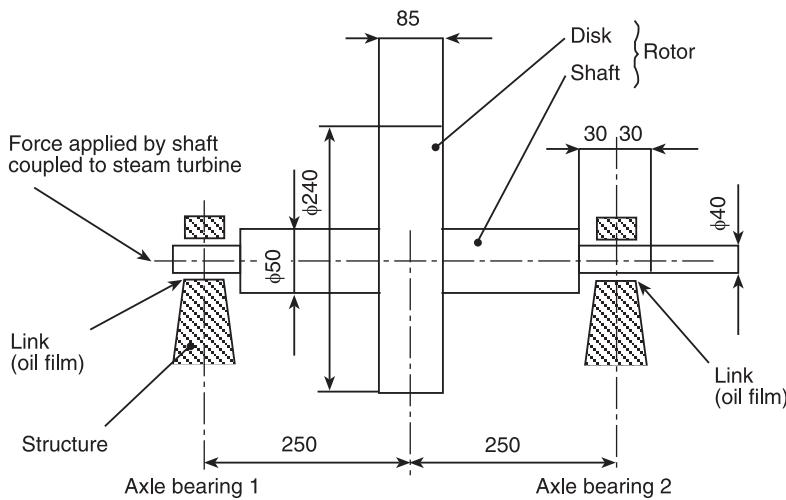

Figure 1 Arrangement of rotor, links, and structure. Connections: circular bearings; diametric clearance: $0.06\mu\text{m}$; oil viscosity: 12 CP_o at 60°C .

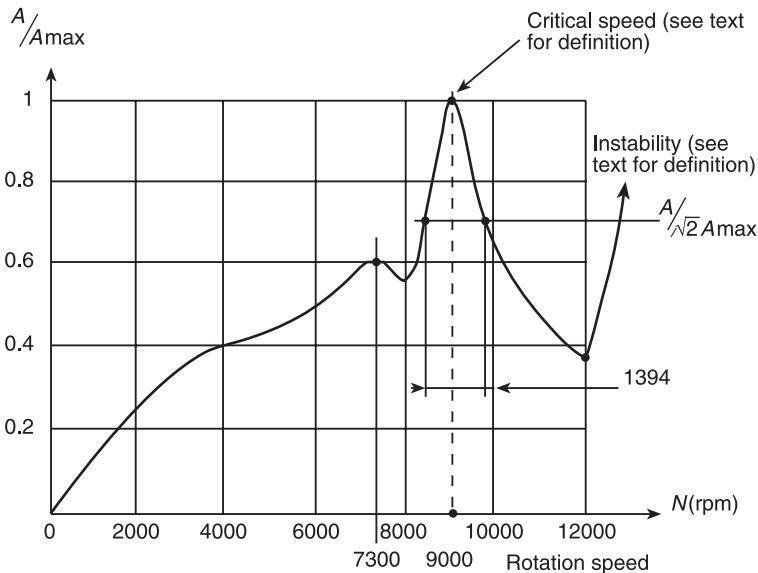

Figure 2 Amplitude of vibration displacement at right-angles to the disk as a function of rotation speed in a vertical direction. Amplification factor: $Q_{3dB} = 9000/1394 = 6.45$; $\xi = 0.775$.

where Re is the real part and $i^2 = -1$.

More generally, the components of centrifugal force due to \bar{CG} , within the referential whose notation is C_{YRZR} are $me\Omega^2 \cos \theta_e$ and $me\Omega^2 \sin \theta_e$. This is

expressed by the transformation formula $0yz$, as: $me\Omega^2 \cos (\Omega t + \theta_e)$ and $me\Omega^2 \sin (\Omega t + \theta_e)$.

When the shaft stiffnesses depend on the anisotropic azimuth, the shaft is represented by an impedance matrix which is expressed in the Galilean referential as:

$$\begin{bmatrix} f_y \\ f_z \end{bmatrix} = \begin{bmatrix} k'_y \cos^2(\Omega t) + k'_z \sin^2(\Omega t) + \sin(\Omega t) \cos(\Omega t) (k'_{yz} + k'_{zy}) \sin(\Omega t) \cos(\Omega t) (k'_z - k'_y) - \sin^2(\Omega t) k'_{yz} + \cos^2(\Omega t) k'_{yz} \\ \sin(\Omega t) \cos(\Omega t) (k'_z - k'_y) - \sin^2(\Omega t) k'_{yz} + \cos^2(\Omega t) k'_{yz} k'_y \sin^2(\Omega t) + k'_z \cos^2(\Omega t) - \sin(\Omega t) \cos(\Omega t) (k'_{yz} + k'_{zy}) \end{bmatrix} = \begin{bmatrix} d_y \\ d_z \end{bmatrix}$$

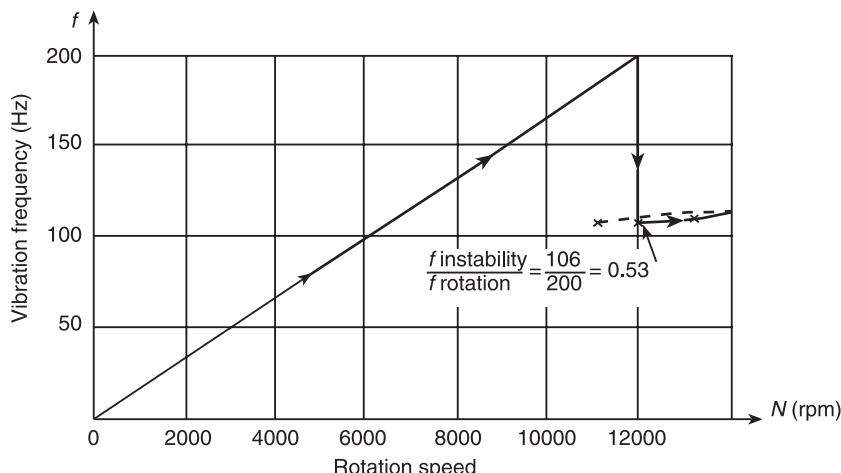

Figure 3 Fundamental vibration frequency as a function of rotation speed.

Section through the disk

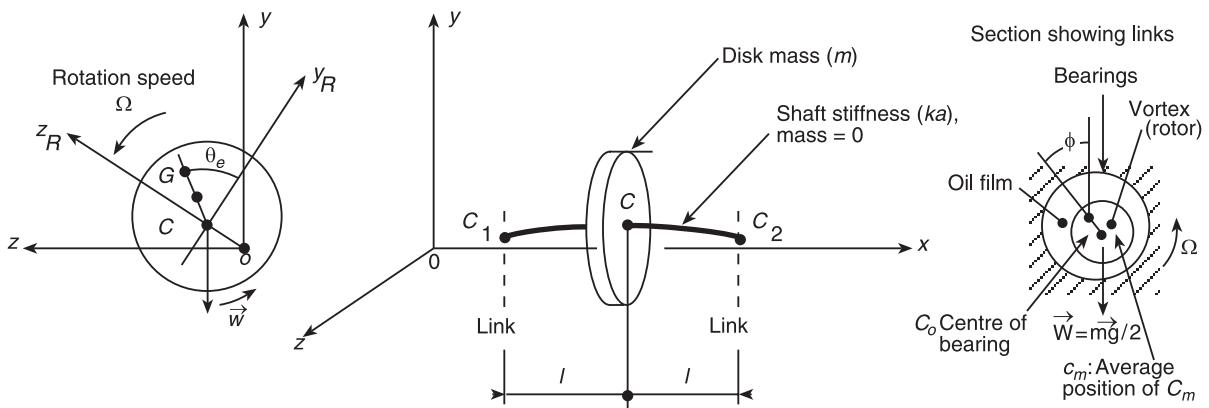

Figure 4 De Laval rotor. Model of right-angle disk. G , Mass of barycenter; C , geometric center (y_c, z_c); \overrightarrow{CG} , eccentricity; $|\overrightarrow{CG}| = e$; $m\overrightarrow{CG}$ = unbalance. Identical links: oil bearings, center of vortex $C_1, C_2(y_1, z_1)$. \overrightarrow{g} = acceleration of gravity; $|\overrightarrow{g}| = g$.

where k'_y and k'_z are the shaft stiffness associated with the deformations d_y and d_z perpendicular to the disk, in the planes $C_{xR}y_R$ and $C_{xR}z_R$, k'_{yz} and k'_{zy} are coupling stiffness, and f_y and f_z are components of the force applied to the disk ($f_y/2, f_z/2$ perpendicular to the links).

Harmonic terms can be introduced as $2\Omega t$. They are due to nonlinearities revealing anisotropy, such as fissures, which a diagnostic method must pick up.

The linear equations given above (eqn [1]) provide a theoretical model enabling us to describe the translation movements of C and C_1 and C_2 , which are identical, around the position of equilibrium due to gravity, which does not have an explicit effect. The vibrations of the shaft bearings are zero, and impedance is very high.

The links are characterized by a transfer matrix:

$$\begin{bmatrix} k_{yy} + sf_{yy} & k_{yz} + sf_{yz} \\ k_{zy} + sf_{zy} & k_{zz} + sf_{zz} \end{bmatrix} \quad [2]$$

where s is the Laplace operator, related to a frequency ω , $s = i\omega$ where $i^2 = -1$.

Referring to the transfer matrix shown in eqn [2], the impedance of displacement is called isomorphic and isochronic, where $s = i\omega$.

The stiffness, $k_{..}$, and damping coefficient, $f_{..}$, depend on the speed of rotation, Ω , and on the force \overline{W} (\overline{mg} , for example) in the direction $0y$, which determines $\overline{C_o C_m}$ (Figure 4) and on the shape of the bearings (see **Balancing**).

However, the connections between a rotor and non-rotating structure are not merely based on bearings and fluid. Sealing and magnetic systems are also contributory factors.

When cylindrical bearings of diameter $2R$, clearance to radius J , and length L are submitted to a static force W , fed by viscosity oil μ , the stiffness and damping coefficient, $|\overline{C_o C_m}| = d$ and angle ϕ (Figure 4) can be expressed by dimensionless values:

$$\begin{aligned}
 k_{..} \frac{J}{W} &= F_k \left(S, \frac{L}{2R} \right) = K_{..} \\
 f_{..} \frac{J\Omega}{W} &= F_f \left(S, \frac{L}{2R} \right) = F_{..} \\
 \frac{d}{J} &= F_d \left(S, \frac{L}{2R} \right) \\
 \phi &= F_\phi \left(S, \frac{L}{2R} \right)
 \end{aligned}
 \quad [3]$$

where

$$S = \frac{\mu\Omega RL}{\pi W} \left(\frac{R}{J} \right)^2$$

and d/J is the relative misaxiality, or eccentricity. The radial pressure on the bearings is equal to $W/2RL$, $K_{..}$ and $F_{..}$ vary with d/J .

Note that particular attention must be paid to the symbol conventions used in eqns [1] and [3].

Using the values defined in eqn [3], where $W = mg/2$, eqn [1] can be rewritten:

$$\begin{aligned}
 \frac{d^2y_{tr}}{d\tau^2} + y_{cr} - y_{1r} &= \left(\frac{\Omega}{\omega_0} \right)^2 \cos \left(\frac{\Omega}{\omega_0} \right) \tau \\
 &= \left(\frac{\Omega}{\omega_0} \right)^2 \operatorname{Re} \left[\exp i \left(\frac{\Omega}{\omega_0} \right) \tau \right] \\
 \frac{d^2z_{cr}}{d\tau^2} + z_{cr} - z_{1r} &= \left(\frac{\Omega}{\omega_0} \right)^2 \sin \left(\frac{\Omega}{\omega_0} \right) \tau \\
 &= \left(\frac{\Omega}{\omega_0} \right)^2 \operatorname{Re} \left[-i \exp i \left(\frac{\Omega}{\omega_0} \right) \tau \right]
 \end{aligned}
 \quad [4]$$

$$\begin{aligned}
 2 \left(k_{yy} \frac{J}{mg/2} \right) y_{1r} + 2 \left(k_{yz} \frac{J}{mg/2} \right) z_{1r} \\
 + 2 \left(f_{yy} \frac{J\Omega}{mg/2} \right) \frac{\omega_0}{\Omega} dy_{1r} + 2 \left(f_{yz} \frac{J\Omega}{mg/2} \right) \frac{\omega_0}{\Omega} dz_{1r} \\
 + H(y_{cr} - y_{1r}) = 0
 \end{aligned}$$

$$\begin{aligned}
 2 \left(k_{zy} \frac{J}{mg/2} \right) y_{1r} + 2 \left(k_{zz} \frac{J}{mg/2} \right) z_{1r} \\
 + 2 \left(f_{zy} \frac{J\Omega}{mg/2} \right) \frac{\omega_0}{\Omega} dy_{1r} + 2 \left(f_{zz} \frac{J\Omega}{mg/2} \right) \frac{\omega_0}{\Omega} dz_{1r} \\
 + H(z_{cr} - z_{1r}) = 0
 \end{aligned}$$

where $y_{..r} = y_{..}/e$; $z_{..r} = z_{..}/e$ (relative displacements) and $\omega_0^2 = k_a/m$; $\tau = \omega_0 t$; $H = J\omega_0^2/g$ where Hagg's number $J/\delta f$ and δf is the static rotor arrow on rigid supports with ball joints.

The terms given in brackets in the last two eqns [4] are defined in eqn [3]. Eqn [1] can be expressed by dimensionless values, taking $\Omega t = \tau$ and without introducing ω_0 .

Natural Frequencies and Stability

Natural frequencies are modal characteristics of the free response. If the right-hand side of the equation is zero, and the displacements are y_0 and z_0 , then the solution to eqn [4] takes the form:

$$\begin{aligned}
 y_c &= Y_c \exp p_r \tau & y_1 &= Y_1 \exp p_r \tau \\
 z_c &= Z_c \exp p_r \tau & z_1 &= Z_1 \exp p_r \tau
 \end{aligned}
 \quad [5]$$

Incorporating eqn [5] into eqn [4] generates four equations with solutions if the determinant of the unknown terms Y_c , Y_1 , Z_c , Z_1 is zero.

Development of the determinant leads to a sixth-degree equation, which relates to complex eigenvalues:

$$pr_l = \frac{\delta_l}{\omega_0} + i \frac{\omega_l}{\omega_0} \quad l = 1, 2, 3; \quad i^2 = -1$$

where δ_l is the growth factor (> 0) or attenuation factor (< 0), ω_l is damped natural frequency, and p_l is complex eigenvalue. $p_l = \delta_l \pm i\omega_l$ is complex eigenvalue.

Designating as ω_a , the natural frequency of the system defined by eqn [4] where $f_{oo} = 0$ (associated conservative system), $\delta_l = \omega_a \xi_l$, $\omega_l = \omega_a \sqrt{1 - \xi_l^2}$ where $\xi_l < 1$ and ξ_l is attenuation factor or level. The notation is identical to the classic notation used for the system of mass, spring, and damper at one degree of freedom.

Equation (5) permits expressing the solutions in the time domain:

$$\begin{aligned}
 y_{cl} &= Y_{cl} \exp (\delta_l + i\omega_l)t + Y_{cl}^* \exp (\delta_l - i\omega_l)t \\
 y_{cl} &= \exp (\delta_l t) A y_{cl} \cos (\omega_l t + \gamma Y_{cl})
 \end{aligned}
 \quad [6]$$

z_{cl} , y_{1l} and z_{1l} are expressed by identical forms (where \bar{n} is an order of u). Free response is defined by:

$$y_c = \sum_{l=1}^z \exp \delta_l t A_{ycl} \cos (\omega_l t + \varphi_{cl}) \quad [7]$$

z_c , y_1 , and z_1 are expressed by identical forms.

The amplitude A , and phase φ , depend on initial conditions which were imposed (see **Rotating machinery, modal characteristics**).

Following eqn [7], so that y_c, z_c, y_1 , and z_1 tend towards zero when $t \rightarrow \infty$, δ_l must be less than zero, whatever the value of l . Otherwise, instability will ensue. When the logarithmic decrease $\Delta_l = -2(\pi\delta_l/\omega_l)$ is greater than one, the margin of stability is suitable.

Figure 5 shows the limits of stability of the rotor shown in Figure 1, guided by two cylindrical bearings characterized by the Sommerfeld number S' , the Haag number H' , and $L/2R = 1$. Instability can be seen ($\delta_l/\omega_o > 0$) around $\Omega/\omega_o \approx 1.1$ at frequency $\omega_l \approx 0.7\omega_o$. Stability is assured for $\Omega < \omega_o$ and for natural frequencies p_2 and p_3 .

To clarify, the limit between stability and instability can be obtained with eqn [4] without a second member, looking for solutions of the form:

$$\begin{aligned} y_{cr} &= Y_{cr} \exp p_r \tau & z_{cr} &= Z_{cr} \exp p_r \tau \\ y_{1r} &= Y_{1r} \exp p_r \tau & z_{1r} &= Z_{1r} \exp p_r \tau \end{aligned}$$

where

$$p_r \tau = (\delta + i\omega)t = \left(\frac{\delta}{\omega_o} + \frac{i\omega}{\omega_o} \right) \tau$$

at the limit $p_r = i\omega/\omega_o$.

From the first two eqns in eqn [4]:

$$Y_{cr} = \frac{1}{1 - (\omega/\omega_0)^2} Y_{1r} \quad Z_{cr} = \frac{1}{1 - (\omega/\omega_0)^2} Z_{1r}$$

The two last eqns in eqn [4] lead to:

$$\begin{aligned} &\left\{ K_{yy} + iF_{yy} \frac{\omega}{\Omega} - \frac{H}{2} \left[1 - \frac{1}{1 - (\omega/\omega_0)^2} \right] \right\} Y_{1r} \\ &+ \left[K_{yz} + iF_{yz} \frac{\omega}{\Omega} \right] Z_{1r} = 0 \\ &\left[K_{zy} + iF_{zy} \frac{\omega}{\Omega} \right] Y_{1r} \\ &+ \left\{ K_{zz} + iF_{zz} \frac{\omega}{\Omega} - \frac{H}{2} \left[1 - \frac{1}{1 - (\omega/\omega_0)^2} \right] \right\} Z_{1r} = 0 \end{aligned}$$

As for a solution to (Y_{1r}, Z_{1r}) , the imaginary and complex parts of the determinant of this system must be zero:

$$\begin{aligned} M &= \frac{H}{2} \frac{(\omega/\omega_0)^2}{(\omega/\omega_0)^2 - 1} \\ &= \frac{F_{yy}K_{zz} + F_{zz}K_{yy} - F_{yz}K_{zy} - F_{zy}K_{yz}}{F_{yy} + F_{zz}} \end{aligned} \quad [8]$$

$$(\omega/\Omega)^2 = \frac{(M - K_{zz})(M - K_{yy}) - K_{yz}K_{zy}}{F_{yy}F_{zz} - F_{yz}F_{zy}} \quad [9]$$

with $H = J\omega_0^2/g$.

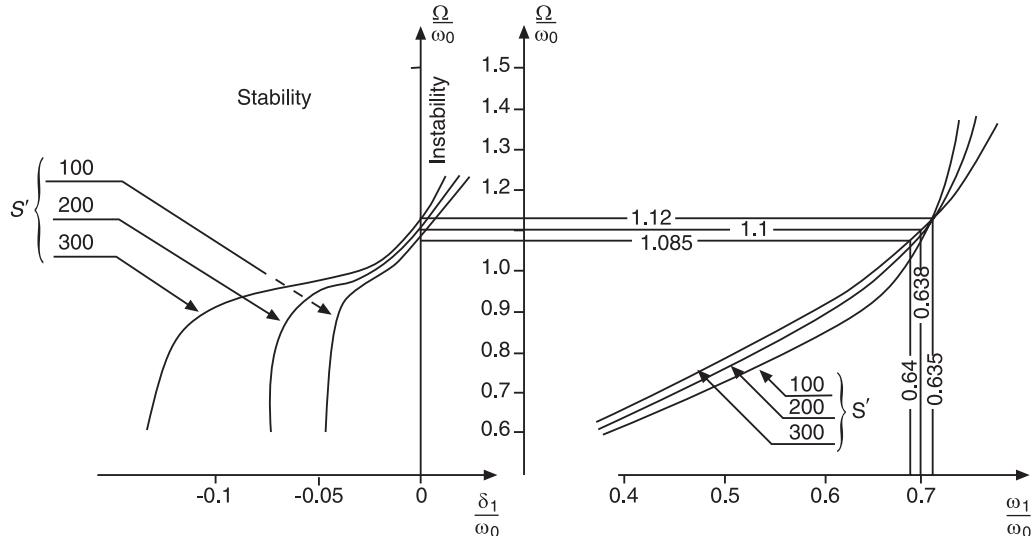

Figure 5 First natural pulsation $\delta_1 + i\omega_1$ of a rotor with oil bearings: instability. Ω : rotation (rad s^{-1}); $\omega = \sqrt{k_a/m}$; $S = \mu\Omega/[(mg/4RL)(J/R)^2] \times (30/\pi)$; Sommerfeld number, $H' = J[(30/\pi)\omega_0]^2/g = 285$; $L/2R = 1$; $g = 9.81 \text{ m s}^{-2}$.

The frequency limit of instability is defined by eqn [8]:

$$\omega_{\text{lins}}^2 = \frac{g}{\delta_f - J/2M}$$

where M depends on F_{\perp} and K_{\perp} defined as a function of disaxiality and $\delta_f = mg/k_a$ is the rotor tip. The corresponding rotation speed is defined by eqn [9], where $M < 0$, frequency ω_{lins} for a flexible rotor is less than that of a rigid rotor ($\delta_f = 0$). ω_{lins}^2 and δ_f are connected by hyperbolic law. $(\omega/\Omega)_{\text{limit}}$ only depend on F_{\perp} and K_{\perp} , and so on S' and $L/2R$. For short cylindrical bearings ($L/2R \leq 0.5$), in 1966 Lund determined $(\omega/\Omega)_{\text{limit}}$ as a function of disaxiality d/J :

$$\begin{aligned} d/J = 0 &\rightarrow (\omega/\Omega)_{\text{limit}} = 0.5; \\ 0 \leq d/J \leq 0.58 &\rightarrow 0.5 \leq (\omega/\Omega)_{\text{limit}} \leq 0.54 \\ d/J = 0.75 &\rightarrow (\omega/\Omega)_{\text{limit}} = 0.1 \end{aligned}$$

Table 1, following Allaire and Flack, defines the stability limits of a rigid rotor (mass m , $W = mg$) on two identical bearings defined in the article on links (see **Bearing vibrations**).

The relationship between speed limits of instability for bearings with two elliptical lobes and with two asymmetric lobes is equivalent to 3.16.

Table 2 shows the stability limits of a De Laval rotor ($W = 1335 \text{ N}$) for two identical cylindrical bearings: $\mu = 0.035 \text{ N sm}^{-2}$; $L = 0.05 \text{ m}$; $D = 0.1 \text{ m}$;

Table 1 Limits of stability: $y = S/H_1 = 0.3$; $H_1 = \Omega\sqrt{J/g}$

Bearing	Sommerfeld number $S = \frac{\mu\Omega RL}{\pi W} \left(\frac{R}{J}\right)^2$	$\frac{\omega}{\Omega} \text{Precession}$	$\frac{\Omega}{\sqrt{J/g}} \text{Rotation}$
Two lobes (elliptical)	1.15	0.495	3.82
Three lobes	1.86	0.470	6.21
Four lobes	1.52	0.475	5.08
Two asymmetric lobes	3.62	0.361	12.07

Table 2 Limits of stability

Tip (δ_f)/Clearance (Cr)	Ω Rotation (rpm)	ω Precession (rpm)	Ω Rotation/ ω Precession
0 (rigid)	9530		
0.1	8730	4385	1.99
10	2090	1060	1.97

$L/D = 0.5$; clearance = $7.5 \times 10^{-2} \text{ mm}$; $2J/D = 1.5 \times 10^{-3}$. Limits decrease when δ_f/Cr increases.

Natural Modes

Eqn [4], without a second member, in the time domain t , with frequency p_l , is written as:

$$\begin{bmatrix} p_l^2 + 1 & 0 & -1 & 0 \\ 0 & p_l^2 + 1 & 0 & -1 \\ A_1 & 0 & A_2 + p_l A_3 & A_4 + p_l A_5 \\ 0 & B_1 & B_2 + p_l B_3 & B_4 + p_l B_5 \end{bmatrix} = \begin{bmatrix} Y_{cl} \\ Z_{cl} \\ Y_{1l} \\ Z_{1l} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad [10]$$

The terms A_i and B_i are defined by the variables of eqn [4]. Three displacements of the matrix column can be calculated using eqn [10], by fixing one of them, for example $Y_{cl} = (Y_{cl})_0 = 1$ to define the natural mode associated with p_l .

$$[(Y_{cl})_0 \quad Z_{cl}^* \quad Y_{1l}^* \quad Z_{1l}]^T$$

where T = transposition.

Natural modes are defined by a multiplicative constant, which is taken by $(Y_{cl})_0$. The terms Z_{cl} , Y_{1l} , and Z_{1l} are generally complex. The natural mode corresponding to p_l^* is defined by:

$$\{(Y_{cl})_0 \quad Z_{cl}^* \quad Y_{1l}^* \quad Z_{1l}^*\}^T$$

Eqn [6] is an expression of natural modes in the spatiotemporal domain for initially imposed conditions which permit expression of natural frequency p_l , and p_l^* , by $(Y_{cl})_0$, Z_{cl} , Z_{cl}^* , Y_{1l} , Y_{1l}^* , Z_{1l} , and Z_{1l}^* .

Unbalance Response: Critical Speed

Displacement

The solution to eqn [4] takes the form:

$$u_r = \text{Re} \left[U_r \exp i \left(\frac{\Omega}{\omega_0} \right) \tau \right] \quad [11]$$

where u_r : y_{cr} ; z_{cr} ; y_{1r} ; z_{1r} . Calculations can be carried out using expressions, equally in the time domain, t :

$$\begin{bmatrix} 1 - (\Omega/\omega_0)^2 & 0 & -1 & 0 \\ 0 & 1 - (\Omega/\omega_0)^2 & 0 & -1 \\ C_1 & 0 & C_2 + i(\Omega/\omega_0)C_3 & C_4 + i(\Omega/\omega_0)C_5 \\ 0 & D_1 & D_2 + i(\Omega/\omega_0)D_3 & D_4 + i(\Omega/\omega_0)D_5 \end{bmatrix} \begin{bmatrix} Y_{cr} \\ Z_{cr} \\ Y_{1r} \\ Z_{1r} \end{bmatrix} = \begin{bmatrix} (\Omega/\omega_0)^2 \\ -i(\Omega/\omega_0)^2 \\ 0 \\ 0 \end{bmatrix} \quad [12]$$

The dimensionless terms $C.$ and $D.$ are defined by the variables given in eqn [1]. The matrix arising from eqn [12] is an impedance matrix $\mathbf{P}.$ Thus:

$$\begin{bmatrix} Y_{cr} & Z_{cr} & Y_{1r} & Z_{1r} \end{bmatrix}^T = \mathbf{P}^{-1} \begin{bmatrix} (\Omega/\omega_0)^2 - i(\Omega/\omega_0)^2 & 0 & 0 \end{bmatrix}^T \quad [13]$$

Dimensionless $Y_{cr}, Z_{cr}, Y_{1r}, Z_{1r}$ obtained by eqn [13] are complex, of the form $V_r = |V_r| \exp i\varphi_r.$ Thus, taken into account eqn [11]:

$$\begin{aligned} y_0/e &= y_{cr} = |Y_{cr}| \cos(\Omega t + \varphi_{yc}) \\ z_0/e &= z_{cr} = |Z_{cr}| \cos(\Omega t + \varphi_{zc}) \\ y_1/e &= y_{1r} = |Y_{1r}| \cos(\Omega t + \varphi_{y1}) \\ z_1/e &= z_{1r} = |Z_{1r}| \cos(\Omega t + \varphi_{z1}) \end{aligned} \quad [14]$$

$(\Omega/\omega_0)^2$ intervenes as a factor in each of the modules of eqn [14] which, like the phase $\varphi,$ varies with speed by Ω/ω_0 and by the Sommerfeld number, on which depend stiffness $k..$ and damping coefficients $f..$ expressed by $C_1 \dots D_5.$ The amplitudes y_c, z_c, y_1, z_1 are in proportion to eccentricity and connected to unbalance, and as a result it becomes possible to reduce them by corrective unbalance which reduces $e.$ For certain values of rotation speed $\Omega,$ the modules $|Y_{cr}|, |Z_{cr}|, |Y_{1r}|,$ and $|Z_{1r}|$ are maximal. This speed is the critical speed.

When the impedance of the links is very great, the critical speed is equal to $\omega_0 = \sqrt{k_a/m}.$ In the radical plane perpendicular to link 1, y_1 and z_1 (Figure 6) are written:

$$\begin{aligned} y_1 &= e|Y_{1r}| \cos(\Omega t + \varphi_{y1}) \\ z_1 &= e|Z_{1r}| \cos(\Omega t + \varphi_{z1} + \pi/2) \\ |\overrightarrow{OC_{1y}}| &= e|Y_{1r}| \\ |\overrightarrow{OC_{1z}}| &= e|Z_{1r}| \end{aligned} \quad [15]$$

The precession pathway C_1 is elliptical, and is even a circumference or perpendicular. The length of its axes and its angular position in the system of reference $0yz$ are defined by $e|Y_{1r}|, e|Z_{1r}|, \varphi_{y1},$ and $\varphi_{z1}.$ The length

of its axes does not depend on the galilean system of reference. The speed for which the length of the great axis passes by a maximum is a critical speed. Around critical speeds:

$$\frac{d|\varphi_{z1} - \varphi_{y1}|}{d\Omega}$$

may be large.

The precession pathways of rotor geometric centers are circumferences when the rotor is symmetrical about its axis, and the links are isotropes. These links are defined later in this article.

The direction of the course of C_1 on its pathway is identical to that of Ω when $3\pi/2 < \varphi_{z1} + \pi/2 - \varphi_{y1} < \pi/2:$ direct precession is inverse when $\pi/2 < \varphi_{z1} + \pi/2 - \varphi_{y1} < 3\pi/2.$

Critical speed is not intrinsic; it depends on the variable used for its determination, unbalance, even excitors. Critical speed may be defined by the vibration of the nonrotating structure.

Critical speed identified by vibrations $y_{1\theta}, z_{1\theta}$ in a system of reference at angle θ of $0yz$ is such that:

$$\begin{Bmatrix} y_{1\theta} \\ z_{1\theta} \end{Bmatrix} = \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix} \begin{Bmatrix} y_1 \\ z_1 \end{Bmatrix}$$

This led to different values from those identified in the system of reference $0yz,$ except if the links are isotropes. The critical speed connected to the components of rotating vectors is not generally intrinsic, in contrast to those defined by maximum values of

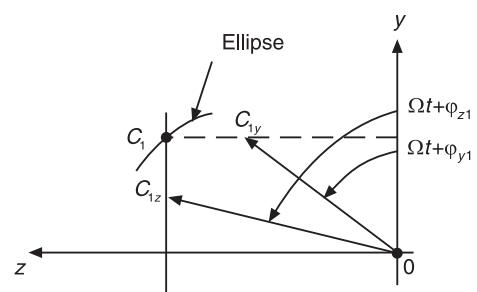

Figure 6 Rotating vectors for displacement of the center C_1 of the vertex.

length of the large elliptical axis, which is the precession pathway.

The preceding considerations are valid for C, the disk center, which in general is more difficult to access for measurements than the centers of vertices C_1 and C_2 .

Generally, critical speed is the speed at which vibration amplitude is maximum. This speed is the resonance speed. The speed at which amplitude is minimal is the antiresonance speed.

Unbalance and run out associated with initial peaks, coaxiality faults, and noise on the tracks for measuring rotors (see **Balancing; Rotating machinery, monitoring**) can lead to antiresonance, as well as unbalance and run outs.

Forces Knowledge of y_1 and z_1 , calculated by measurement, makes it possible to determine the components f_{1y} and f_{1z} of force applied by the rotor on the bearing. According to eqn [15]:

$$\begin{aligned} y_1 &= e|Y_{1r}| \operatorname{Re} \left[\exp i(\Omega t + \varphi_{y1}) \right] \\ z_1 &= e|Z_{1r}| \operatorname{Re} \left[-\exp i(\Omega t + \varphi_{z1}) \right] \end{aligned} \quad [16]$$

In a similar way:

$$\begin{aligned} f_{1y} &= |F_{1y}| \operatorname{Re} \left[\exp i(\Omega t + \varphi_{f_{1y}}) \right] \\ f_{1z} &= |F_{1z}| \operatorname{Re} \left[\exp i(\Omega t + \varphi_{f_{1z}}) \right] \end{aligned}$$

The two last equations of eqn [1] lead to:

$$\begin{aligned} &\begin{bmatrix} |F_{1y}| \exp i\varphi_{f_{1y}} \\ |F_{1z}| \exp i\varphi_{f_{1z}} \end{bmatrix} \\ &= \begin{bmatrix} 2(k_{yy} + i\Omega f_{yy}) & 2(k_{yz} + i\Omega f_{yz}) \\ 2(k_{zy} + i\Omega f_{zy}) & 2(k_{zz} + i\Omega f_{zz}) \end{bmatrix} \begin{bmatrix} e|Y_{1r}| \exp i\varphi_{y1} \\ e|Z_{1r}| \exp i\varphi_{z1} \end{bmatrix} \end{aligned} \quad [17]$$

The stiffness $k_{..}$ and damping coefficient $f_{..}$ are as calculated and confirmed by measurement, in particular that of temperature and oil, of $\overrightarrow{|C_o C_m|} = d$ and ϕ . Multiplication of the square matrix by the column matrix containing measured variables permits the determination of components of force.

As with displacement of the center C_1 (Figure 6), the elliptical pathway of the extremity of force can be determined in the same way as critical speed regarding this force and its components. Uncertainty regarding physical links may be caused by nonlinear behavior, which is not taken into account.

When the vibration amplitude of the bearing containing the ball bearing is significant in relation to $e|Y_{1r}|$ and $e|Z_{1r}|$, the relative vibration of the rotor journal in relation to the bearing must be substituted for y_1 and z_1 .

Determining the force by measurement is preferable to determining it by calculation. These measurements, which may reduce machine reliability, are not generally performed by manufacturers.

Essentially, complex natural frequency $p_l = \delta_l + i\omega_l$, and associated complex natural modes enable to express free vibratory responses in rotor flexion, following initial imposed conditions.

In the region of linear performance or so-called small movement, stability is insured when all real parts, δ_l , of complex frequency, are negative. During instability a pseudoperiodic evolution operates on the imaginary part ω_l . Corresponding spatial configuration is seen as natural modes which, like natural frequency, depend on rotation speed. The increase in amplitude, for catastrophes, is not systematically observed in machines. Nonlinearity is observed via cycle limits of fixed amplitude which may be acceptable.

The unbalance response permits identification of critical flexion speed for which the vibration amplitude is maximum. This speed is not generally intrinsic. It partly becomes so with the length of the long axis of the elliptical pathway of precession.

The knowledge of stiffness and damping coefficients, associated with calculated or measured vibration, enable to determine force components transmitted to the bearing by the rotor, and corresponding critical speed.

Axial vibration, in the direction of the rotor axis, is acquired by measurements; they result from couplings, axial thrust, and faults, for example of misalignment. Theoretical models are difficult to establish.

The De Laval rotor model enables an interpretation of the performance of a rotating machine when the gaps between natural frequencies $\omega_{l-1}; \omega_l, \omega_{l+1}$ and attenuation factors, or development factors, $\delta_{l-1}; \delta_l, \delta_{l+1}$ are small in relation to ω . This property is a result of modal decomposition, which is defined in the article **Rotating machinery, modal characteristics**, reduced to a term whose form is identical to that of the De Laval rotor. This form makes it possible to estimate a damping factor ξ_l and amplification factor $Q_{3dB} = 1/2\xi_l$ which is useful for prediction of increase in vibration on passage of a critical speed. As an example, Figure 2 defines an amplification factor $Q_{3dB} = 6.45$ and damping factor $\xi = 0.0775$. These values are appropriate.

Model with Isotropic Links

Stability

Particular impedance A liaison is isotropic when the relationship between vibrations and forces in the direction of eqn [17] is independent of the system of reference.

Consider a matrix:

$$\begin{bmatrix} k + i\Omega c & c\lambda\Omega \\ -c\lambda\Omega & k + i\Omega c \end{bmatrix} \quad [18]$$

This is a matrix of isochronic transfer and impedance, representing isotropic link where k is stiffness, c is the damping coefficient, and λ is the coefficient.

$$\lambda \approx 0.5 \text{ where } |\overrightarrow{C_o C_m}| \approx 0$$

$$\lambda \approx 0.45 \text{ where } |\overrightarrow{C_o C_m}| \approx \frac{1}{2}\Delta R$$

The terms $k + i\Omega c$ express radial forces; $c\lambda\Omega$ expresses tangential forces creating coupling.

The equation of natural frequency is written:

$$(mp^2 + k_a)(-k - k_a - pc + ic\lambda\Omega) + k_a^2 = 0 \quad [19]$$

The limit between stability and instability is determined setting out $\delta = 0$ and so $p = i\omega$. Eqn [19] leads to:

$$\Omega_l^2 = \frac{k_g}{\lambda^2 m} \rightarrow \Omega_l = \frac{\omega_{og}}{\lambda} \quad \text{where} \quad \frac{1}{k_g} = \frac{1}{k_a} + \frac{1}{k} \quad [20]$$

where $\omega_{ins} = \lambda\Omega_l$ and $\omega_{og}^2 = k_g/m$; Ω_l = speed at which instability appears at frequency ω_{ins} .

Where $p = \delta + i\omega$ and $\omega = \omega_{ins} + \varepsilon$; δ and ε , which are small, instability is confirmed when $\Omega > \Omega_l$.

The formulae [20] show that:

- Ω_l and ω_{ins} do not depend on c
- instability arises from the coupling term $c\lambda\Omega$ which expresses a tangential force
- where $\lambda = \frac{1}{2}$, the speed limit Ω_l is equal to twice natural frequency ω_{og} of the associated conservative system ($c = 0$)
- the instability frequency ω_{ins} is equal to half rotation speed

The model defined by matrix [18] clarifies the role of coupling terms and describes the ‘oil whip’, which Newkirk was interested in in 1925, and which is described in many monographs. Diagnostic

technicians have focused on the law $\omega_l = \Omega_l/2$, which the French call *fouettement*.

General impedance Let us consider an isotropic link. Its model is:

$$\begin{bmatrix} Z_d(\omega) & Z_c(\omega) \\ -Z_c(\omega) & Z_d(\omega) \end{bmatrix} \quad [21]$$

where $Z_d = Z_d^r + iZ_d^i$ and $Z_c = Z_c^r + iZ_c^i$ and the indices r : real and i : imaginary: $i^2 = -1$. Z_d and Z_c are functions of ω ; they depend on Ω . At the limit of stability:

$$\begin{aligned} (k_a - m\omega^2)(k_a + Z_d^r + Z_c^i) - k_a^2 &= 0 \\ (k_a - m\omega^2)(Z_d^i - Z_c^r) &= 0 \end{aligned} \quad [22]$$

From which $Z_d^i = Z_c^r$ and as a result $\omega_{ins} = F(\Omega)$; substituting the first equation of eqn [22] makes it possible to calculate speed limit Ω_l , at which instability appears.

If $Z_d^r = Z_c^i = 0$, the stability limit cannot be determined. The role of coupling terms is fundamental. Within eqn [18] and eqn [21] they represent a tangential force.

A rigid rotor is defined by $k_a \rightarrow \infty$. In eqn [1] the terms $k_a(y_c - y_1)$ and $k_a(z_c - z_1)$ are replaced by forces and $y_c = y_1$, $z_c = z_1$. With the model [21] at the stability limit:

$$\begin{aligned} -m\omega^2 + Z_d^r + Z_c^i &= 0 \\ Z_d^i - Z_c^r &= 0 \end{aligned}$$

Confirming the role of Z_c as descriptive parameter.

Internal friction in the rotor In the system of reference $O\xi\eta$, in rotation at Ω , internal friction may be caused by rubber and neoprene coupling elements, at insufficient friction of a disk on a shaft. It is expressed by force component:

$$C_i \frac{d\xi_c}{dt} \quad C_i \frac{dy_c}{dt}$$

where C_i is friction coefficient, and ξ_c and η_c are components of \overrightarrow{OC} .

In a galilean system of reference, this force induces a force of radial friction and tangential force. When, perpendicular to links, displacement is zero, i.e. when impedance modules are very great, performance is stable if:

$$\frac{|\Omega|}{\omega_0} < \frac{C}{C_i} + 1 \quad [23]$$

where $\omega_0^2 = k_a/m$, C = coefficient of internal friction.

In instability frequency is equal to ω_0 . Following eqn [22], the stability speed limit increases linearly with C and diminishes hyperbolically when C_i increases. In general weak hysteretic damping of materials does not bring about instability.

Tangential force When a tangential force of components $k_t y_c$ and $-k_t z_c$, where k_t is stiffness, is applied to the rotor disk on rigid links, where displacement is zero, stability is insured when:

$$-2\xi < \frac{k_t}{k_a} < 2\xi$$

where $\xi = c/2\sqrt{k_a m}$ is the damping ratio. When $\xi = 0.02$, the amplification factor is defined by $Q_{3dB} = 1/2\xi = 25$. k_t/k_a must be less than 0.04.

Response to Unbalance: Critical Speed

With the transfer matrix [18]:

$$|Y_{1r}| = |Z_{1r}| = \frac{(\Omega/\omega_0)^2}{\left[1 - (\Omega/\omega_0)^2\right]\left[\alpha + 2i\xi(1-\lambda)\Omega/\omega_0\right] - 1}$$

where $\alpha = 1 + k/k_a$ and $\xi = c/2\sqrt{mk_a}$. Critical speed is defined by:

$$\Omega_{cr} \rightarrow \text{MAX}|Y_{1r}|$$

Substituting ξ :

$$\Omega_{cr} = \sqrt{\frac{k_a k}{k_a + k}} / m$$

m, k_a are known and Ω_{cr} is measured, k is determined.

Optimization

An important margin of stability, characterized by $\Omega_{max} \ll \Omega_{limit}$, and weak amplitude at critical speed may need optimization in which damping plays an important role. Also, the resistance of the bearings to significant unbalance resulting from a loose element, for example a blade, and from misalignment must be taken into account.

Cycle Limits

Nonlinearities The equations of the models studied above are linear. In instability when $\delta_l > 0$, vibration amplitude tends towards infinity at ω_l . In reality, nonlinearity intervenes to limit amplitude, as long as this intervention is realized before destruction and catastrophe.

Vibration sets in on permanent cycles covering a frequency which may be close to ω_l where $\Omega > \Omega_{limit}$. Steady state may disappear when amplitude causes wear and tear. Oil whip occurs in a situation of instability at a cycle limit.

Tangential force: nonlinearity The equation of movement of a De Laval rotor subjected to nonlinear tangential force is defined by:

$$m \frac{d^2 U_c}{dt^2} + b \frac{dU_c}{dt} + k_a U_c + iU_c k_t(|U_c|) = 0 \quad [24]$$

where $U_c = y_c + iz_c$ where $i^2 = -1$ and b = friction coefficient > 0 ; $k_t(|U_c|)$ = stiffness; $|U_c|$ = module of U_c . A solution of the form $|U_c| \exp i\omega t$ can be assumed. Where $k_t(|U_c|)$ is defined by Figure 7, two permanent cycles can be seen at 1 and 2 with amplitude $|U_{c1}|$ and $|U_{c2}|$. These cycles are described as frequency $\sqrt{k_a/m}$ independent of rotation speed. By perturbation imposed on the rotor, cycles can be initialized. The notion of instability, in the direction of small movements, is not necessary for performance at limit cycles, which can result in chaotic performance.

Other situations may occur. To explain the observed $\omega_l = \Omega_l/2$, Newkirk and Taylor used the conservation of oil flow in a bearing shown schematically in Figure 8. Ignoring marginal leaks and admitting incompressible oil, it is easy to show that $\omega = \Omega/2$. Equality between ω and ω_l cannot explain friction. In contrast, precession at ω , equal to half rotation speed Ω , suggests the possibility of a different phenomenon.

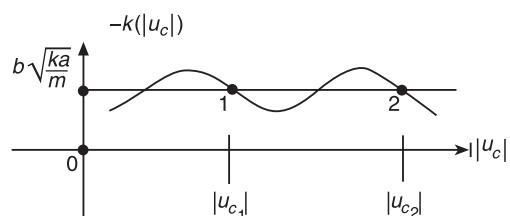

Figure 7 Stiffness of tangential force.

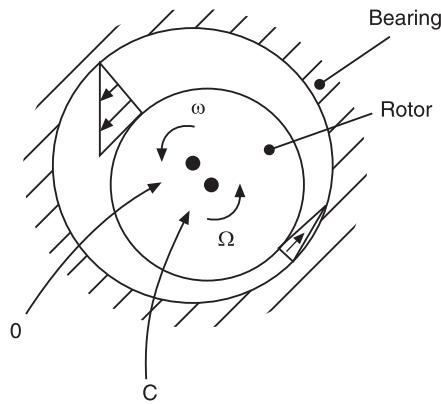

Figure 8 Movement of a whirl in a cylindrical bearing.

For an improved description, eqn [24] becomes:

$$m \frac{d^2 U_c}{dt^2} + b \frac{dU_c}{dt} + k_a U_c + b_i \left[\frac{dU_c}{dt} - i\lambda(|U_c|)\Omega U_c \right] + [k_f + \psi(|U_c|)] U_c = 0$$

$\lambda(|U_c|)\Omega$ expresses the average fluid speed in a bearing, with $\lambda = 0$ for $|U_c| = \text{clearance}$, $\lambda = \frac{1}{2}$ for $|U_c| = 0$. The amplitude $|U_c|$ of cycle limit on a circumference is defined by:

$$\sqrt{\frac{1}{m} [\psi(|U_c|) + k_a + k_f]} = \frac{\Omega b_i \lambda(|U_c|)}{b + b_f}$$

Frequency ω of precession is defined by:

$$\omega = \frac{\Omega b_f \lambda(|U_c|)}{b + b_f}$$

when b is small and $\lambda = \frac{1}{2}$, $\omega = \Omega/2$. This is a rotor.

The rotor frequency on a cycle limit is proportional to the rotation speed Ω . A different situation can be seen. The whip frequency on a cycle limit is close to the natural frequency, which is not very sensitive to Ω .

Rotor and friction can exist on the same machine. Models exist making it possible to justify the passage from one situation to another. Bently and Muszynska in 1988 used the impedance complex Z_c at the center of an elastic rotor disk guided by a link with high impedance and by a cylindrical bearing characterized by stiffness K_B , damping coefficient D , and average speed of fluid $\lambda\Omega$. The disk is subjected to a damping force which is proportional to its precession speed. K_B , D , and λ depend on the relationship d/J , of the distance d between the rotor center and the bearing center, at radial clearance J . Canceling Z_c makes it possible to calculate the precession frequency ω of

rotation speed Ω . For small values of Ω rotor is evident at $\omega \approx \Omega/2.5$.

For $\omega \approx \Omega/2.7$, a transitional rate of flow appears, expressing the passage from rotor to friction at perceptibly constant frequency, independent of speed. The situation varies with different numerical values of the relevant parameter.

In 1990 Grandall adopted the tangential force F_B at right-angles to each of two cylindrical bearings, defined by Robertson in 1933. Balance is expressed by equality between $2F_B$ and the sum of the forces at right-angles to the disk caused by centripetal acceleration and damping leads to $\omega \approx \Omega/2$ and $\omega = \omega_n$, which expresses rotor and friction.

Generally, mathematical models are used to attempt to explain precession observed at cycle limits for frequency in proportion to rotation speed and for frequency close to natural quasi-independent frequency of rotation speed. These states, rotor and friction, are a result of instability. They are explained by varying hypotheses with dominant role to tangential forces to explain instability and cycle limits. Bearings with oscillating runners characterized by impedance matrix, of which the coupling terms are theoretically zero, facilitate stability.

Contacts between rotor and stator have been studied using nonlinear models, which specifically show precession at $\omega \approx \Omega/2$, inscribed between chaotic performance.

Nonlinear performance, which can be approached using theoretical models formed using differential nonlinear equations, can be characterized at a rotation speed Ω by spectral frequency components $\omega_{pq} = (p/q)\Omega$ where p and q are integers.

When ω_{pq} is equal to the natural frequency ω_l , the spectral component amplitude is proportional to amplification factor $Q_{3dB} = 1/2\xi$ as long as gaps $\omega_{l+1} - \omega_l$ and $\omega_l - \omega_{l-1}$ are sufficient. Affecting amplitude changes at such resonance must be qualified by varying Ω , which may lead to significant variations in amplitude. It is important to change the rotation speed in order to avoid any very high amplitude variation.

Harmonic resonance permits the recognition of natural frequency which is greater than rotation speed and confirmation of lower natural frequency at rotation speed, which is encountered at machine start-up and stopping. Gyroscopic couples and link impedance generally depend on rotation speed, and so on the natural frequency. As a consequence, resonance, which is connected to natural frequency, is only defined for the corresponding speed. Nonlinearity may be caused by rotor anisotropy in the poles of electric machines, rotor cracks, coupling faults, contact between rotor and stator, stator faults,

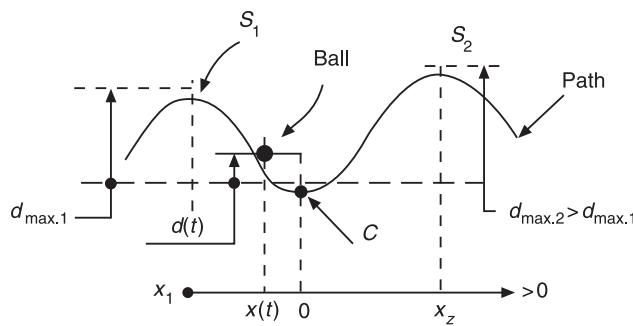

Figure 9 Path of a ball bearing.

significant rotating forces caused by unbalance and peaks, and misalignments.

Stability, Instability, and Chaos

Consider the classic situation of a ball on a track (Figure 9). The position of the ball subject to gravity is defined by $d(t)$. Let us take the point of equilibrium as C .

At the point t_0 , $d_0 < d_{\max,1}$ defines the ball's initial position. At time t , the position is defined by $d(t)$. It is still possible to find $d_0 = \eta$, such that $d(t) \leq \varepsilon$, when ε is imposed: greater than 0 but less than $d_{\max,1}$. Equilibrium at C is stable. Around C , the stability zone is defined by $d(t) < d_{\max,1}$ where $x > x_1$ and $d(t) < d_{\max,2}$. Let the equilibrium point be S_1 .

At the moment t_0 , $d_0 < d_{\max,1}$ defines the ball's initial position. At time t the position is defined by $d(t)$. It is not possible to find $d_0 = \eta$ such that $d(t) \leq \varepsilon$ when $\varepsilon \geq d_{\max,1}$: equilibrium at S_1 is unstable.

Instability can be seen whatever the sphere considered around S_1 . The same is true around S_2 . These analyses are facilitated by effecting original changes which make it possible to introduce variables which are zero at C , S_1 , and S_2 . Essentially, stability and instability are defined in a sphere around a point of equilibrium. If it is very small, local stability-instability is found.

These approaches are due to the definition of Ljapunov (1857–1918), a Russian mathematician who published *General Problem of the Stability of Motion* in 1892.

Consider a system possessing an entry $e(t)$ and an exit $s(t)$. Its state of equilibrium is defined by:

$$e = s = 0$$

At the moment t_0 , disturbance $e(t_0) = e_0$ for $t \geq t_0$ leads to variation in $s(t)$. $e(t_0)$ and $s(t_0)$ characterize the initial state. $|s(t)|$ is compared to a value ε which is chosen, which permits one to define a quality by a constraint ($N m^{-2}$) or displacement (μm). If

$|s(t)| < \varepsilon$, the system is stable. If $|s(t)| > \varepsilon$, whatever $|e_0|$, the system is unstable. If $|s(t)| \rightarrow 0$ when $t \rightarrow \infty$, the stability is asymptotic. The checking for stability and instability uses these presentations.

Geometric approaches can be made by pathways in the plane of phase $s(t)$, $ds(t)/dt$. Figure 10 defines the pathway γ_o of a permanent state and γ_p of a disturbed state; stability and instability can be checked by the distance between maximum dimensions of γ_o and γ_p which must be less than a fixed value. The geometric approach is useful for characterizing control of an engine route.

For a system represented by n variables u_i , the definition of stability and instability can be made by applying in perturbation:

$$P_0 = \left[\sum_i u_i^2(0) \right]^{1/2}$$

and observing:

$$R(t) = \left[\sum_i u_i^2(t) \right]^{1/2}$$

Stability is insured if $R(t) < \varepsilon$, asymptotic if $R(t) \rightarrow 0$, when $t \rightarrow \infty$.

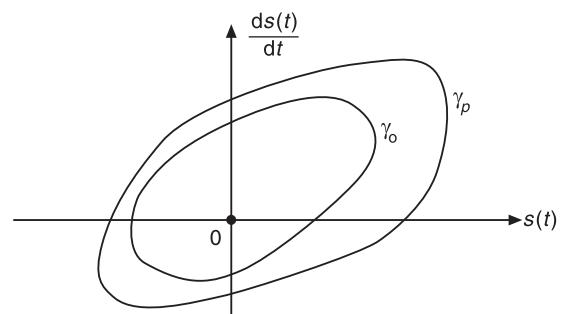

Figure 10 γ_o = pathway of a permanent state; γ_p = pathway of a disturbed state.

Taking into account a number of values less than n may lead to different conclusions. Certain authors stability consider if it is asymptotic.

The procedure which permits determination of the state as stable or unstable may be directly linked to Ljapunov's definition, which leads to perturbation and evolution of variables u_i ; such a procedure is computable. Ljapunov defined two different methods of this direct procedure.

Sensitivity to Initial Conditions (SIC): Chaos

Regarding nonlinear equations, Poincaré evoked unpredictability: 'A very small cause, which escapes us, determines considerable effect which we cannot see, and so we say that this effect is due to chance'.

In the Poincaré phase plane, 'this may happen, or else a point which is very close to the closed pathway remains very close to it, or else it goes further towards infinity, which is at times very close, or else infinite, which once it has gone into the distance remains very far away'.

Poincaré approached SIC and stability and instability without the benefits of a computer.

Lorenz, who was an American meteorologist, in 1963 proposed a system of three nonlinear deterministic and autonomous equations which represented atmospheric circulation:

$$\begin{aligned}\frac{dX}{dt} &= -\sigma X + \sigma Y \\ \frac{dY}{dt} &= rX - Y - XZ \\ \frac{dZ}{dt} &= -bZ + XY\end{aligned}\quad [25]$$

The three states of equilibrium ($dX/dt = dY/dt = dZ/dt = 0$) are defined by:

$$\begin{aligned}X_1 &= Y_1 = Z_1 = 0 \\ X_2 &= Y_2 = -\sqrt{b(r-1)} \\ Z_2 &= r-1 \\ X_3 &= Y_3 = \sqrt{b(r-1)} \\ Z_3 &= r-1\end{aligned}$$

By computing for the above, the American Lanford showed that, when $r < 1$, X , Y , and Z tend towards 0, whatever the initial conditions: this is asymptotic stability.

When $r > 1$, the appearance of convective circulation makes it possible to define instability.

Whene $r = 28$; $\sigma = 10$; $b = 8/3$, the pathways in a three-dimensional system of reference (X , Y , Z) which appear risky are in fact regular when observed over a significant period of time, and centers around two points, whatever the initial conditions.

It is possible to specify strange attractors by a determinist chaos installed around two points. In so far as dimensions of the domain containing pathways are less than fixed values, it is possible to attribute geometric stability to this state.

The pendulum makes it possible to introduce non-autonomous systems to nonlinear ones, i.e., excited systems.

The equation of the pendulum in the field of gravity, excited at right-angles to its mass element is:

$$\begin{aligned}ml_0^2 \frac{d^2\theta}{dt^2} + c \frac{d\theta}{dt} + m l_0 g \sin \theta &= C_e \cos \omega t \\ \frac{d^2\theta}{dt^2} + \frac{c}{ml_0^2} \sqrt{\frac{g}{l_0}} \frac{d\theta}{dt} + \sin \theta &= \frac{C_e}{ml_0} g \cos \frac{\omega}{\omega_0} t\end{aligned}$$

where

$$\omega/\omega_0 = 2/3; \quad \frac{C_e}{ml_0 g} = 1.5; \quad \frac{c}{(ml_0^2)} \sqrt{g/l_0} = 0.25$$

from two initial conditions ($i = 1, 2$) which are very close, such that:

$$0 < \theta_0^i < 1; \quad -1 < \left(\frac{d\theta}{dt}\right)_0^i < 0$$

the evolution of θ and of $d\theta/dt$ in the phase plane are very different and become chaotic. When:

$$\omega/\omega_0 = 2/3; \quad \frac{c}{ml_0^2} \sqrt{g/l_0} = 0.5; \quad 0.5 \leq \frac{C_e}{ml_0 g} \leq 1.5$$

chaos sets in around strange attractors. It is possible to attribute this to geometric stability.

When $1.5 < C_e/ml_0 g < 0.5$, chaos is not seen. States, in forced excitation, are permanent.

When $C_e = 0$, the pendulum is autonomous and stable, towards its attractor, $\theta = 0$. Where there are small movements around the position of equilibrium $\theta = 0$, θ can be substituted for $\sin \theta$ by a Taylor series; excited or autonomous states are stable, and there is no chaos. Around the position of equilibrium, $\theta = \pi$, there is instability.

Generally, variables v and dv/dt , represented in the phase plane, are functions of time; they are checked at the moments $t_n = t_0 + n\Delta t$ (where $n = 1, 2 \dots ; \Delta t$:

low-value increment). When they describe the vibratory behavior of a rotating machine, it is current practice to adopt $t_{p,q} = t_0 + (p/q)\Omega/2\pi$ (where Ω = rotation speed, and p and q are integers). The function of the plane phase comprises an arrangement of points identified by $t_n(t_{p,q})$; it results from fragmentation; it is fractal. The theory of fractals, introduced in 1975 by Mandelbrot, made it possible to study specific objects.

Initial Deformation and Unbalance

At zero speed, the initial deformation characterized by its module f_0 and its angular position θ_f is defined at the center C of the De Laval rotor disk, in relation to centers C_1 and C_2 of the journal (Figure 4). The terms of second members of eqn [1] are:

$$\begin{aligned} & me \Omega^2 \cos \Omega t + k_a f_0 \cos (\Omega t + \theta_f) \\ & me \Omega^2 \sin \Omega t + k_a f_0 \sin (\Omega t + \theta_f) \\ & - k_a f_0 \cos (\Omega t + \theta_f) \\ & - k_a f_0 \sin (\Omega t + \theta_f) \end{aligned}$$

Generally, unbalance cannot compensate for a peak whatever the speed. There exist critical speeds and particular situations: $|Y_{cr}|$ is canceled for speed Ω_{ya} , for which $|Z_{cr}|$ does not cancel. This speed is called antiresonance. It is greater than critical speed when $f_0 \gg e$. Perpendicular to the links:

$$\begin{aligned} |Y_{1r}| &= |Y_{1r}|_{y=0} \\ |Z_{1r}| &= |Z_{1r}|_{y=0} \end{aligned}$$

These values are independent of $k_{..}$ and $f_{..}$.

$|Z_{cr}|$ is canceled for speed Ω_{za} for which $|Y_{cr}|$ is not canceled. This speed is called antiresonance. It is

greater than critical speed when $f_0 >> e$. Perpendicular to the links:

$$\begin{aligned} |Y_{1r}| &= |Y_{1r}|_{z=0} \\ |Z_{1r}| &= |Z_{1r}|_{z=0} \end{aligned}$$

These values are independent of $k_{..}$ and $f_{..}$.

In addition, $|Y_{1r}|_{y=0} = |Z_{1r}|_{z=0}$ and $|Z_{1r}|_{y=0} = |Y_{1r}|_{z=0}$.

When links are isotropic $|Y_{cr}|$ and $|Z_{cr}|$ are canceled for the same speed Ω_{yza} . The journal centers describe a circumference of the same radius, which is independent of $k_{..}$ and $f_{..}$.

When vibrations at right-angles to links are zero (the impedance of the links is very great), and there exists damping C_a at right-angles to the disk, the pathway from the disk center C is a circumference of radius e , whatever the rotation speed, when:

$$f_0/e = 1; \cos \theta_f = 2\xi_a^2 - 1 \quad \text{where } \xi_a = \frac{c_a}{2\sqrt{mk_a}}$$

When $\xi_a = 0$, $\theta_f = \pi$. When $\xi_a = 0.1$ (amplification factor $Q_{3dB} = 5$), the calculation leads to $\theta_f = 168^\circ 30'$.

Coaxiality Fault

Figure 11 defines the rotor. When the rotation speed is low, centers C_1 and C_2 describe circumferences of radius $d/2$; the phase difference between $\overrightarrow{OC_1}$ and $\overrightarrow{OC_2}$ is equal to π . Therefore, whatever the speed, $e_1 = e_2$ and $\theta_G = \pi$. When:

$$\operatorname{tg}\theta_d = \frac{e_1 + e_2 \sin \theta_G + \varepsilon d \sin \theta_d}{e_1 + e_2 \cos \theta_G + \varepsilon d \cos \theta_d}$$

when $\varepsilon = 1$, the center C_1 is fixed, at 0; the point C_2

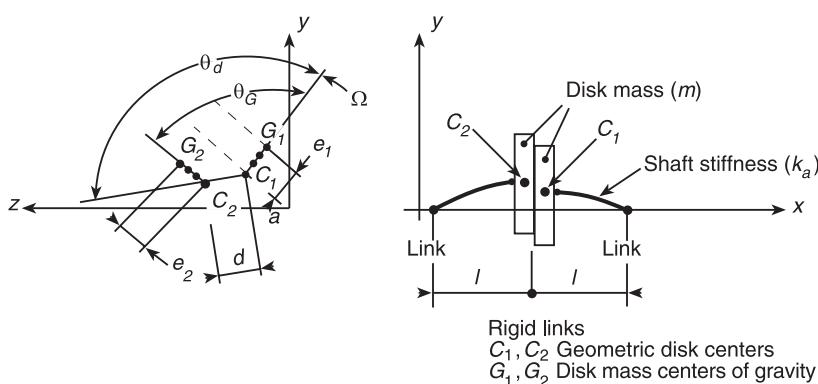

Figure 11 Coaxiality fault in a rotor.

describes a circumference of radius d . When $\varepsilon = -1$, the center C_1 is fixed, at 0; the point C_2 describes a circumference of radius d , whatever the speed. The coaxiality fault brings about antiresonance.

Gyroscopic Couple and Run Out

Formulation

Following Newton (1886–87), and d'Alembert (1743), the Swiss Euler in 1760 extended $\vec{F} = \vec{m}\dot{\vec{\psi}}$ to the solid in rotation by $\vec{M}_c = I_\omega (\mathrm{d}\omega/\mathrm{d}t)$ when \vec{M}_c is the moment of exterior forces; I_ω is the moment of inertia in relation to the rotation axis: $\vec{\omega}$.

Figure 12 shows a De Laval rotor guided by high-impedance links (displacements \approx zero from C_1 and C_2); the disk is subject to run outs characterized by angles V_z and V_y .

Within the referential $C_{x_Ry_Rz_R}$ the components of moments caused by run outs are small; for a thin disk:

Following $C_{y_R} : I_{x_Rz_R} \Omega^2 = -(I_{x_R} - I_{z_R}) V_y \Omega^2$
Following $C_{z_R} : I_{x_Ry_R} \Omega^2 = -(I_{x_R} - I_{y_R}) V_z \Omega^2$

Within the galilean referential:

According to 0y:

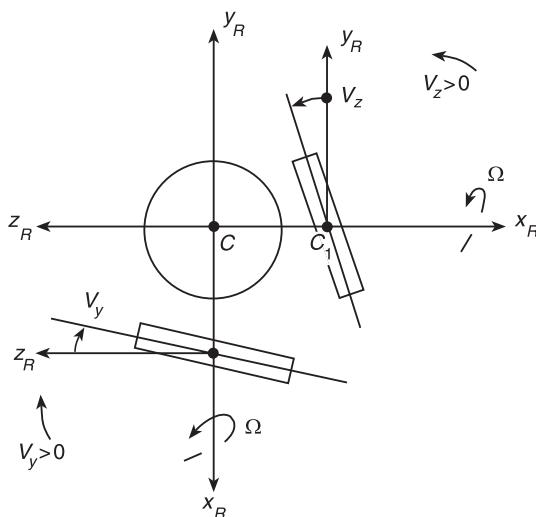

$$[-(I_{x_R} - I_{z_R}) V_y \cos \Omega t + (I_{x_R} - I_{y_R}) V_z \sin \Omega t] \Omega^2$$

According to 0z:

$$[-(I_{x_R} - I_{z_R}) V_y \sin \Omega t + (I_{x_R} - I_{y_R}) V_z \cos \Omega t] \Omega^2$$

In isotropy, where:

$$I_{y_R} = I_{z_R} = I_{d_R} = \frac{mR^2}{4} \quad I_{x_R} = \frac{mR^2}{2}$$

the equations of movement are:

$$\left. \begin{aligned} & I_{d_R} \frac{d^2\psi_y}{dt^2} + I_{x_R} \Omega \frac{d\psi_z}{dt} + k_{ra} \psi_y \\ &= \Omega^2 (I_{x_R} - I_{z_R}) (-V_y \cos \Omega t + V_z \sin \Omega t) \\ &= \Omega^2 \frac{mR^2}{4} \sqrt{V_y^2 + V_z^2} \cos (\Omega t + \psi_v + \pi) \\ & I_{d_R} \frac{d^2\psi_z}{dt^2} - I_{x_R} \Omega \frac{d\psi_y}{dt} + k_{ra} \psi_z \\ &= \Omega^2 (I_{x_R} - I_{z_R}) (-V_y \sin \Omega t + V_z \cos \Omega t) \\ &= \Omega^2 \frac{mR^2}{4} \sqrt{V_y^2 + V_z^2} \sin (\Omega t + \varphi_v + \pi) \end{aligned} \right\} [26]$$

when k_{ra} = stiffness of shaft flexion (couple/rotation around C); ψ_y , ψ_z are rotations around parallel axes at 0y and 0z:

$$\tan \psi_v = V_z / V_y$$

If P disks are arranged on the shaft, the angular distances $(\varphi_p/p) = 1 \dots p - 1$ between the angles representing the run outs are expressed by substituting:

$$\Omega t + \varphi_p \quad \text{for} \quad \Omega t$$

The terms

$$I_{x_R} \Omega \frac{d\psi_z}{dt} \quad \text{and} \quad -I_{x_R} \Omega \frac{d\psi_y}{dt}$$

express coupling by a moment and gyroscopic couple. In 1852, the Frenchman Foucault constructed a gyroscope to show and observe the north, after his experience at the Pantheon in Paris in 1851. The

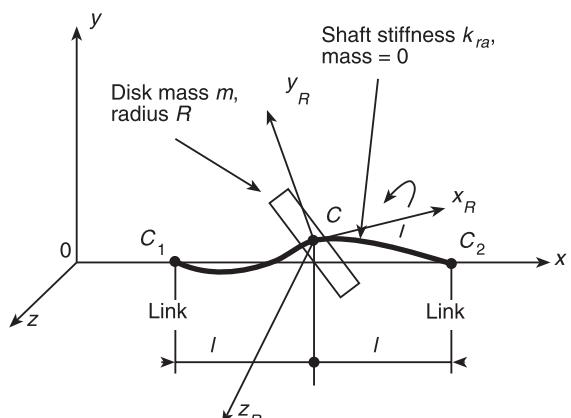

Figure 12 De Laval rotor. Model of run out disk. $C_{x_Ry_Rz_R}$ = referential linked to the disk; C = geometric center of the disk; moments of inertia I_{x_R} , I_{y_R} , I_{z_R} in relation to C_{x_R} , C_{y_R} , C_{z_R} ; $I_{x_Rz_R}$, $I_{x_Ry_R}$ in relation to C_{x_R} , C_{z_R} , and C_{x_R} , C_{y_R} .

accelerations were demonstrated by the French mathematician Coriolis in 1835, and once applied to the pendulum show the earth's rotation.

Natural Frequencies

The four natural frequencies of the model defined by eqn [26] take the form $p = \delta + i\omega$. As damping is zero, $\delta = 0$ and thus:

$$\begin{aligned} \frac{2\omega}{\omega_0} &= \frac{\Omega I_{x_R}}{\omega_0 I_{d_R}} \pm \sqrt{\left(\frac{\Omega}{\omega_0}\right)^2 \left(\frac{I_{x_R}}{I_{d_R}}\right)^2 + 4} \rightarrow \frac{\omega_1}{\omega_0}; \frac{\omega_2}{\omega_0} \\ \frac{2\omega_x}{\omega_0} &= \frac{-\Omega I_{x_R}}{\omega_0 I_{d_R}} \pm \sqrt{\left(\frac{\Omega}{\omega_0}\right)^2 \left(\frac{I_{x_R}}{I_{d_R}}\right)^2 + 4} \left[\rightarrow \frac{\omega_3}{\omega_0} = \frac{-\omega_1}{\omega_0} \right. \\ &\quad \left. \rightarrow \frac{\omega_4}{\omega_0} = \frac{-\omega_2}{\omega_0} \right]. \\ \omega_0^2 &= \frac{k_{ra}}{I_{d_R}} \end{aligned}$$

Figure 13 shows ω/ω_0 as a function of Ω/ω_0 . Free movement is expressed by the vector and components ψ_y and ψ_z whose extremities describe a circumference with pulsation ω_4 (equal to $-\omega_2$) or frequency ω_1 (equal to $-\omega_3$) according to initial imposed conditions. To obtain ω_4 :

$$\dot{\psi}_{y0} = -\omega_4 \psi_{z0}; \quad \psi_{y0} = 0; \quad \dot{\psi}_{z0} = 0$$

or

$$\dot{\psi}_{z0} = -\omega_4 \psi_{y0}; \quad \psi_{z0} = 0; \quad \dot{\psi}_{y0} = 0$$

To obtain ω_1 :

$$\dot{\psi}_{y0} = -\omega_1 \psi_{z0}; \quad \psi_{y0} = 0; \quad \dot{\psi}_{z0} = 0$$

or

$$\dot{\psi}_{z0} = -\omega_1 \psi_{y0}; \quad \psi_{z0} = 0; \quad \dot{\psi}_{y0} = 0$$

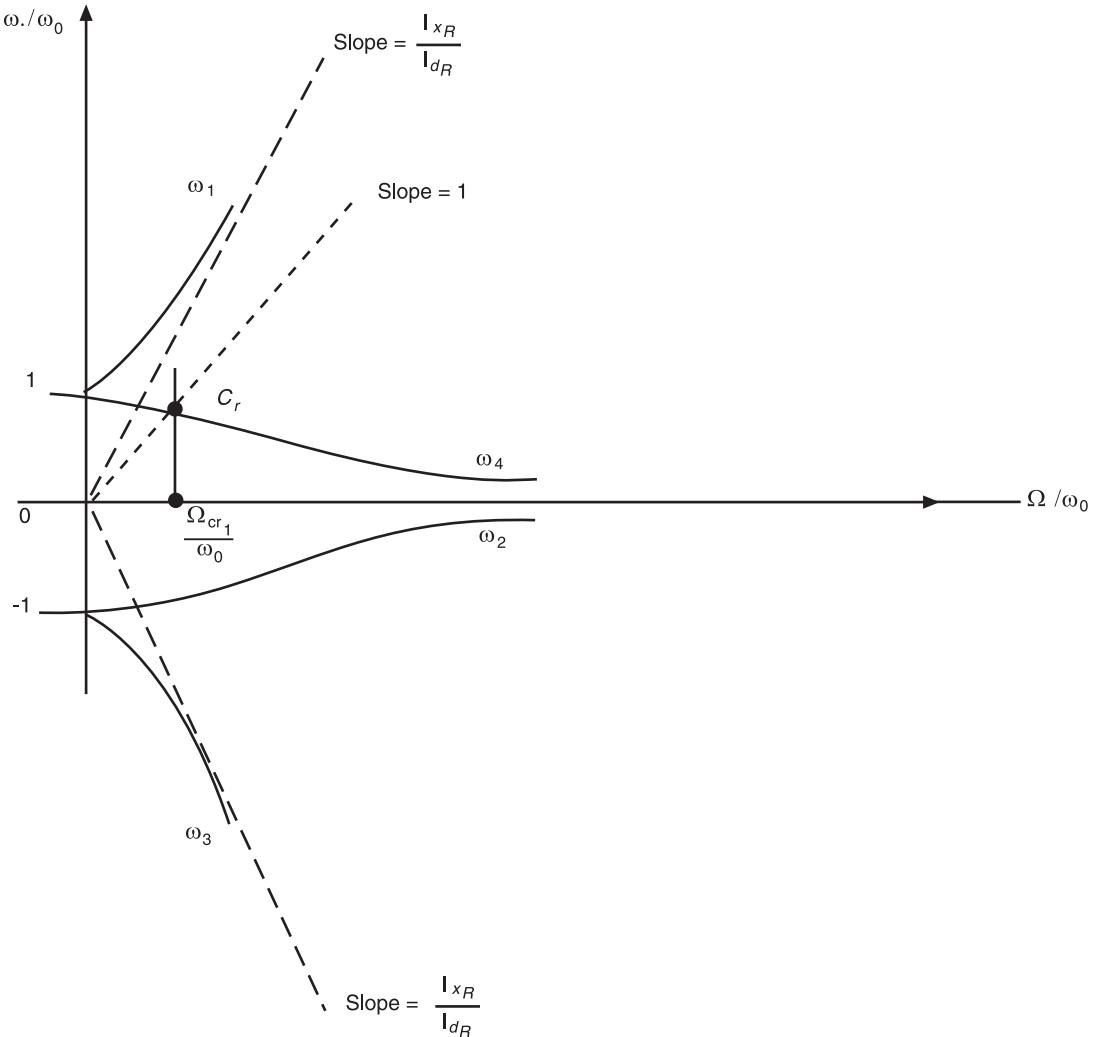

Figure 13 Natural frequencies $\omega_1, \omega_2, \omega_3, \omega_4$. Critical speed Ω_{cr1} .

Precession is inverse. Variation in natural frequency with Ω results from gyroscopic couple and generally, from variation in impedance of fluid links with Ω , expressed by the Sommerfeld number. Natural frequency of a free disk ($k_{ra} = 0$) subject to a damping couple of components $f\dot{\psi}_y, f\dot{\psi}_z$, subject to the speed Ω , are $p = -(f/I_{d_R}) \pm i(I_{x_R}/I_{d_R})\Omega$. The launched disk oscillates in translation by ψ_y and ψ_z on frequencies $(I_{x_R}/I_{d_R})\Omega$. The movement may become unstable if $f < 0$. Challenges are posed to those throwing frisbees and boomerangs: they have to find the right direction to throw when $f > 0$ and good initial conditions to reach their goal.

Critical Speed

In eqn [26] the damping is zero. As a result, the amplitude at critical speed is infinite. The solution to eqn [26] takes the form:

$$\psi_y = \text{Re}[A_y \exp i\Omega t] \quad \psi_z = \text{Re}[A_z \exp i\Omega t]$$

The determinant of the equations in A_y and A_z is written as:

$$(k_{ra} - I_{d_R}\Omega^2)^2 - I_{x_R}^2\Omega^4 = 0$$

$$(k_{ra} - I_{d_R}\Omega^2 - I_{x_R}\Omega^2)(k_{ra} - I_{d_R}\Omega^2 + I_{x_R}\Omega^2) = 0$$

The critical speed is defined by:

$$\frac{\Omega_{cr1}}{\omega_0} = \frac{1}{\sqrt{1 + (I_{x_R}/I_{d_R})}} \quad \frac{\Omega_{cr2}}{\omega_0} = \frac{1}{\sqrt{1 - (I_{x_R}/I_{d_R})}}$$
[27]

Eqn [27] can be written as:

$$\frac{d^2 U_r}{d\tau^2} - i \frac{I_{x_R}}{I_{d_R}} \frac{\Omega}{\omega_0} \frac{dU_r}{d\tau} + U_r = \left(\frac{\Omega}{\omega_0}\right)^2 \frac{mR^2}{4I_{d_R}} \exp i\left(\frac{\Omega\tau}{\omega_0} + \psi_v + \pi\right)$$
[28]

where:

$$U_r = \frac{\psi_y + i\psi_z}{\sqrt{V_y^2 + V_z^2}} \quad \tau = \omega_0 t$$

To determine the critical speed:

$$U_r = U_{r1} \exp i \frac{\Omega}{\omega_0} \tau$$

In eqn [28]:

$$U_{r1} = \frac{\frac{mR^2}{4I_{d_R}} \left(\frac{\Omega}{\omega_0}\right)^2 \exp i(\psi_v + \pi)}{1 - \left(\frac{\Omega}{\omega_0}\right)^2 + \frac{I_{x_R}}{I_{d_R}} \left(\frac{\Omega}{\omega_0}\right)^2}$$

The value of Ω/ω_0 which cancels the denominator defines critical speed as:

$$\frac{\Omega}{\omega_0} = \frac{1}{\sqrt{1 - \frac{I_{x_R}}{I_{d_R}}}}$$
[29]

As damping is zero, critical speed is equal to the natural frequency, $\omega_1 = \Omega_{cr}, \omega_2 = \Omega_{cr}$:

$$\frac{\Omega_{cr2}}{\omega_0} = \frac{1}{\sqrt{1 - \frac{I_{x_R}}{I_{d_R}}}}$$
[30]

When $\omega_3 = \Omega_{cr}, \omega_4 = \Omega_{cr}$:

$$\frac{\Omega_{cr2}}{\omega_0} = \frac{1}{\sqrt{1 + \frac{I_{x_R}}{I_{d_R}}}}$$
[31]

Formulae [27]–[31] define two critical speeds: Ω_{cr1} occurs whatever the value of I_{x_R}/I_{d_R} and Ω_{cr2} occurs if $I_{x_R}/I_{d_R} < 1$. This condition is expressed in Figure 13. Ω_{cr2} is only seen with drum rotors characterized by $I_{x_R}/I_{d_R} > 1$

Damping modifies the critical speed. In Figure 13 the abscissa of the point of intersection C_r is close to critical speed. The system [26] permits calculation of amplitudes and phase difference of angles ψ_y and ψ_z as a function of Ω .

General Formulation

In a galilean referential, equations of movements of an arrangement of rotor, links, and nonrotating structure result from the principle of Newton-d'Alembert and the theorem of kinetic moment. They are written:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{A}_v\dot{\mathbf{u}} + \mathbf{K}_d\mathbf{u} = \mathbf{S}$$
[32]

\mathbf{M} = mass matrix

$\mathbf{A}_v = \mathbf{A}_e + \mathbf{A}_i + \mathbf{G}$

\mathbf{A}_e = matrix of external damping

\mathbf{A}_i = matrix of internal damping

\mathbf{G} = matrix of gyroscopic effects

$$\mathbf{K}_d = \mathbf{K} + \mathbf{K}_i$$

\mathbf{K} = stiffness matrix

\mathbf{K}_i = stiffness matrix due to internal damping

The link impedance is expressed in \mathbf{A}_e and \mathbf{K} ; they may depend on speed Ω . The matrices defined above are square; their order is equal to number of degrees of freedom of rotor and stator elements.

$$\mathbf{U} = \left\{ \dots y_l \quad \psi_{yl} \quad z_l \quad \psi_{zl} \dots f_{yp} \quad f_{zp} \dots \right\}^T$$

y_l, z_l = displacement components of geometric center C_l of element l

ψ_{yl}, ψ_{zl} = rotation components of geometric center C_l of element l

f_{yp}, f_{zp} = force components to right-angles of section p : forces of links, sealing systems, between elements.

The matrix \mathbf{S} permits expression:

- of forces caused by unbalance; for a section k associated with displacement:

$$y_k : m_k e_k \Omega^2 \cos(\Omega t + \psi_k)$$

$$z_k : m_k e_k \Omega^2 \sin(\Omega t + \psi_k)$$

- of moments due to run outs, of an element of slight thickness, of section r associated with rotation: ψ_{yr}, ψ_{zr} :

$$\begin{aligned} \psi_{yr} &\rightarrow \Omega^2 (I_{x_r} - I_{z_r}) \sqrt{V y_r^2 + V z_r^2} \\ &\times \cos(\Omega t + \psi_{vr} + \pi + \varphi_r) \\ \psi_{zr} &\rightarrow \Omega^2 (I_{x_r} - I_{y_r}) \sqrt{V y_r^2 + V z_r^2} \\ &\times \sin(\Omega t + \psi_{vr} + \pi + \varphi_r) \end{aligned}$$

Moments of inertia $I_{..}$ are related to a system of reference $0_R x_R y_R z_R$ in rotation at Ω , around (Figure 12) Cx_R :

- of forces due to initial peaks, in section q according to $0y$: $\alpha_q f_0 \cos(\Omega t + \theta_q)$ according to $0z$: $\alpha_q f_0 \sin(\Omega t + \theta_q)$
- of forces due to coaxiality faults
- of harmonic forces, spectral components of periodic forces

Where $\mathbf{u} = \mathbf{U} \exp pt$ and $\mathbf{S} = \mathbf{0}$, eqn [32] makes it possible to calculate complex natural frequency $p_n = \delta_n + i\omega_n$ and natural connected modes \mathbf{U}_n . Expressing \mathbf{S} by the operator Re , solutions for frequency Ω are obtained by posing $\mathbf{U} = \text{Re}[\mathbf{U} \exp j\Omega\tau]$

Particular preceding cases clarify these developments. p_n and \mathbf{U}_n are modal characteristics which are discussed in the article on modal characteristics (see **Rotating machinery, modal characteristics**). Eqn [32] makes it possible to calculate the static state with $\ddot{\mathbf{u}} = \dot{\mathbf{u}} = \mathbf{0}$ and static forces in \mathbf{S} , in particular caused by gravity.

Computer software enables one to handle eqn [32] to derive frequency and natural modes of free states and responses to imposed forces and couples; eqn [32] may be set in the form described by Dowson Duncan, which is defined in the article **Rotating machinery, modal characteristics**. Conditions at the limits may be problematic to express; models of elasticity and volume masses must conform to physical values. In certain software, nonlinearities, for example, clearance between exterior cages of bearings and their supports may be introduced. It is important to be aware of tests and their results which make it possible to define domains where the available software give useful results.

Temporary States

A De Laval rotor on rigid links subject to a force of friction (damping factor C) is defined by a mathematical model, as shown in Figure 4:

$$\begin{aligned} m \frac{d^2 U_c}{dt^2} + c \frac{d U_c}{dt} + k_a U_c &= m e [\Omega^2 - i\alpha] \exp i\Omega t \\ \frac{d^2 (U_c/e)}{d\tau^2} + 2\xi \frac{d(U_c/e)}{d\tau} + \frac{U_c}{e} &= \left[\left(\frac{\Omega}{\omega_0} \right)^2 - i \frac{\alpha}{\omega_0^2} \right] \exp i \left(\frac{\Omega}{\omega_0} \right) \tau \end{aligned} \quad [33]$$

when:

$$\begin{aligned} i^2 &= -1; \quad U_c = y_c + iz_c; \quad \xi = \frac{c}{2\sqrt{k_a m}}; \\ w_0^2 &= k_a/m; \quad \tau = \omega_0 t \end{aligned}$$

$\Omega = \Omega_0 + \alpha t$; Ω_0 = initial speed; α = constant; > 0 for acceleration; < 0 for deceleration:

$$\frac{\Omega}{\omega_0} = \frac{\Omega_0}{\omega_0} + \frac{\alpha}{\omega_0^2} \tau$$

Eqn [33] shows that $|U_c/e|$ depends on:

$$\xi; \quad \frac{\Omega_0}{\omega_0}; \quad \gamma = \frac{\alpha}{\omega_0^2}$$

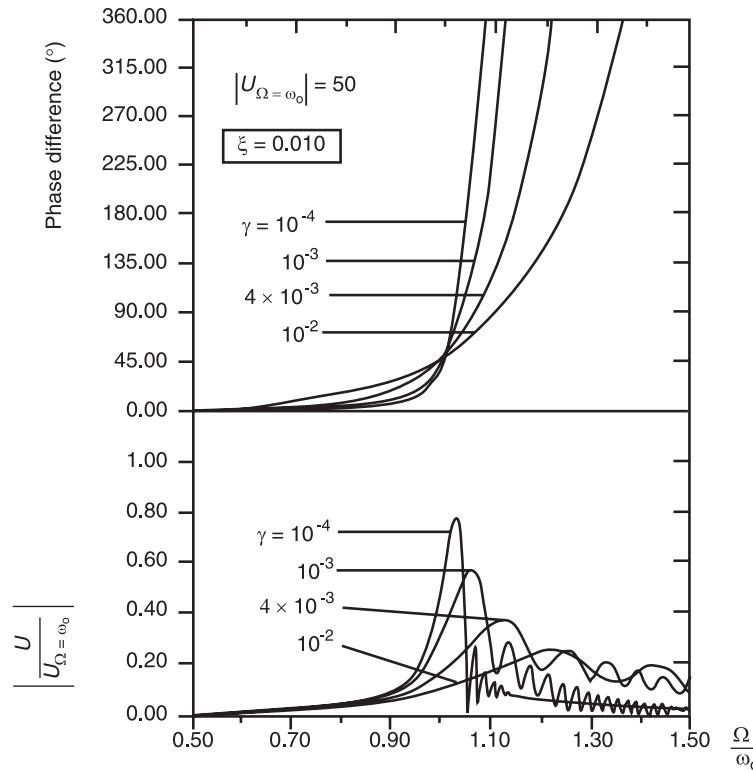

Figure 14 Increase in speed.

In a permanent state ($\alpha = 0$) where $\Omega = \omega_0$ (critical speed), $|U_c/e| = \frac{1}{2}\xi$. The solution in Figures 14–16 is determined by numerical integration with a time increment equal to $\frac{1}{500}(2\pi/\Omega)$.

For values Ω_0 close to $0.5\omega_0$ or $1.5\omega_0$, the results do not vary. $|\Omega_{\max} - \omega_0|$ increases with $|\alpha|(\Omega_{\max} \rightarrow$ maximum speed of $|U_c|)$; where $\Omega \gtrless \Omega_{\max}$, $|U_c|$ can oscillate in frequency close to the magnitude of difference between Ω and ω_0 ; the damping level ξ , determined by $\Delta\Omega/\Omega_{cr} (\rightarrow Q_{3dB})$ increases with $|\alpha|$.

Figures 17 and 18 define the displacement magnitude and critical speed as a function of $\alpha/\omega_0^2 = \gamma$. Where $\omega_0 = 94.2 \text{ rad s}^{-1}$ (900 rpm), $\xi = 0.02$ ($Q_{3dB} = 25$), $\alpha/\omega_0^2 = 2 \times 10^{-3} (\rightarrow \alpha = 17.75 \text{ rad s}^{-2} \rightarrow 170 \text{ rpm s}^{-1})$ the relation between amplitude of temporary and permanent rate of flow is close to 0.7; apparent critical speed is about 6%.

The information provided by the De Laval rotor permits to estimate the rotor performance when the gaps between critical speeds are important.

Acceleration (increase in speed) and deceleration (decrease in speed) are obtained by a couple around the rotation axis. The mathematical model comprises three equations which express equilibrium in three fixed directions: $0y$, $0z$, and $0x$, close to the axis of rotation. $|U_c/e|$ depends on:

$$\xi = \frac{c}{2\sqrt{k_a m}}$$

$$\frac{e}{r} \quad \text{with} \quad r^2 = \frac{I_{x_R}}{m}$$

where I_x is inertia in relation to the axis \approx parallel to $0x$. When the initial position and speed are zero, and when:

$$\frac{C_x}{I_{x_R} \omega_0^2} = \xi = \frac{e}{r} = 0.01$$

the maximum value for $|U_c/e|$ at $\Omega \approx 1.2 \omega_0$ is equal to 14; in a permanent rate of flow where $\Omega \approx \omega_0$ it is equal to $1/2\xi = 50$; where $\omega_0 = 100 \text{ rad s}^{-1}$ (critical speed ≈ 955 rpm), initial acceleration is equal to $10^2 \text{ rad s}^{-2} \rightarrow 955 \text{ rpm s}^{-1}$.

Torsion

The rotor shown in Figure 19 is in permanent rotation around its axis $0x$. Each section vibrates in relation to this rotation. Between sections k and $k + 1$, neglecting the axial moment of inertia, the theorem of the critical moment leads to:

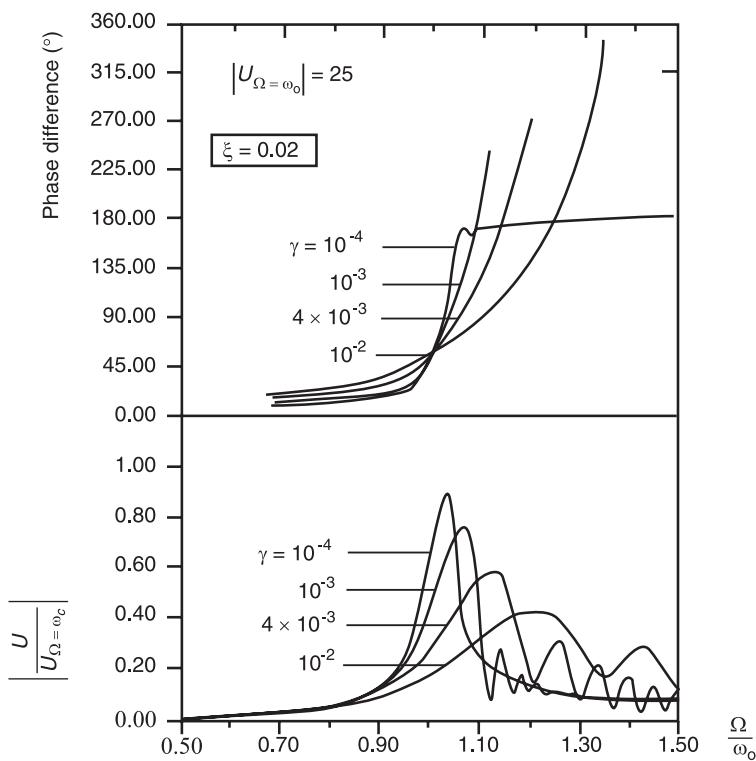

Figure 15 Increase in speed.

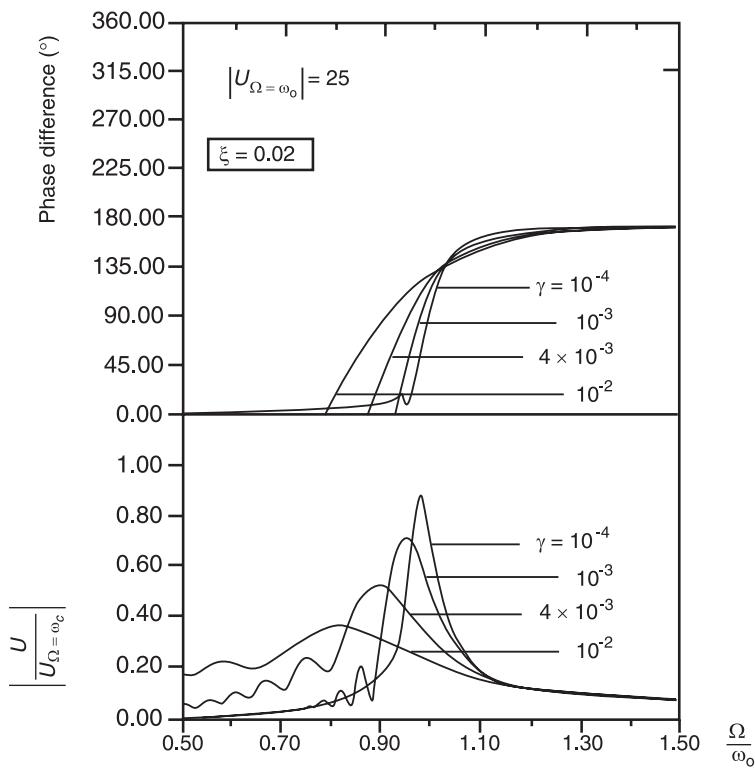

Figure 16 Decrease in speed.

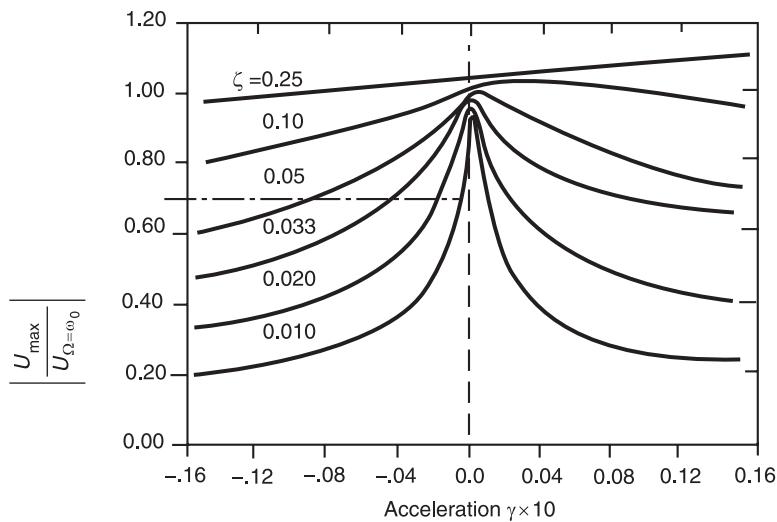

Figure 17 Displacement module U_{max} in transient state.

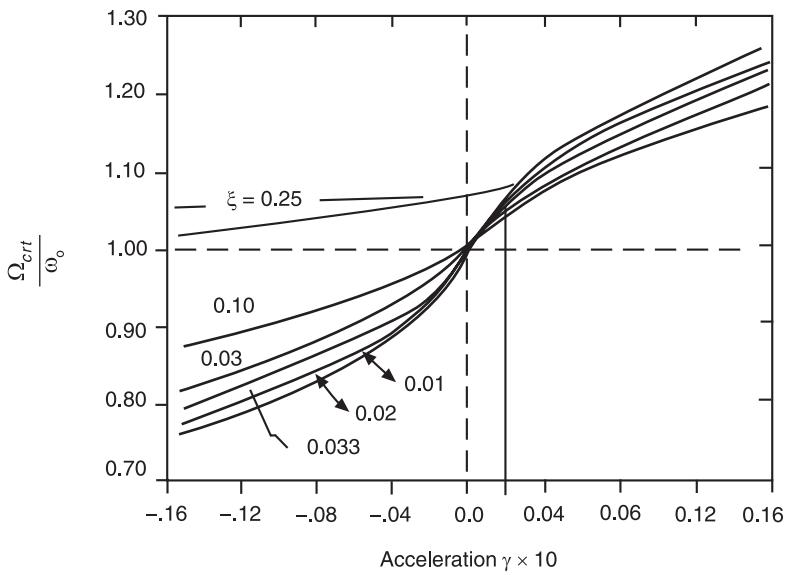

Figure 18 Critical speed Ω_{crt} in transient state.

$$c_{k+1} = c_k = (r_{k+1} - r_k)K_{k+1}^k$$

$pt; r_i = R_i \exp pt$ (where the dot . refers to the section index):

where c_i = moment of torsion; r_i = angle of rotation in relation to Ωt , K^x = torsion stiffness. Between sections $k + 1$ and $k + 2$, admitting indeformability:

$$c_{k+2} - c_{k+1} + C_{e,k+1} = I_{k+2}^{k+1} \frac{d^2 r_{k+1}}{dt^2} \quad [34]$$

where I^x = moment of inertia; and C_e = exterior moment. In a free state ($C_e = 0$) with: $c_i = C_i \exp$

$$\begin{bmatrix} C_{k+1} \\ R_{k+1} \\ 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ \frac{K_{k+1}^k}{I_{k+2}^{k+1}} & 0 & 1 \end{bmatrix} \begin{bmatrix} C_k \\ R_k \\ 1 \end{bmatrix}$$

$$\begin{bmatrix} C_{k+2} \\ R_{k+2} \\ 1 \end{bmatrix} = \begin{bmatrix} 1 & I_{k+2}^{k+1} p^2 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} C_{k+1} \\ R_{k+1} \\ 1 \end{bmatrix}$$

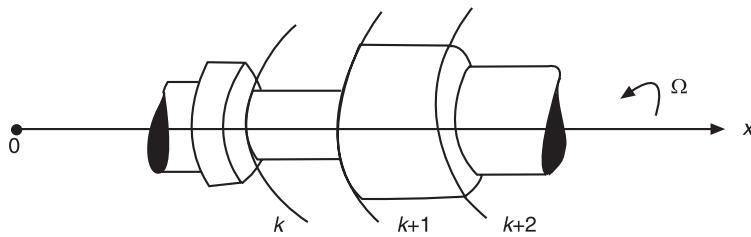

Figure 19 Turning rotor.

where:

$$\mathbf{M}_{k+1} = T_{k+1} \mathbf{M}_k; \quad \mathbf{M}_{k+2} = T_{k+2} \mathbf{M}_{k+1}$$

T are elementary transfer matrices. Between section 0 and section N of the extremity:

$$\mathbf{M}_N = T_N T_{N-1} \dots T_1 \mathbf{M}_0$$

After expressing two conditions at the limits [$C = (C)_l$, $R = (R)_l$], determining the global transfer matrix $T_N T_{N-1} \dots T_1$ leads to the equation with the natural frequency. Natural modes are determined more closely by matrices T . In a forced rate of flow, $c_e = C_e \cos(\omega t + \varphi_e)$ where $c \rightarrow C$; $c_e \rightarrow C_e \exp i\varphi_e$; $r \rightarrow R$.

Eqn [34] becomes:

$$\begin{bmatrix} C_{k+2} \\ R_{k+2} \\ 1 \end{bmatrix} = \begin{bmatrix} 1 & -I_{k+2}^{k+1} \omega^2 & -C_e \exp i\varphi_e \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} C_{k+1} \\ R_{k+1} \\ 1 \end{bmatrix}$$

The global transfer matrix, after expressing two conditions at the limits, leads to two equations with second members which make it possible to calculate C and R using elementary transfer materials. Critical frequencies, or resonances, are determined by variations in ω ; they must be avoided in piston machines excited by periodic forces. Other methods are used which deal with a system of N equations, in the same form as system [32].

ROTOR-STATOR INTERACTIONS

R Bigret, Drancy, France

doi: 10.1006/rwvb.2001.0095

Introduction

The rotor and stator of rotating machinery are connected by elements which enable the rotor to rotate within the stator. Other links insure effective sealing. Forces and displacements are transferred by means of such elements. Forces can also be transmitted by fluids manipulated by rotors, especially turbomachine rotors, as well as by magnetic fields and coupling. These forces and displacements and their variations must guarantee constant stability, low vibratory limits, in particular at critical speed, and rotor-stator distances which are greater than fixed limits but below which the risk of contact is significant. In certain areas the rotor-stator distances are small to avoid a negative effect on the output. Contact can lead to wear and tear, deterioration, and even catastrophe. Particular behavior may be seen as limited cycles of instability or chaotic cycles.

HD Taylor, an engineer for General Electric (New York), published in 1924 *Rubbing Shafts Above and Below the Resonance (Critical Speed)*. In 1925 Thomas, a German engineer, described violent vibrations of a vertical rotor whose critical speed was greater than its nominal speed. In 1926 Newkirk published *Shaft Rubbing*, demonstrating that the speed of significant vibration was less than critical speed, and that this vibration could increase. This was termed the Newkirk effect. These studies, which attempt to explain observations using theoretical models, were the inspiration for numerous publications and research studies.

Contact as a Machine Slows Down

Example

After the alternator has been activated, when a 1000-MW turboalternator rotor slows down from 1500 rpm to ≈ 0 rpm, significant levels of vibration are seen on the bearings of a high-pressure turbine. If it is started up 15 min after being turned to 8 rpm, levels of vibration which are above the limit interrupt operation. If it is changed after 2 h, the positions of the vortices of the high-pressure turbine rotor in

relation to the bearings, measured by relative magnetic captors, go from 41 to 29 μm and from 35 to 20 μm .

The height of the sealing systems at the edges of the high-pressure rotor is increased by 0.3 mm. When the machine starts up and slows down after this point, the levels of vibration are appropriate. These operations support the hypothesis of a rotor peak following anisotropic overheating, caused by contact with sealing systems.

Cycle Limited to Low Frequency and Light Contact

Figures 1 and 2 show the first harmonic of the two relative vibrations measured on-site. A so-called pseudoperiod of ≈ 10 h 30 min can be seen.

Using a theoretical model of the rotor-stator arrangement, as shown in Figure 3, an explanation for the behavior shown in Figures 1 and 2 can be proposed. The equations for the model proposed by Kellenberger are a product of the following essential hypotheses:

- The peak at C is the sum of a mechanical peak ρ_M due to unbalance ($m_r e$) and of a thermal peak ρ_T caused by overheating provoked by rotor-stator contact. A distance of 1°C between two opposing generations of a rotor of diameter 0.5 m, of length 2 m (≈ 3000 kg), yields a neighboring peak of 10 μm (unbalance equivalence: 0.120 kg at 0.25 m).
- On contact the stator applies a force F_f on the rotor, where $F_f = F_R - i\mu F_R$ ($i^2 = -1$; where μ is the coefficient of friction).
- The thermal peak $|\rho_T|$ is proportional to the temperature difference T between two generations of the rotor: $|\rho_T| = \alpha_1 T$ where:

$$\frac{d|\rho_T|}{dt} = \frac{\alpha_1 \alpha_3}{\alpha_2} \mu \frac{\Omega}{\omega_0} \frac{\Phi}{2} |F_R| - \frac{\alpha_4}{\alpha_2 \omega_0} |\rho_T|$$

where: $\omega_0 = \sqrt{k_r/m_r}$; $Q = \alpha_2(dT/dt)\Delta t$ (heat quantity)

$Q = Q_1 - Q_2$; $Q_1 = \alpha_3 \mu \Omega (\Phi/2) |F_R| \Delta t$ (heat quantity received by rotor with friction)
 $Q_2 = \alpha_4 T \Delta t$ (heat quantity supplied by external rotor).

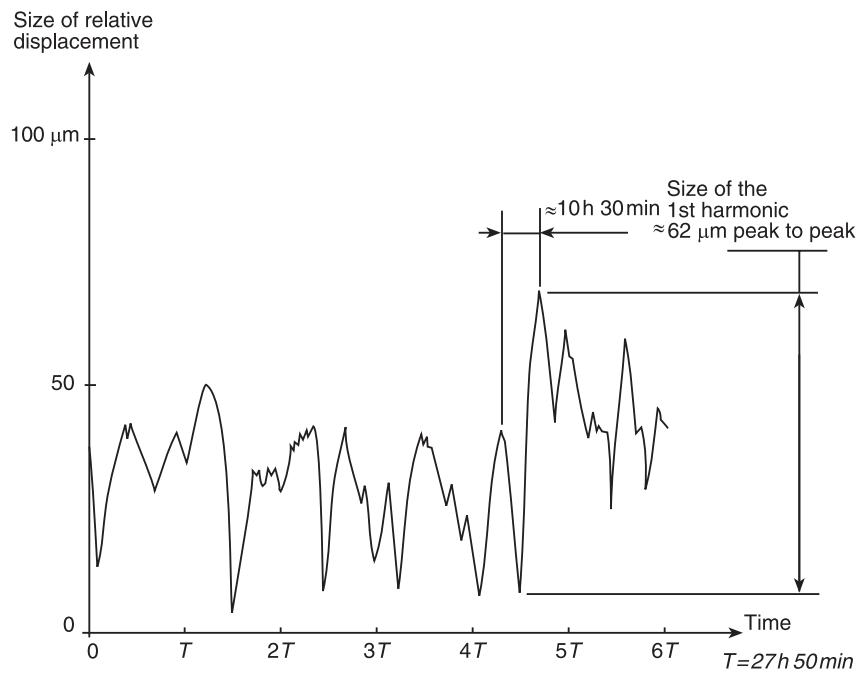

Figure 1 Size of the first harmonic (frequency = rotation speed) of relative displacement of the high-power turboalternator rotor with relation to the labyrinth of the sealing device of the low-pressure body near the alternator.

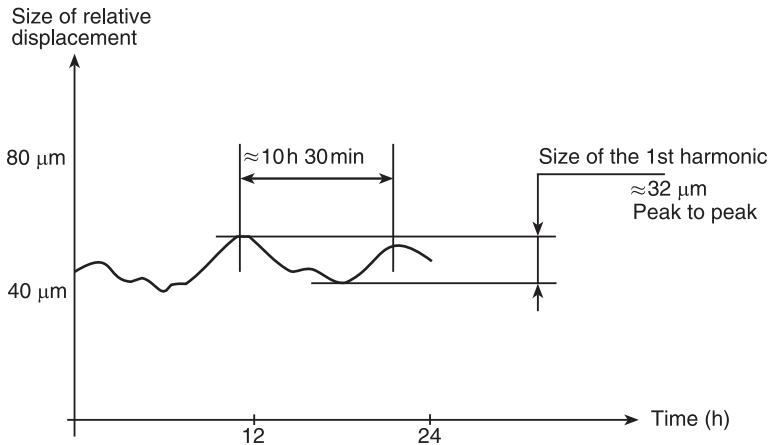

Figure 2 Size of the first harmonic (frequency = rotation speed) of relative displacement of the high-power turboalternator rotor with relation to the bearing arranged between the low-pressure body and the alternator.

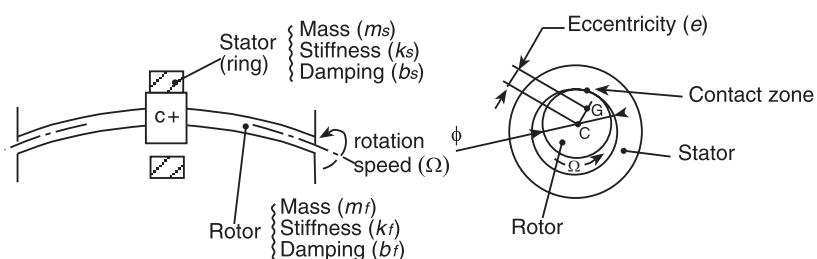

Figure 3 Rotor-stator arrangement in contact. C , geometric center of rotor; G , mass barycenter of rotor.

- ρ_M and ρ_T provoke a rotating force at rotation speed Ω .
- Balance between rotor and stator is expressed by the d'Alembert principle ($\vec{F} = \vec{m}\gamma$).

Admitting F_R , ρ_T , and $d\rho_T/dt$ in the same direction, so that the variations in ρ_T are slow:

$$A \frac{d\rho_T}{d\tau} + B\rho_T = e \left(\frac{\Omega}{\omega_0} \right)^2 \text{ where } \tau = \omega_0 t$$

$$\rho_T = e \left(\frac{\Omega}{\omega_0} \right)^2 \frac{1}{B} \left[1 - \exp \left(-\frac{B}{A} \tau \right) \right] \text{ where } \rho_T(0) = 0$$

A and B are complex numbers which depend on the characteristics of the set. It is stable if the real part of $-B/A$ is negative.

Figure 4 shows the regions of stability and instability. Instability can be seen for $\Omega/\omega_0 < 1$ (see (2) on Figure 4) and for $1 > \Omega/\omega_0 > 1$ (see (1) on Figure 4). In fact, measured observations (Figures 1 and 2) show the range of cycle limits due to nonlinearities excluded from theoretical models. Cycles modulate the range of the first harmonic, of which the frequency equals $\Omega/2\pi$.

In 1926, Newkirk studied the reason for instability at $\Omega/\omega_0 \ll 1$. When rotor speed Ω is less than the first critical flexion speed ($\approx \omega_0$), the phase difference φ between rotating force due to unbalance, and deformation induced by it is between 0 and $\pi/2$,

close to $\pi/2$ for $\Omega = \omega_0$ (resonance). The contact between rotor and stator causes local rotor overheating and so an increase in deformation. The rotating force arising as a result of this deformation is comprised of a rotating force due to unbalance, and this force acts at the angle φ of deformation. Parallel lines to the rotor axis at the stator contact is different from that of preceding phases. The contacts which follow are a result of the same process. They can overheat different parallel lines to the rotor axis, leading to instability.

This subject has led to a number of different studies. The results from theoretical models are similar in quality. Situations vary depending on the hypothesis. Chaos may occur.

Deterministic Contacts

The violent appearances of unbalance following rotor deterioration (broken blade, winding, crack developing) may bring about destructive contacts which require repair and analysis *a posteriori*, after machine shutdown, activated by a protection system which is sensitive to vibration.

Without immediate deterioration, contacts are seen by a transformation in vibratory states (see **Rotating machinery, modal characteristics**).

One particular study shows the influence of clearance. Carried out by Yamamoto in 1954, it

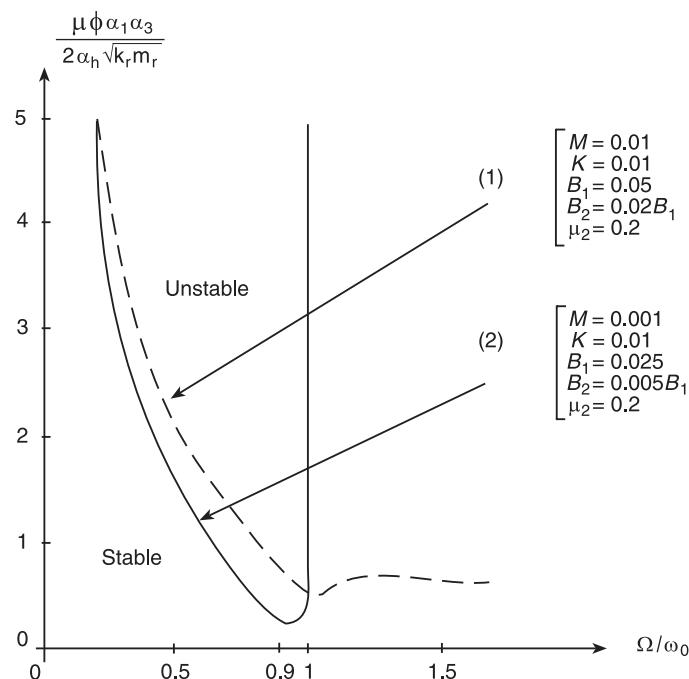

Figure 4 Regions of stability and instability. $M = m_s/m_r$, $K = k_s/k_r$, $B_1 = b_r/\sqrt{k_r/m_r}$ and $B_2 = b_s/\sqrt{k_r/m_r}$.

considered a vertical De Laval rotor (not taking into account gravity) with unbalance me . The stiffness of the shaft, k_a , and the damping coefficient, c , led to $\omega_0 \approx \sqrt{k_a m}$, $\zeta = c/2\sqrt{k_a m}$. The shaft is guided by two cylindrical bearings. Clearance is represented by J . When amplitude A of vibration at rotation speed Ω is less than J , the shaft bending is zero, and the forces perpendicular to the bearings are equal to $k_c A$. When $A > J$, the shaft bending results from k_a and k_c . Figure 5 shows a situation where, with resonance $\Omega \approx \omega_0$; $A/e \approx 1/2\zeta = 20$. This amplitude is close to that of the rotor guided by links, where $J = 0$. Orbit relating to an increase and decrease in speed are very different from each other.

In 1987 Choi and Noah and in 1991 Kim and Noah introduced radial forces to bearings; analyses carried out using a perturbation method essentially confirmed Yamamoto's results.

Theoretical models have been proposed to analyze the vibration behavior. These models comprise elastic, friction, and even damping forces. These forces are expressed by displacement of order 1 (region of linearity), and 2, 3 ... (region of nonlinearity). Other nonlinearities may be taken into consideration, particularly intermittent contacts which may produce chaos.

Malkin has shown that, in a system represented by nonlinear equations, excited at frequency Ω , resonance may occur for Ω such that:

$$u\Omega = \sum_{k=1}^n N_k \omega_k$$

where $u = 1, 2, 3 \dots$; $N_k = 0, \pm 1, \pm 2 \dots$; $\omega_k =$

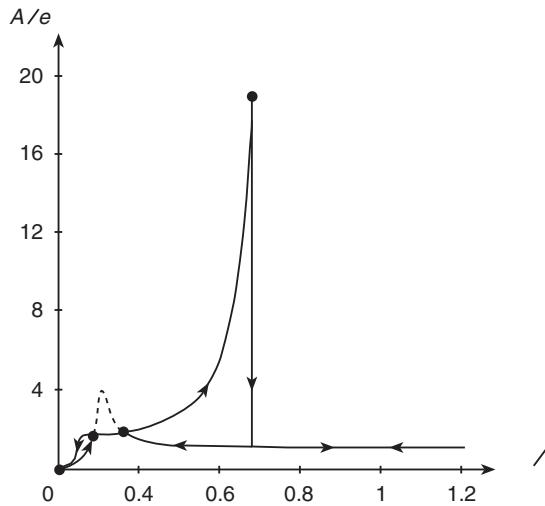

Figure 5 Size A at rotation speed Ω .
 e : eccentricity; $k_c/k_a = 0.04$; $\xi = 0.025$; $J/e = 1.5$.

natural frequency of the associated conservative linear system. This relation allows:

$$\Omega = p\omega_k (p = 1, 2, 3); \quad \Omega = \frac{\omega_k}{u}; \quad \Omega = p \frac{\omega_k}{u}$$

Example 1

A model with elastic nonlinear recall is expressed by:

$$m \frac{d^2y}{dt^2} + k_1 y + k_3 y^3 = me\Omega^2 \cos \Omega t \quad [1]$$

This equation was formulated by Duffing in 1918 (see **Bearing vibrations**).

Research into a solution using perturbation methods ($y = y_1 + \Delta y$) leads to a Mathieu equation $(d^2u/dt^2) + (a - 2q \cos 2\tau)u = 0$. The terms of this equation are dimensionless: $0 < a < \infty$; $-\infty < q < \infty$. Instability appears for:

$$\Omega = \Omega_{\text{ins}} \approx \frac{1}{\sqrt{a}} \omega_0 \sqrt{1 + \frac{3k_3}{2k_1} Y_1^2} \quad [2]$$

where $\omega_0 = \sqrt{k_1/m}$; Y_1 = amplitude where $C_3 = 0$; $a = 1, 4, 9, 16 \dots$ When $(3k_3/2k_1)Y_1^2 \approx 0$, $\Omega_{\text{ins}} \approx \omega_0/\sqrt{a} = \omega_0; \omega_0/2; \omega_0/4 \dots$ The model's forced rate of flow represented by Duffing's equation with damping expressed by $c(dy/dt)$ in eqn [1] was studied by Timoshenko and colleagues.

Around the critical speed, Figure 6 shows the amplitude of the solution $y_1 = Y_{1T} \cos(\Omega t - \psi)$. At the point C_r , the amplitude is violently reduced (in a jump) for a weak variation of Ω according to the pathway $C_r B'$. Around the state C_r the state is unstable.

Y_{1T} is defined by:

$$\frac{3}{4} \frac{k_3}{k_1} Y_{1T}^3 = \left[\left(\frac{\Omega}{\omega_0} \right)^2 - 1 \right] Y_{1T} + e \left(\frac{\Omega}{\omega_0} \right)^2 \sqrt{1 - 2\xi \left(\frac{\omega_0}{\Omega} \right) \frac{Y_{1T}}{e}} \quad [3]$$

where

$$\xi = \frac{c}{2\sqrt{k_1 m}}$$

ψ is defined by

$$\operatorname{tg}(\psi) = \frac{2\xi\Omega/\omega_0}{1 - (\Omega/\omega_0)^2 + \frac{3}{4} \frac{k_3}{k_4} Y_{1T}^2}$$

$(Y_{1T})_{cr}$ is defined by:

$$\frac{(Y_{1T})_{cr}}{e} = \frac{1}{2\xi} \frac{\Omega_{cr}}{\omega_0}$$

$(Y_{1T})_{cr}$ and Ω_{cr} are determined using eqn [3].

When $\xi = 0$, eqn [3] leads to the equation describing the curve C_oC_r (Figure 6). Comparing between eqns [2] and [3] results in: $Y_1 = \sqrt{2}Y_{1T}$.

At the limit of stability, the amplitude Y_1 of movement in the linear range is greater than the amplitude Y_{1T} of movement in the nonlinear range.

Free movement ($me = 0$) of the associated conservative system ($c = 0$) initialized by $y(0) = Y_m$; $dy(0)/dt = 0$, can be seen with the components of frequencies:

$$(2k + 1)\omega_{lk}; k = 0, 1, 2 \dots$$

For the first approximation, where $k = 0$:

$$\frac{3k_3}{4k_1} Y_m^2 = \left(\frac{\omega_{l0}}{\omega_0}\right)^2 - 1$$

This form is identical to that of the curve C_oC_r shown in Figure 6. For the second approximation, where $k = 1$:

$$\frac{3k_3}{4k_1} Y_m^2 - \frac{3}{128} \left(\frac{k_3}{k_1}\right)^2 Y_m^4 = \left(\frac{\omega_{l1}}{\omega_0}\right)^2 - 1$$

ω_{lk} and the amplitudes of components at frequency $(2k + 1)\omega_{lk}$ are defined. For frequencies close to the resonances, severe jumps or instability can occur.

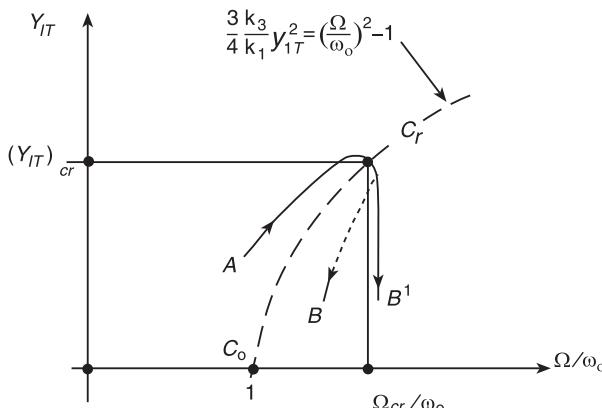

Figure 6 Critical speed where elastic force is $k_1y + k_3y^3$ (eqn [1]) and damping force $c(dy/dt)$.

Example 2

A model with periodic contact is expressed as a first approximation by:

$$m \frac{d^2Z}{dt^2} + c \frac{dZ}{dt} + k_a Z + F(t)K_0 Z = 0 \quad [4]$$

where $Z = y_c + iz_c$, and y_c and z_c are coordinates of the geometric center of the disk. K_0 is stiffness caused by the stator, which may be great in relation to k_a , shaft stiffness. For $F(t)$ a pulse train, pulse width τ_c , period $T_p = 2\pi/\omega$, ω : precessing frequency.

The term $F(t)K_0Z$ appears when the argument $Z = \beta$, where β is the average angular position in relation to the axis 0y of the zone of contact between rotor and stator. Decomposition of the Fourier series $F(t)$ leads to a set of equations originating from eqn [4] and pinpointed by $n = 1, 2 \dots$:

$$\frac{d^2Z}{dt_n^2} + c_n \frac{dZ}{dt_n} + (a_n + 2q_n \cos 2\tau_n)Z = 0 \quad [5]$$

where:

$$\tau_n = \frac{n\omega}{4} [2t - (T_p - \tau_c)]; \quad c_n = \frac{2c}{m\omega_n}$$

$$\begin{aligned} a_n &= \left(\frac{2}{n\omega}\right)^2 \frac{1}{m} \left\{ k_a + K_0 \left[1 - \frac{\omega}{2\pi} (T_p - \tau_c) \right] \right\} \\ &= \left(\frac{2}{n\omega}\right)^2 \omega_{oc}^2 \\ q_n &= \left(\frac{2}{n\omega}\right)^2 \frac{K_0}{m\pi n} \sin \frac{n\omega}{2} (T_p - \tau_c) \end{aligned} \quad [6]$$

Eqn [5] is called Mathieu's equation with damping.

When $c = 0$, for $a_n = a = 1, 4, 9, 16 \dots$ and $q_n = 0$, instability (sometimes designated by parametric resonance) may be seen. When $q_n \neq 0$, the area of instability is even greater, since a_n is low, around 1, 4, 9, 16. Following eqn [5] instability may develop on frequency of precession ω , such that:

$$\omega = \frac{2}{n} \frac{1}{\sqrt{a}} \omega_{oc} \rightarrow \omega_{oc}; \quad \frac{\omega_{oc}}{2}; \quad \frac{\omega_{oc}}{3} \dots$$

This relation neglects the variation of ω_{oc} with ω . For a short length of contact time $\tau_c \omega_{oc} \approx \omega_0 = \sqrt{k_a/m}$. Where $q_n = 0$, stability may be achieved. Frequency components of the precession vibrations are equal to $n\Omega$ when $a = 4, 16 \dots$ and $n\Omega/2$ when $a = 1, 9, 25 \dots$ when $\omega = \Omega$; Ω = rotation speed and $n = 1, 2, 3 \dots$.

When $c \neq 0$, a solution can be reached using numerical calculations. Where:

$$\frac{d^2Z}{dt^2} + (\omega_0^2 - 2q \cos 2\omega t)Z + c \frac{dZ}{dt} = 0$$

and where $\omega_0 = 0.8 \text{ rad s}^{-1}$, $c = 0.06(\text{s}^{-1})$ around $\omega = \omega_0$, $\omega_0/2$, $\omega_0/3$, $\omega_0/4$ the dimensions of areas of instability are less than those corresponding to $c = 0$.

Contact is caused by unbalance, which is neglected here, or by external perturbation. Transient regimes arise once the contact X has been released; contact $X+1$ is reached with initial conditions which have an influence on the behavior of the contact $X+1 \dots$ and on the behavior of the contact $X+2$, $X+3 \dots$. This behavior is the result of nonlinear deterministic equations under initial conditions which depend on the movements that they introduce: deterministic chaos may ensue.

Contacts and Chaos

The collision of stator and rotor may give rise to deterioration which eventually necessitates machine shutdown, or wear and tear and, with time, significant damage.

During the wear-and-tear phase, dangerous vibratory behavior may be recognized as signals in the temporal area and spectra in the frequential area. Numerous studies showed that this behavior may be typical of deterministic chaos.

With regard to rotating machinery, the De Laval rotor is widely used for studies which make it possible to discover the origins of the components whose frequencies are fractions of the rotation speed $\Omega(p/q)\Omega$, where p and q are integers) and of chaotic chance components. The situations are strongly affected by the theoretical model hypothesis and numerical values. In the article on the dynamics of rotating machinery (see **Rotor dynamics**), instability of the cycle limit of precession at a frequency which is close to half rotation frequency is explained by a nonlinear theoretical model.

The following descriptions use the work of Agnes Muszynska and Paul Goldman. The equations of movement perpendicular to the line of rotation are expressed within a fixed referential, following the Newton-d'Alembert principle ($\vec{F} = \vec{m}\vec{\gamma}$).

The behavior of the disk which is in contact with the stator, either with or without friction, is computed by the following equations:

$$\begin{aligned} M \frac{d^2z}{dt^2} + (D + \delta D_f) \frac{dz}{dt} + Kz \\ + \delta K_f(z - c \exp i\psi) + \Delta K(x - iy) \\ + i\delta F_c(1 + a/|z|) \exp i\psi \\ = mr\Omega^2 \exp i(\Omega t + \alpha) + S \exp iy \\ F_\tau = D_c \left(\frac{d\psi}{dt} |z| + \Omega a \right) \\ + f \left[D_f \frac{d|z|}{dt} + K_f(|z| - c) \right] \operatorname{sign} \left(\frac{d\psi}{dt} |z| + \Omega a \right) \end{aligned} \quad [7]$$

where: $z = x + iy$; $i^2 = -1$; x and y are coordinates of the geometric center of the cylindrical disk; M is the disk mass; $2K = K_x + K_y$; K_x , K_y is the global stiffness of the arrangement shaft and links in two perpendicular directions; isotropic shaft (stiffness independent of the azimuth); $2\Delta K = K_x - K_y$; K_f is the stator stiffness; D is the friction coefficient to the right of the disk; D_f is the friction coefficient in contact with the stator; D_c is the friction coefficient at a tangent to the rotor and stator; mr , α is the modulus and angular position of unbalance; Ω is the rotation speed which is constant for each particular value; S , γ is the modulus and angular position with relation to the referential axis x of a force applied at right-angles to the disk; f is the friction coefficient; a is the disk radius; c is the radius clearance between disk and stator; $\psi = \operatorname{arc tg} y/x$.

$$\delta \text{ (Kronecker symbol)} = \begin{cases} 1 & \text{if } |z| \geq c \\ 0 & \text{if } |z| < c \end{cases} \quad |z| = \sqrt{x^2 + y^2}$$

The term $(d\psi/dt)|z| + \Omega a$ which appears in F_τ to express the speed of the point of contact between the rotor and stator; $d\psi/dt$ represents rotation speed of the precession movement of the geometric center of the disk. When $(d\psi/dt)|z| + \Omega a = 0$, the disk rolls over the stator without slipping:

$$\frac{d\psi}{dt} = \frac{-\Omega a}{c}$$

Shaft torsion is not taken into account.

Eqn [7] can be expressed by dimensionless terms in order to determine z/c as a function of Ω/ω_r , where $\omega_r^2 = K_x/M$ or $\omega_r^2 = K/M$ when $K_x = K_y = K$:

$$\begin{aligned} \frac{D}{\sqrt{K_f M}}; \frac{D_f}{\sqrt{K_f M}}; \frac{D_c}{\sqrt{K_f M}}; \\ \frac{K_x}{K_y}; \frac{K_f}{\sqrt{K_x}}; \frac{mr}{Mc}; \alpha; \frac{S}{cK_y}; \gamma \frac{a}{c}; f \end{aligned}$$

Transitory regimes at the start and end of contact are calculated using the following terms which define initial conditions:

- At the beginning of contact:

$$\left(\frac{d|z|/c}{dt} \right)_- ; \quad \left(\frac{d\psi}{dt} \right)_-$$

- At the end of contact:

$$\left(\frac{d|z|/c}{dt} \right)_+ ; \quad \left(\frac{d\psi}{dt} \right)_+$$

The contact time τ_c is calculated. This makes it possible to determine the coefficient of tangential restitution:

$$K\tau = \exp \left(\frac{-aD_c\tau_c}{cM} \right)$$

which, when used with:

$$\left(\frac{d\psi}{dt} \right)_- ; \frac{a}{c}; \frac{\Omega}{\omega_r}; \frac{fa}{c}; \left(\frac{d|z|/c}{dt} \right)_- ; K_n$$

enables one to determine $(d\psi/dt)_+$. The normal coefficient of restitution:

$$K_n = - \frac{\left(\frac{d|z|/c}{dt} \right)_+}{\left(\frac{d|z|/c}{dt} \right)_-}$$

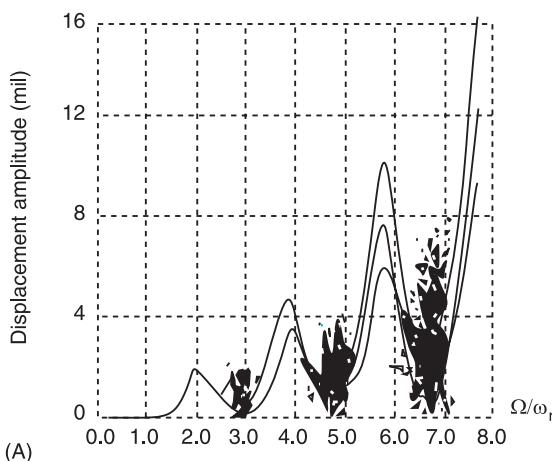

Figure 7 Contact without friction.

is defined as a function of $\xi = D_f/2\sqrt{K_f M}$ linked to friction (D_f) with stator and with stiffness (K_f).

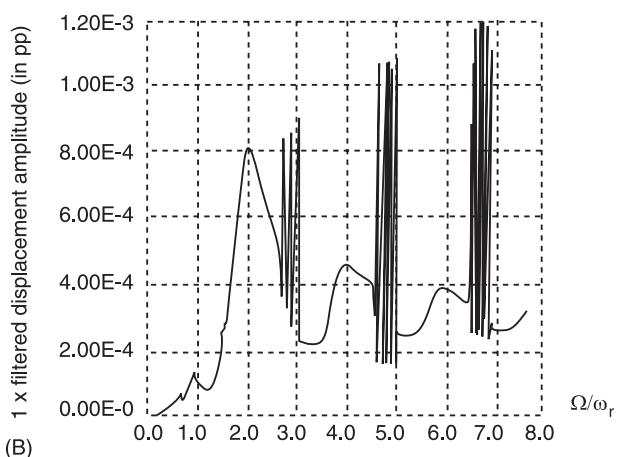

Calculations are carried out in numerical order with a speed increase equal to 30 rpm, after 200 revolutions to avoid temporary ratings. Signals are sampled once they have been categorized into harmonic, subharmonic, or chaotic. As an indication, Figure 7 shows contact without friction.

The ordinates represent elongations measured at each revolution of the rotor. The procedure utilizes a stroboscope. From Figure 7A it can be seen that:

- where $\Omega/\omega_r \leq 2.6$, the fundamental frequency of the signal is equal to Ω ; harmonic components exist: $k\Omega$ ($k = 1, 2 \dots$)
- when $2.6 \leq \Omega/\omega_r \leq 3.1$, the signal is erratic (there is chaos)
- when $3.1 \leq \Omega/\omega_r \leq 4.2$, the fundamental frequency of the signal is equal to $\Omega/2$; harmonic components exist: $k\Omega/2$
- when $4.2 \leq \Omega/\omega_r \leq 5.1$, the signal is erratic (there is chaos)
- when $5.1 \leq \Omega/\omega_r \leq 6.2$, the fundamental frequency of the signal is equal to $\Omega/3$; harmonic components exist: $k\Omega/3$

This procedure is used in Figures 7B and 8A-D. The abscissa Ω/ω_r in Figure 7A and 8D is the stochastic parameter. Bifurcations are seen between the chaotic zones, which are unstable and chaotic.

Figure 7B shows the maxima of the fundamental component around $\Omega/\omega_r = n$ (where $n = 1, 2, 4, 6$); this component frequency is always equal to Ω . Where $n = 1$, the fundamental component frequency is ω_r . When $n = 2$, the fundamental component frequency is $2\omega_r$: its period is double the rotation period: there is one oscillation for every two revolutions.

When $n = 4$ there is one oscillation for every four revolutions: the resonance is subharmonic. Chaotic zones appear around $\Omega/\omega_r = 3, 5, 7$, beyond $\Omega/\omega_r \approx 2.5$.

Figure 8A-D shows contact with friction. Figure 8A and B depict chaotic zones where $\Omega/\omega_r \gtrsim 2.5$. Precession paths are shown. Figure 8C and 8D shows the amplitude of the fundamental frequency components which are equal to Ω and $\Omega/2$.

Consider the De Laval rotor (shaft disk stiffness K_1 and K_2 , mass M , damping coefficient D_1 , force S at angle γ , and unbalance mr at 0°) guided by a link with zero perpendicular vibrations, and by a rotor of mass M_t (damping coefficient D_2) on friction (coefficient f) within a bearing (radius a , clearance c). There are

small regions of speeds mainly around the rotation speed or twice where chaotic regimes may occur.

Analysis of measurements obtained on machines which have configurations like a De Laval rotor make it possible to describe, in temporal and frequential domains, forms similar to those originating from theoretical models. These theoretical models use numerical values but it is difficult to know the accuracy as related to physical values, in particular stiffness and damping coefficients at contact.

Chaos

The preceding section discussed vibration of a De Laval rotor. Chaotic behavior may be seen here,

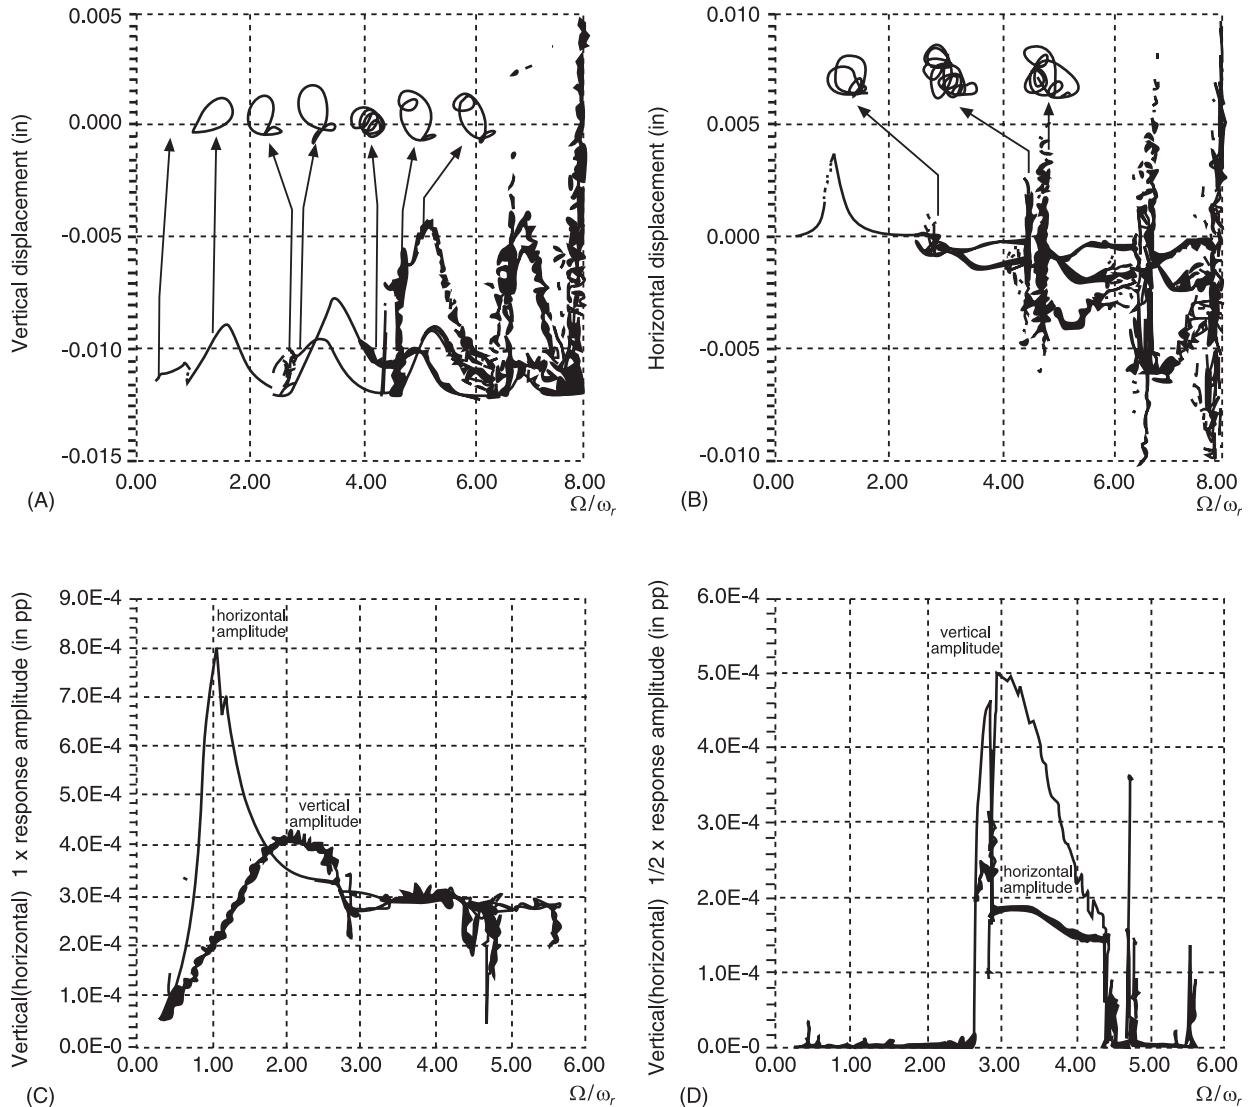

Figure 8 Contact with friction.

as well as in other systems. This section gives three such examples.

Consider a horizontal magnetic needle on a pivot, acted on by a fixed magnetic field, and a magnetic field which is turning at constant speed, at frequency f_r , around the pivot. The natural frequency of the needle in the fixed field is designated f_0 . The fields are very close to the horizontal plane of the needle. For different values of f_r , the needle is strobed at frequency f_0 . When only one position is determined, the needle oscillates at frequency f_0 . Its movement may be described by the components of frequency kf_0 , where $k = 1, 2, 3, \dots$. When two positions are determined, the needle oscillates at frequency $f_0/2$, where components are $k(f_0/2), \dots$. At 2^n position, $k(f_0/2^n)$ components are associated.

For certain values of the stochasticity parameter f_r/f_0 , erratic, chaotic behavior appears: the Fourier spectrum is continuous. The needle oscillates around the fixed field or rotating field. This behavior can be described by $f(x) = 4\lambda x(1-x)$ by an iterative process: $x_0 \rightarrow f(x_0) = x_1 \rightarrow f(x_1) = x_2, \dots$. For $\lambda < 3/4$ measurement is characterized by one frequency; for $0.86 > \lambda > 3/4$ by two frequencies.

Consider a car driven by two persons F and H . Speed V is defined by:

$$\frac{dV}{dt} = aV + bV^2$$

a is defined by F , b by H at the moments $t_0 + n\tau$, where $n = 1, 2, 3, \dots$. Speed V_0 is the result of an iterative process around the higher speed limit V_l . Let us consider:

$$\frac{V_{n+1}}{V_l} = \mu \frac{V_n}{V_l} \left(1 - \frac{V_n}{V_l}\right)$$

where:

$$\mu = 1 + a\tau \quad \frac{b\tau V_l}{1 + a\tau} = -1$$

given that:

$$a = \frac{\mu - 1}{\tau}; \quad b = -\frac{1}{V_l} \left(a + \frac{1}{\tau}\right)$$

μ is the stochasticity parameter; F induces acceleration when $a > 0$; H induces slowing down when $b < 0$. When $\tau = (1/100)^h$, $V_l = 130 \text{ km h}^{-1}$:

- when $\mu = 2$, stability is insured: $V_n/V_l = 0.5$
- when $\mu = 3.3$, speed varies between 62.4 and 107.9 km h^{-1} in a period equal to 2τ

- when $\mu = 3.7$, there is chaos when $V_{\max} = 120.25 \text{ km h}^{-1}$
- when $\mu = 3.83$, speed varies between 21 and 65 km h^{-1} in a period equal to 4τ

Frequencies $1/2\tau$ and $1/4\tau$ can be seen.

Consider a pendulum represented by:

$$I\ddot{\theta} + c\dot{\theta} + mlg \sin \theta = 0$$

where I is the moment of inertia; c is the damping coefficient; l is the length of the cord; m is the mass; g is the acceleration of gravity; and θ is the angle with relation to vertical.

In Santiago de Compostela, in Galicia, Spain, men manipulate the pendulum:

$$l = l_0 + \Delta l \cos \omega_D t$$

As a result, the model becomes:

$$\begin{aligned} \dot{\omega} &= -\frac{c}{I}\omega - \frac{ml_0 g}{I} \sin \theta - \frac{mlg}{I} \Delta l \sin \theta \cos \phi \\ \dot{\theta} &= \omega; \quad \dot{\phi} = \omega_D \end{aligned}$$

Adopting a simplified form with direct excitation on the mass solid, m :

$$ml^2 \ddot{\phi} = -c\omega - mlg \sin \theta + M \cos \omega_D t$$

where $\dot{\theta} = \omega$ and $\dot{\phi} = \omega_D$:

$$\frac{\dot{\omega}}{\omega_0^2} = -\frac{c}{ml^2} \frac{\omega}{\omega_0^2} - \sin \theta + \frac{M}{ml^2 \omega_0^2} \sin \frac{\omega_D \tau}{\omega_0}$$

where $\omega_0^2 = g/l$ and $\omega_0 t = \tau$:

$$\frac{\dot{\theta}}{\omega_0} = \frac{\omega}{\omega_0}; \quad \frac{\dot{\phi}}{\omega_0} = \frac{\omega_D}{\omega_0}$$

Table 1 shows the characteristics of movement of the mass solid m as a function of stochasticity parameter $M/ml^2 \omega_0^2$.

Misalignment

Misalignment and Nonlinearity

Static forces on the bearings of a rotor guided by two links are the result of external forces: the system is isostatic. When the number of links is greater than two, static forces result from the relative positions of the links, from their impedance, and external forces: the system is hyperstatic. Variations in the relative

positions may come about as a result of deformation of casings and foundations through deterioration and thermal gradients.

The force perpendicular to a link helps to define the average position of the center of the vortex within a fluid bearing. Around this position the vibratory components may be described by nonlinear equations. Thus the vibration spectra has many harmonics.

Roller Bearings

The force at right-angles to a rolling link plays a part in its lifespan, which may be very short when the force is significant. **Figure 9** depicts an arrangement of rotor, roller bearings, and bearings. When there is vertical displacement, δ imposes by misalignment on the third bearing force F_r , which, applied to the roller bearing, is defined by:

$$F_r = \frac{k_r/k_a}{1 + k_r/k_a} \delta ka; 0 < F_r < \delta k_a$$

where $k_r = 0$; $F_r = 0$ and where $k_r \rightarrow \infty$; $F_r < \delta k_a$.

This force reduces the lifespan. It may lead to the rapid destruction of the rolling bearing.

The stiffness k_a of a rotor of 1000 kg of natural frequency which is equal to 100 rad s⁻¹ (≈ 16 Hz) is equal to $10^4 \times 10^3 = 10^7$ N m⁻¹. Where $k_r = \infty$, dis-

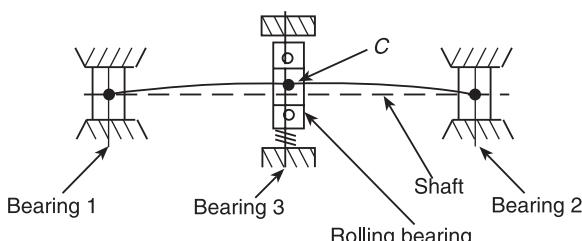

Figure 9 Rolling bearing. Shaft stiffness at $C = k_a$. Stiffness between bearing and rolling bearing k_r .

placement $\delta = 1$ mm induces a force of 10^4 N, close to its weight (9.81×10^3 N). Flexible couplings between two rotors make it possible to reduce hyperstaticity, as well as to reduce forces within the roller bearings caused by eventual relative displacements between links and avoiding destructive nonlinearities. Thus, misalignments within the couplings may provoke their deterioration and raised vibratory levels. Couplings may also be affected by faults which require maintenance operations.

Hyperstaticity and Instability

High-power machines, in particular power generating turboalternators producing electric energy, are generally made up of horizontal rotors (high- or low-pressure, and alternators) which are rigidly coupled together. Variations in relative positions of the bearings (misalignment) which contain oil bearings cause variations in radial static forces. For a 1000-MW turboalternator operating at 1500 rpm, relative variations of forces caused by relative vertical displacements of the 1-mm bearings may be included between:

- 0 and 90% when the rotor is guided by 10 bearings
- 0 and 20% when the rotor is guided by 6 bearings

With regard to the limits of stability and amplitude at critical speed, it may be more problematic to achieve alignment with 6 bearings than with 10 bearings.

Misalignment can lead to nonlinear behavior due to squeezing of films of oil as a result of variations in amplitude at frequency rotation f_r (first harmonic) and harmonic frequencies (nf_r where $n = 2, 3 \dots$). Equally, it may lead to instability, or whip, in limit cycles where the amplitude may be significant and dangerous. This instability may be seen when the distance between the center of a vortex and the center of a cylindrical bearing is small. Variations in amplitude of the first harmonic resulting from misalignment must not be confused with those arising from variation in unbalances (see **Balancing**). Misalignment may cause contact between rotor and stator.

Example: rotor on three bearings **Figure 10** shows a rotor and bearings.

Table 2 defines rotation speed Ω_l and the limit of stability obtained by linear equations in which stiffness and damping coefficients depend on m and λ . Misalignment of 20 μm increases the speed limit of stability. A 10°C increase in temperature in the 0.2-m high bearing causes 20 μm misalignment, which increases the speed limit of stability.

Example: rotor on four bearings Figure 11 shows an arrangement of rotor, links, and structure. Figure 12 shows the real part δ and the imaginary part ω of the complex natural frequency $p = \delta + i\omega$ calculus (see **Rotor dynamics**). Instability can be seen where $d/J \approx 2.25(d \approx 0.67 \text{ mm})$ at bearing 2, $d/J \approx 0.5(d \approx 0.15 \text{ mm})$ at bearing 3. The frequency of instability is close to 130 rad s^{-1} if:

$$\Omega_{rl}/\omega_{ins} \approx 314/130 = 2.42, \text{ where } \omega_{ins}/\Omega_{rl} \approx 0.41$$

With normal alignment, where $d/J = 0$, natural frequency ω_n is close to 175 rad s^{-1} :

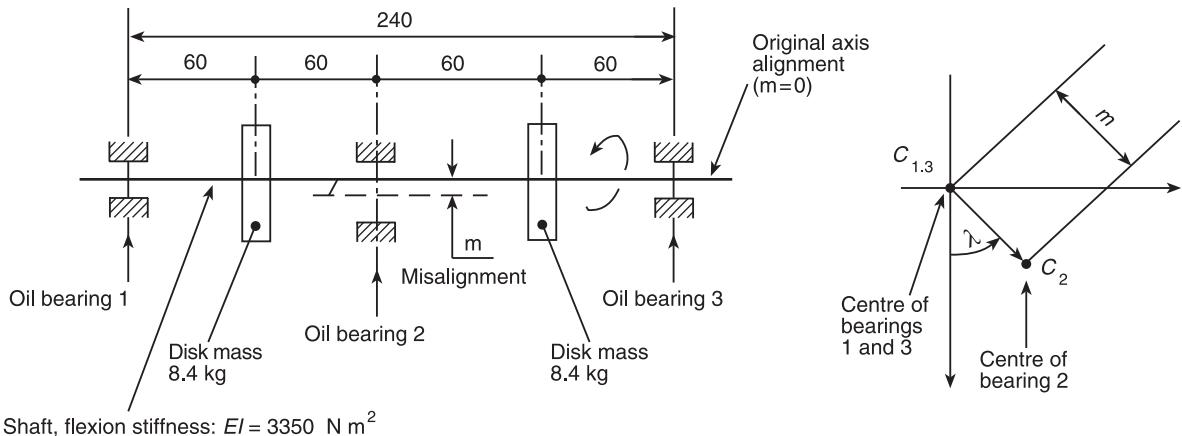

$$\omega_{ins}/\omega_r \approx 130/175 \approx 0.74.$$

Critical speed is $\approx 1670 \text{ rpm}$.

Table 2 Limit of stability

$m(\mu\text{m})$	$\lambda (\text{°})$	Clearance = $25 \mu\text{m}$	$\Omega_l (\text{Hz})$
0		0	~ 300
5	225	0.2	~ 230
20	110–270	0.8	360–450

In the hyperstatic rotor-stator arrangements described above, variation in speed limits of stability is caused by variation in static forces perpendicular to the bearings. This variation is a result of misalignment of the bearings subject to deformations of the stators or structures. It may arise through variation of the position of the sealant systems; and variation of the aerodynamic radial forces in the turbines, com-

pressors, and pumps, linked to their conditions of function (flow, pressure). Temperature variation of fluid pressure supplying the bearings may also cause instability.

Deterioration in the Supports and Foundation

There may be deterioration in the metallic supports, such as cracks, or fractures of soldering or anchoring bolts, and cracks and disintegration in the concrete foundations. This may lead to critical speed or resonance in the domain of machine rotation speed, and so too vibration above fixed limits.

Seismic Excitation

A rotating machine senses earth movement through the foundation on which its base is placed. Misalignments may result, as well as seismic vibrations. As an example, the theoretical model of a De Laval rotor guided by two cylindrical bearings within a fixed referential is defined by the following equations:

$$\begin{aligned} m \frac{d^2x}{dt^2} + k(x - x_c) &= -m \frac{d^2x_m}{dt^2} + mg \\ m \frac{d^2y}{dt^2} + k(y - y_c) &= -m \frac{d^2y_m}{dt^2} \\ k(x - x_c) + 2F_x &= 0 \\ k(y - y_c) + 2F_y &= 0 \end{aligned}$$

where x, y are displacement components from the disk center; x_c, y_c are displacement components from the journal center; x_m, y_m are displacement components from the foundation imposed on the seismic vibrations; m is the disk mass (4.4×10^4 kg); k is shaft stiffness

$$N_c = \frac{1}{2\pi} \sqrt{\frac{k}{m}} = \frac{1}{2\pi} \omega_c = 600 \text{ cycle min}^{-1}$$

g is gravity acceleration (9.81 m s^{-2}); F_x, F_y are components of force imposed on the shaft by oil bearings ($L = 331 \text{ mm}$; $L/D = 0.5$; 2 clearance/ $D = 0.003$; $y = 5.6 \times 10^{-3} \text{ Pa s}$); Ω is rotation speed (nominal 3600 rpm).

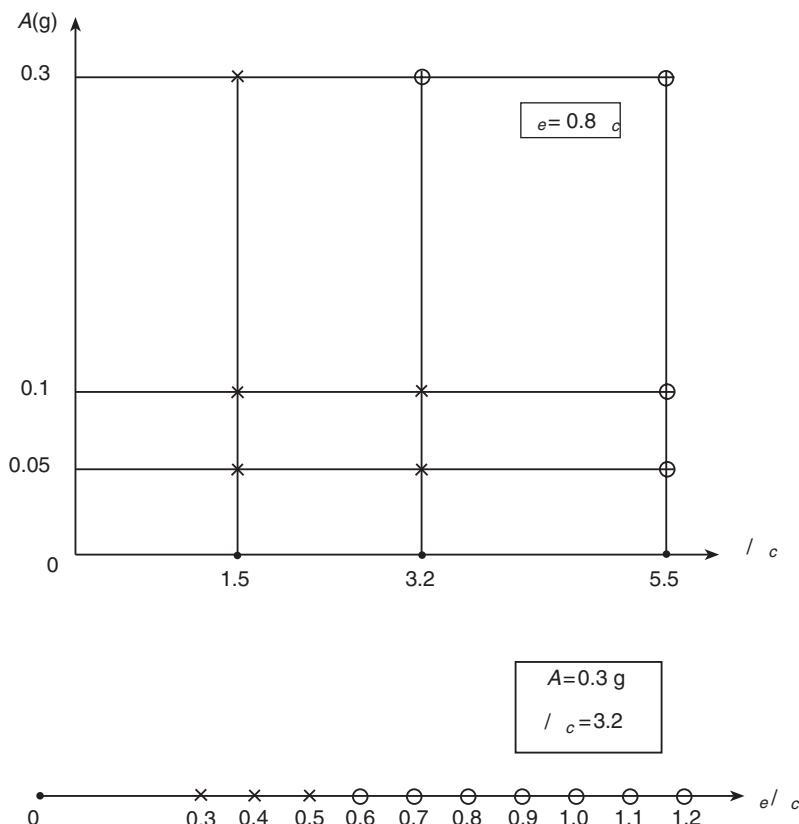

Figure 13 Earthquake upheaval. Crosses, stability; circles, instability.

Natural frequencies of the free rotor

$$\frac{d^2x_m}{dt^2} = \frac{d^2y_m}{dt^2} = 0$$

where $\Omega/\omega_c = 3.2$, are calculated modeling the bearings by stiffness and damping coefficients, or linearization.

$$i^2 = -1$$

$$p_l = \delta_l \pm i\omega_l$$

$$\delta_l/\omega_c = -0.0039; -0.0016; -5.56$$

$$\omega_l/\omega_c = 0.746; 0.953; 0.535$$

Stability is insured ($\delta_l < 0$); $\delta_l/\omega_c = 0$ (instability) where $\Omega_{\text{inst}}/\omega_c = 4.714$. When:

$$\frac{d^2x_m}{dt^2} = 0;$$

$$\frac{d^2y_m}{dt^2} = \begin{cases} A \sin \omega_c t & \text{where } 0 \leq t \leq 2\pi/\omega_c \\ 0 & \text{where } 0 > t > 2\pi/\omega_c \end{cases}$$

F_x and F_y are calculated using the equation and conditions at Reynolds limits (see **Bearing vibrations**). Nonlinearities are taken into account.

The equation system is solved by the Runge-Kutta-Gill method with a step equal to 0.002 s. Instability can be seen by displacement of the vortex center on cycle limits of the radius equal to the clearance. Figure 13 shows conditions of stability and instability.

In a free state instability is seen for $N \geq N_{\text{inst}} = 4.714 \times 600 = 2828$ rpm. In a state which is disturbed by a seismic vibration of amplitude at 0.3 g and frequency $\omega_l = 0.8\omega_c = 76.4 \text{ rad s}^{-1}$ (480 cycle min⁻¹) instability can be seen for $N \geq N_{\text{inst}} = 3.2 \times 600 = 1920$ rpm.

This chapter addresses a number of user and/or environmental issues that often affect the quality of measurements. The five main issues considered here are accelerometer cross-axis sensitivity, the basic behavior of a force transducer when used in three common test environments, the effect of bending moment sensitivity, and the removal of force transducer mass loading effects on measured frequency response function (FRF) data. In addition, a list of small items from cable noise to temperature effects are reviewed. This chapter delineates effects that have been clearly identified over the past 10 years.

Cross-axis Sensitivity

Transducers are usually sensitive to the input variable in a plane perpendicular to the design sensing direction. In piezoelectric-based transducers, this cross-axis sensitivity is mainly due to contact surface irregularities between the piezoelectric crystals and their mating surfaces, while for strain gauge-based transducers it is due to slight strain gauge misalignment.

Single Accelerometer Cross-axis Sensitivity

McConnell and Han (1991) developed a model to explain cross-axis sensitivity. Consider the orientation of the effective sensing axis (S_o) relative to the designed sensing direction (z) and the xy cross-axis plane for an accelerometer, as shown in Figure 1. The sensitivity vector \mathbf{S}_o is given by:

$$\begin{aligned}\mathbf{S}_o = & \{S_o \sin (\phi) \cos (\theta)\}\mathbf{i} \\ & + \{S_o \sin (\phi) \sin (\theta)\}\mathbf{j} \\ & + \{S_o \cos (\phi)\}\mathbf{k}\end{aligned}\quad [1]$$

while the corresponding transducer acceleration can be written as:

$$\mathbf{a} = a_x\mathbf{i} + a_y\mathbf{j} + a_z\mathbf{k} \quad [2]$$

The output voltage is proportional to the dot product of these two vectors, giving:

$$\begin{aligned}E_z = K\mathbf{S}_o \cdot \mathbf{a} &= (KS_o) \\ &= [\{\sin (\phi) \cos (\theta)\}a_x \\ &\quad + \{\sin (\phi) \sin (\theta)\}a_y + \cos (\phi)a_z]\end{aligned}\quad [3]$$

or:

$$E_z = S_{zx}a_x + S_{zy}a_y + S_{zz}a_z \quad [4]$$

When the angle ϕ is small so that $\sin (\phi) < 0.06$, the sensitivities become:

$$\begin{aligned}S_{zx} &= (KS_o) \sin (\phi) \cos (\theta) \cong (KS_o\phi) \cos (\theta) \\ S_{zy} &= (KS_o) \sin (\phi) \sin (\theta) \cong (KS_o\phi) \sin (\theta) \\ S_{zz} &= (KS_o) \cos (\phi) \cong (KS_o)\end{aligned}\quad [5]$$

It is clearly evident from eqn [4] that the output signal is contaminated by the cross-axis terms. These contamination terms can be very large when the a_z acceleration component is small compared to the resultant in-plane acceleration component. For example, let $a_z = 1.0\text{ g}$ while the in-plane acceleration component is 100 g . Then, a 5% cross-axis sensitivity gives a maximum output signal 6 g , an error of 6 vs 1. Hence, it is good practice to use a triaxial accelerometer in unknown acceleration situations so that potential measurement errors reveal themselves.

Triaxial Accelerometer Cross-axis Sensitivity

When eqn [4] is applied to a triaxial accelerometer, the resulting output voltage equations become:

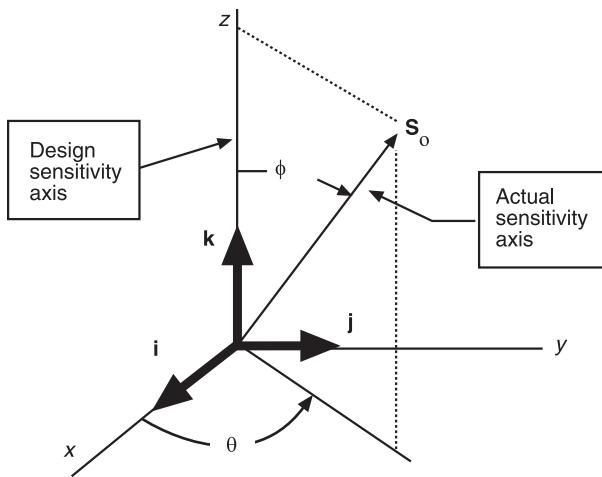

Figure 1 Orientation of design sensitivity axis and actual sensitivity axis creating cross-axis sensitivity due to xy -plane acceleration components. Reproduced with permission from McConnell KG and Han SB (1991) *Proceedings of the 9th International Modal Analysis Conference*, Society for Experimental Mechanics.

$$\begin{aligned} E_x &= S_{xx}a_x + S_{xy}a_y + S_{xz}a_z \\ E_y &= S_{yx}a_x + S_{yy}a_y + S_{yz}a_z \\ E_z &= S_{zx}a_x + S_{zy}a_y + S_{zz}a_z \end{aligned} \quad [6]$$

Then, dividing the p th equation by its dominant sensitivity S_{pp} in eqn [6], the result is the apparent p th acceleration b_p for $p = x, y$, and z , respectively. This gives the apparent acceleration \mathbf{b} as:

$$\mathbf{b} = \boldsymbol{\varepsilon} \mathbf{a} \quad [7]$$

where $\varepsilon_{pq} = S_{pq}/S_{pp}$ is the cross-axis sensitivity ratio and $\varepsilon_{pp} = 1.0$ is the design axis sensitivity ratio. Then, the actual accelerations can be estimated from:

$$\mathbf{a} = \boldsymbol{\varepsilon}^{-1}\mathbf{b} \quad [8]$$

where $\boldsymbol{\varepsilon}^{-1}$ is the correction matrix. Most commercial triaxial accelerometers have cross-axis values of ε_{pq} limited to $\pm 5\%$, so that eqn [8] can be approximated by:

$$\begin{aligned} a_x &= +b_x - \varepsilon_{xy}b_y - \varepsilon_{xz}b_z \\ a_y &= -\varepsilon_{yx}b_x + b_y - \varepsilon_{yz}b_z \\ a_z &= -\varepsilon_{zx}b_x - \varepsilon_{zy}b_y + b_z \end{aligned} \quad [9]$$

The major difficulty with these correction schemes is that the values of ε_{pq} often change with transducer use, particularly with high levels of acceleration.

Removing Cross-axis Contamination from FRF Measurements

It has been shown by Han and McConnell (1989, 1991) that cross-axis sensitivity can cause false mode shapes and natural frequencies to be measured when doing experimental modal analysis. These effects can be effectively removed by using eqn [9] to correct the measured FRF's, as demonstrated by their example using the free-free beam shown in Figure 2. Here, a triaxial accelerometer is attached at the left-hand end, the x -axis is along the beam's length, the y -axis is out of the page, and the z -axis is vertical. Node 1 is at the left end and node 24 is at the right end. The input direction S is inclined about 42° above the y -axis. The uncompensated magnitude and phase FRF data for the y -direction's first natural frequency are shown in Figure 3 when the beam is impacted in the S direction. A false peak and valley occur at points A and B that look like a resonance condition in the y -direction. The peak at A corresponds to the beam's first natural frequency in the z -direction, while the large peak corresponds to the beam's first natural frequency in the y -direction. The data correction scheme of eqn [9] removes this false data in both magnitude and phase so that only the correct information for the y -direction remains. When wide-band data including

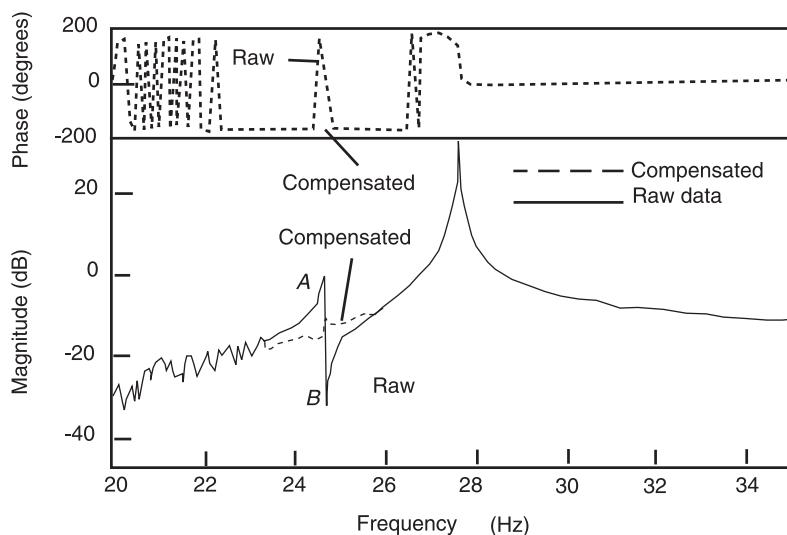

Figure 3 *y*-direction FRF acceleration magnitude and phase for *S*-direction input showing raw and compensated results where the false peak and valley are completely removed. Reproduced with permission from McConnell KG and Han SB (1991) *Proceedings of the 9th International Modal Analysis Conference*, Society for Experimental Mechanics.

the first four natural frequencies were taken and analyzed, the modal analysis program was fooled into reporting seven natural frequencies and mode shapes when there should only be four natural frequencies and mode shapes for the *y*-direction data. The presence of the three extra mode shapes caused severe distortions in the modal parameter estimates. The same modal analysis software reported the correct four natural frequencies, mode shapes, and damping estimates over the same frequency range when the cross-axis corrections were applied to the measured FRFs. It should be noted that the first two natural frequencies appeared as a single natural frequency for the first mode since the wide-band frequency analysis had a Δf that smeared these two peaks together. Consequently, it is important to measure sufficient data to determine if cross-axis signal contamination is occurring and to take appropriate action to correct the data if serious contamination is occurring.

Force Transducers

The accelerometer's main effect on measurements is its inertia, which can shift the natural frequencies of light-weight structures. However, the force transducer can and often does interact significantly with the structures under test since the transducer is connected between two different structures, one on each side. We shall explore the effects of this interaction for three different types of applications: the rigid foundation, the impact hammer, and attached between an exciter and the structure under test, as described by McConnell (1993).

Rigid Foundation

The force transducer is mounted on a rigid foundation, as shown in Figure 4. The mathematical model representing this situation is given by eqn [1] from **Transducers for absolute motion** as:

$$m\ddot{z} + c\dot{z} + kz = F(t) - m\ddot{x} \quad [10]$$

where base excitation \ddot{x} is zero due to the rigid foundation. In this case, the frequency domain relative motion is given by:

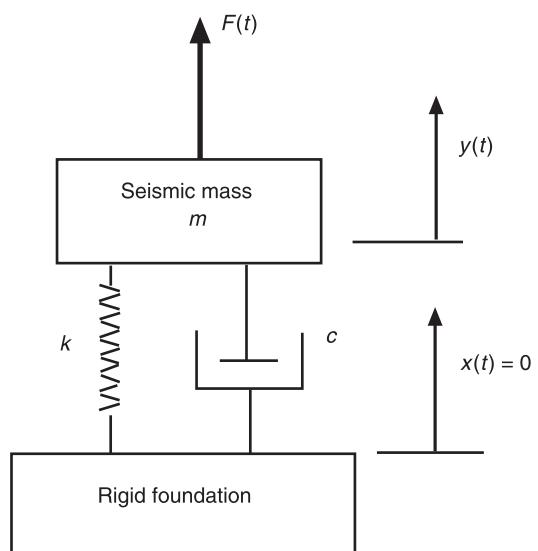

Figure 4 The force transducer mounted on a rigid foundation so that $x = 0$ and $z = y$.

$$z(\omega) = \frac{F(\omega)}{k - m\omega^2 + jc\omega} \quad [11]$$

This is the classical single-degree-of-freedom (SDOF) model with mechanical resonance that is affected by any attachment mass that is used. This mass must be added to the instrument's seismic mass and included in the inertia parameter m . Hence, the instrument will respond within 5% of the applied force as long as the frequency of that force is $< 0.2\omega_n$.

Force Transducer Attached to a Hammer

The physical arrangement of a force transducer attached to an impact hammer is shown schematically in Figure 5. In this case the transducer's seismic mass is increased due to the impact head so that $m_1 = m + m_{\text{head}}$ while the base mass is increased by the hammer body mass so that $m_2 = m_{\text{base}} + m_{\text{hammer}}$. Then, using eqn [1] and noting that the base acceleration \ddot{x} is the applied force divided by the total mass, the effective voltage sensitivity (S_f^*) of the hammer is related to the load cell's voltage sensitivity (S_f) by:

$$S_f^* = \left[\frac{m_2}{m_1 + m_2} \right] S_f \quad [12]$$

Eqn [12] shows that the effective sensitivity is changed when either the impact head and/or the hammer body mass are changed. In most situations, the hammer body mass is much larger than the

impact head mass so it is the body mass change that causes the largest change in the effective voltage sensitivity. Han and McConnell (1986) have verified eqn [12] over a broad range of mass ratios (m_2/m_1) from near unity to over 10. When dealing with very small impact hammers, the operator's hand mass can significantly contribute to mass, m_2 . Hence, in these cases, the person using the hammer should be the person who calibrates it so any hand mass effects are accounted for.

Force Transducer Used with a Vibration Exciter and Stinger

The force transducer is attached directly to the structure under test (SUT) on one end and the other end is attached to a vibration exciter through a stinger, as shown in Figure 6A. The corresponding free body diagram (FBD) and motions are shown in Figure 6B. For this case, the analysis starts with eqn [2] from **Transducers for absolute motion**, which is written here in the frequency domain as:

$$(jc\omega + k)z(\omega) = F(\omega) - m\ddot{y}(\omega) \quad [13]$$

where k , c , and m are the force transducer's parameters. In this case, the seismic mass acceleration $\ddot{y}(\omega)$ is related to the structure's driving point acceleration $A_s(\omega)$ and the interface force $F(\omega)$ by:

$$\ddot{y}(\omega) = A_s(\omega)F(\omega) \quad [14]$$

Combining eqns [13] and (14) gives the transducer voltage as:

$$E_f(\omega) = S_f H_f(\omega)[1 - mA_s(\omega)]F(\omega) \quad [15]$$

where the transducer's mechanical FRF $H_f(\omega)$ is given by:

$$H_f(\omega) = \frac{k}{k + j\omega} \quad [16]$$

Eqn [15] shows that the largest effect of the $mA_s(\omega)$ term occurs when the accelerance is most significant at the SUT's resonant conditions, the region where the SUT's dynamic behavior is of greatest interest.

In order to illustrate the nature of these errors, McConnell (1990) used a SDOF structural system with a driving point accelerance given by:

$$A_s(\omega) = \frac{-\omega^2}{k_s - m_s\omega^2 + j\zeta_s\omega} \quad [17]$$

where the s subscript refers to the SUT. Then, the error ratio (ER) of actual measured voltage divided by the correct measured voltage can be shown to be:

$$\begin{aligned} \frac{\tilde{E}_f(\omega)}{E_f(\omega)} = ER &= \left[\frac{k_s - m_s\omega^2 + j\zeta_s\omega}{k_s - (m_s + m_1)\omega^2 + j\zeta_s\omega} \right] \\ &= \left[\frac{1 - r^2 + 2j\zeta_s r}{1 - (1 + M)r^2 + 2j\zeta_s r} \right] \end{aligned} \quad [18]$$

where M is the mass ratio of m_1/m_s , ζ_s is the structural damping, and $r = \omega/\omega_{ns}$ is the dimensionless frequency ratio based on the SUT's natural frequency. The magnitude and phase of eqn [18] are plotted in Figure 7 for a mass ratio $M = 0.01$ and structural damping of 0.01 in the region of the SUT's resonance. It is seen that the error ratio peaks at 1.269 just before resonance and has a minimum of 0.783 at resonance when the numerator of eqn [18] is a minimum. A rather rapidly changing phase angle is also seen to occur. This plus 27% and minus 22% change in measured force near the resonance conditions can lead to slight shifts in measured natural frequency and possibly the damping estimates when using this data for experimental modal analysis.

Bending Moment Sensitivity of Force Transducers

Force transducers have both bending moment and shear force sensitivity. This sensitivity is dependent on the direction of the shear force and bending

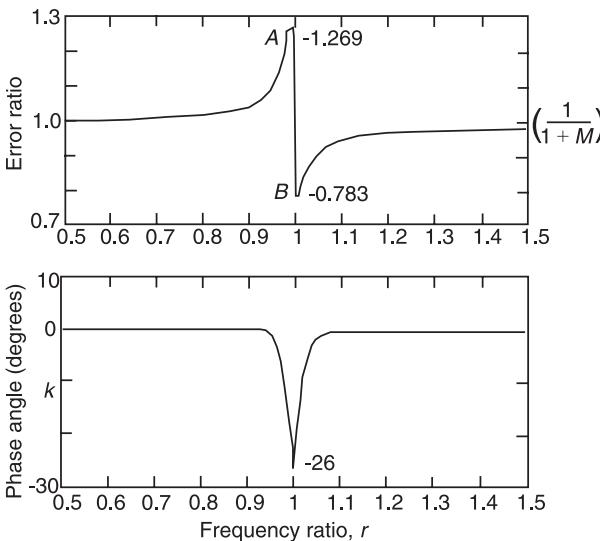

Figure 7 Magnitude and phase of error ratio as a function of dimensionless frequency ratio r for a mass ratio M of 0.01 and a structural damping ratio of 0.01. Reproduced with permission from McConnell KG (1993) *Modal Analysis: The International Journal for Analytical and Experimental Modal Analysis*, Society for Experimental Mechanics.

moment relative to the transducer. Recent research has shed some light on bending moment characteristics. This section will address both the bending moment sensitivity of a force transducer and the coupling that occurs in a transducer designed to measure a single force and two moments. Shear force sensitivity is not addressed here.

Bending Moment Sensitivity in a Single Force Transducer

The bending moment sensitivity model of a force transducer was developed by McConnell and Varoto (1993) to explain the behavior of a transducer when mounted on a nearly rigid foundation with steel bar attached as shown in Figure 8A. The steel bar was impacted at locations 1, 2, and 3, with the calibration results shown in Figure 8B. This dramatic difference in behavior led to the development of a two-degree-of-freedom (2-DOF) transducer model that involved both linear and angular transducer motions, y and θ . From these motions, they showed that the frequency domain ratio of output voltage ($E_f(\omega)$) to input force ($F_o(\omega)$) at location l from the transducer's center is given by:

$$\frac{E_f(\omega)}{F_o(\omega)} = \left\{ \frac{(S_F + lS_M)(1 - \alpha r_\theta^2 + j2\zeta_\theta \alpha \gamma r_\theta)}{\left(1 - r_y^2\right) + j2\zeta_y r_y(1 - r_\theta^2 + j2\zeta_\theta \gamma r_\theta)} \right\} [19]$$

where S_F (V per unit force) and S_M (V per unit moment) are the force and bending moment sensitivities, $r_y = \omega/\omega_{ny}$ is the linear dimensionless natural frequency ratio, and $r_\theta = \omega/\omega_n$ is the angular dimensionless natural frequency ratio. The dimensionless parameters α , β , and γ are given by:

$$\begin{aligned} \alpha &= \frac{\beta^2 S_F + lS_M}{\beta^2 (S_F + lS_M)} \\ \beta &= \frac{\omega_{ny}}{\omega_{n\theta}} = \frac{r_\theta}{r_y} \\ \gamma &= \frac{\beta S_F + lS_M (\zeta_y \zeta_\theta)}{\beta (S_F + lS_M)} \end{aligned} [20]$$

For this case, $\omega_{ny} \gg \omega_{n\theta}$ so that $r_\theta \gg r_y$ and $\beta \gg 1.0$. Then, eqn [19] has several interesting features. First, at low frequencies when $r_\theta \ll 1$ and $r_y \ll \ll 1$, the apparent force sensitivity is:

$$S_{F_a} = S_F + lS_M [21]$$

which is an anticipated result. Second, two natural frequencies are involved. Third, a notch occurs whenever $\alpha r_\theta^2 = 1.0$. However, eqn [20] shows that α is either greater than unity when lS_M is negative or less than unity when lS_M is positive. Thus, this notch can occur either before or after the torsional resonance. Fourth, when $r_\theta \gg 1$, the apparent force sensitivity becomes:

$$S_{F_a} \cong \alpha(S_F + lS_M) \cong S_F + \frac{lS_M}{\beta^2} [22]$$

For fairly large values of β , eqn [22] shows that the apparent sensitivity is essentially the normal force sensitivity. Eqn [19] is plotted in Figure 9 for parameters that simulate the measured data shown in Figure 8B. The bending moment sensitivity S_M changes with the angular orientation of the steel bar for the transducer tested.

The One-force, Two-moment Transducer

Dong *et al.* (1998) studied the coupling that occurred in a one-force (F_z) and two-moment (M_x and M_y) transducer using the set-up shown in Figure 10. The plate was impacted at locations of 0 , ± 30 , ± 45 , ± 60 , ± 90 , etc. degrees at radius r . The transducer force F_z and moments M_x and M_y responses and the corresponding impact force were measured. It takes three sets of measurements to obtain the cross-sensitivity matrix $\boldsymbol{\epsilon}$. The ± 45 and ± 135 degree data are used for this purpose since these positions give the best bending moment signal-to-noise ratios. The measured moments M_{xm} and M_{ym} and force F_{zm} are corrected using $\boldsymbol{\epsilon}$ cross-sensitivity matrix by:

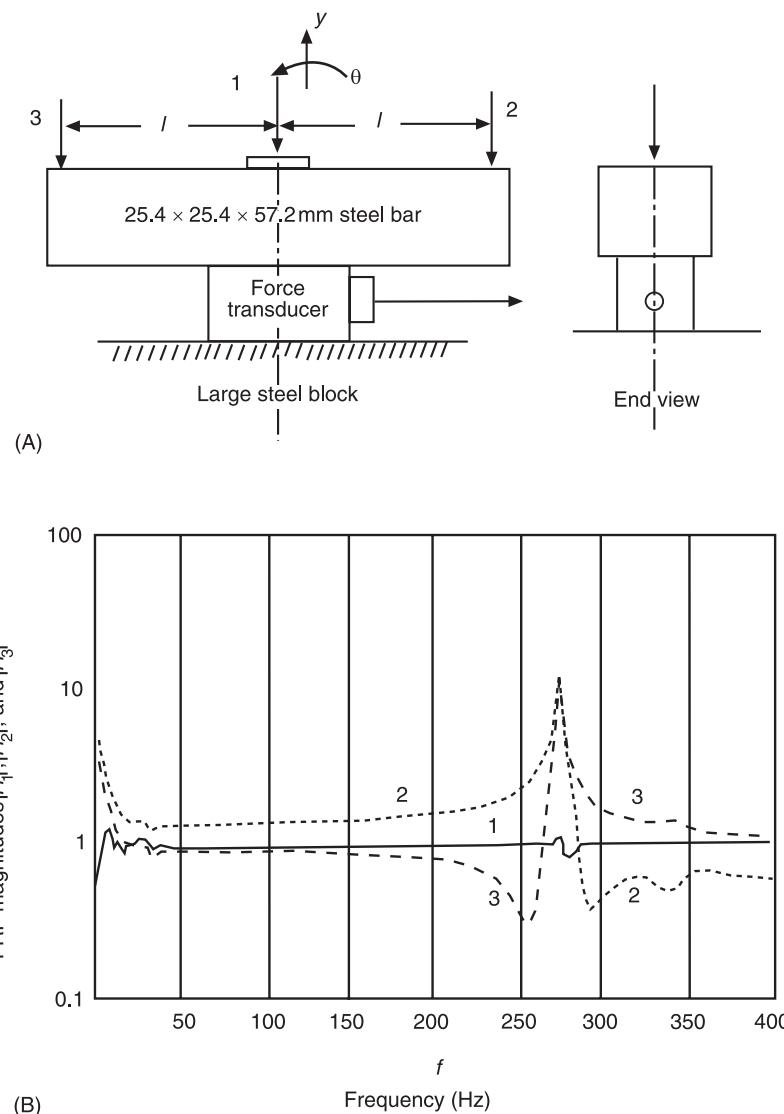

Figure 8 (A) Force transducer bending moment experimental set-up. (B) Experimental calibration FRFs showing effects of bending moments on results. Note rotational resonance at about 275 Hz. Reproduced with permission from McConnell KG and Varoto PS (1993) *Proceedings of the 11th International Modal Analysis Conference*, Society for Experimental Mechanics.

$$\begin{Bmatrix} M_{xc} \\ M_{yc} \\ F_{zc} \end{Bmatrix} = \begin{bmatrix} \varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{yx} & \varepsilon_{yy} & \varepsilon_{yz} \\ \varepsilon_{zx} & \varepsilon_{zy} & \varepsilon_{zz} \end{bmatrix}^{-1} \begin{Bmatrix} M_{xm} \\ M_{ym} \\ F_{zm} \end{Bmatrix} \quad [23]$$

The measured ε matrix was reported to be:

$$\varepsilon = \begin{bmatrix} 0.9825 & 0.00971 & 1 \times 10^{-4} \\ -0.0393 & 0.9631 & 3.5 \times 10^{-4} \\ -0.4133 & 0.6555 & 0.9597 \end{bmatrix} \quad [24]$$

where the diagonal terms should be close to unity. The elements ε_{xz} and ε_{yz} are small compared to the other terms since they relate moments to forces where the instrument moment arm is very small.

Load Cell Anomaly When Loaded Through the Bolt

The transducer employed by Dong *et al.* (1998) during this test has a bolt pass through its center, as shown in Figure 10B. When the impact load was applied directly to the bolt, as shown in Figures 10B and 11A, the sensitivity was found to be 10.58% low compared to other measurements and the manufacturer's sensitivity specification. When the plate was impacted through a loading cylinder that passed around the nut and applied the load directly to the plate, as shown in Figure 11B, the calibration agreed with the manufacture. An analysis of the spring and loading arrangements shown in Figure 11A and 11B shows that the plate deflection per unit input force, S_{plate} , is related to the bolt deflection per unit force, S_{bolt} , by:

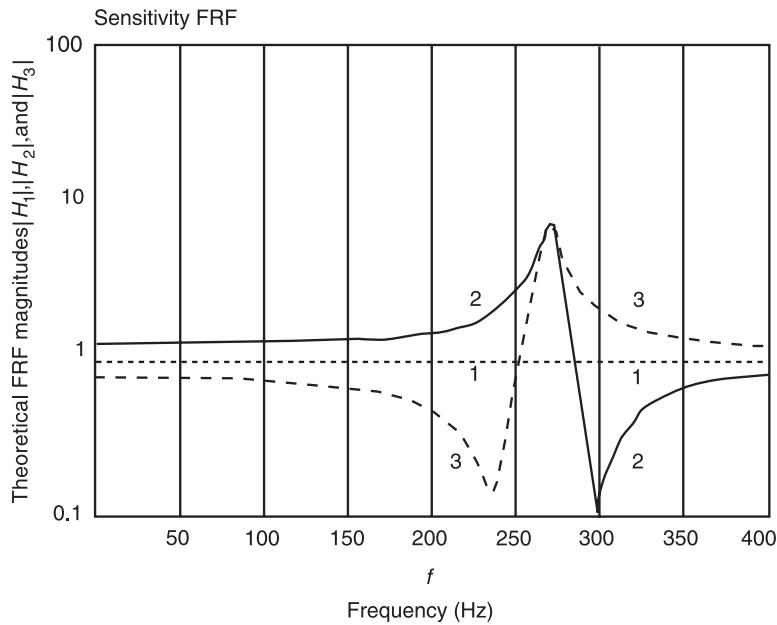

Figure 9 Plot of eqn [19] showing theoretical calibration FRFs for impacts at locations 1, 2, and 3 in **Figure 8B**. Note similarities with measured data. Reproduced with permission from McConnell KG and Varoto PS (1993) *Proceedings of the 11th International Modal Analysis Conference*, Society for Experimental Mechanics.

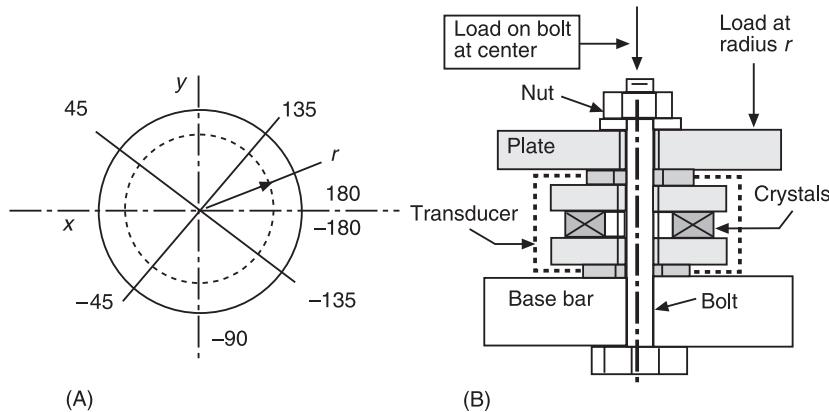

Figure 10 Two-moment, single-force load cell test set-up. (A) Top view of aluminum impact plate showing impact locations at radius r . (B) Cross-section showing impact plate, bolt, transducer, sensing crystals, and washer. Reproduced with permission from Dong J et al. (1998) *Proceedings of the 16th International Modal Analysis Conference*, Society for Experimental Mechanics.

$$S_{\text{plate}} = \left\{ 1 + \frac{K_{\text{bolt}}}{4K_{\text{nut}}} \right\} S_{\text{bolt}} \quad [25]$$

where the bolt deflection per unit of force is given by:

$$S_{\text{bolt}} = \frac{1}{K_{\text{bolt}} + 4K_{\text{trans}} + (K_{\text{trans}} K_{\text{bolt}} / K_{\text{nut}})} \quad [26]$$

The implications of eqns [25] and [26] indicate that the sensitivity supplied by the manufacturer may not be valid for the user's application since the point of loading and the bolt and nut used may be sufficiently

different to cause serious errors when compared to how the manufacturer calibrated the transducer.

Removing Force Transducer Mass Loading Effects from FRF Data

In **Transducers for absolute motion** and again in this article, it was observed that the measured force is contaminated by the effective seismic inertial force $m\ddot{y}$. In this section, a correction scheme is developed that removes this contamination from both the driving point $A_{pp}(\omega)$ and transfer $A_{qp}(\omega)$ accelerances where p is the driving point and q is the transfer point.

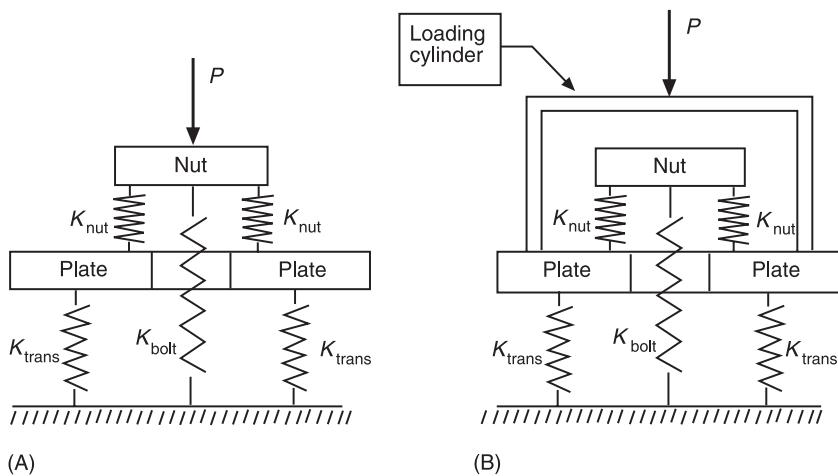

Figure 11 Model of transducer when loaded (A) through the central bolt and (B) through the plate via a loading cylinder placed around the nut. Reproduced with permission from Dong J et al. (1998) *Proceedings of the 16th International Modal Analysis Conference*, Society for Experimental Mechanics.

In addition, the effects of measurement system phase and magnitude on the correction scheme are reviewed.

Basic Definitions

The driving point accelerance in the frequency domain is:

$$A_{pp}(\omega) = \frac{A_p(\omega)}{F_p(\omega)} \quad [27]$$

while the transfer accelerance in the frequency domain is:

$$A_{qp}(\omega) = \frac{A_q(\omega)}{F_p(\omega)} \quad [28]$$

where $A_p(\omega)$ and $F_p(\omega)$ are the corresponding acceleration and force frequency spectra. The output acceleration voltage frequency spectra, $E_{a_q}(\omega)$, at point q is given by:

$$E_{a_q}(\omega) = H_{a_q}(\omega) \frac{S_{a_q}}{g} A_q(\omega) \quad [29]$$

and the input force voltage frequency spectra, $E_{F_q}(\omega)$, at driving point p is given by:

$$F_{E_r}(\omega) = H_{E_r}(\omega)S_{E_r}\{1 + m_c A_{pp}(\omega)\}F_p(\omega) \quad [30]$$

where $H_{a_q}(\omega)$ is the accelerometer's FRF and $H_{F_p}(\omega)$ is the force transducer's FRF. These two instrument FRFs include all mechanical, electrical, and analyzer dynamic characteristics, including the antialiasing filters. S_{a_q} and S_{F_p} are the transducer voltage sensitivities. The connector mass, m_c , includes the force

transducer's seismic mass, all connection mechanism mass, and the driving point accelerometer mass.

Correcting Driving Point Accelerance

McConnell (1995) shows that the measured driving point accelerance $A_{pp}^m(\omega)$ is given by:

$$A_{pp}^m(\omega) = \left(\frac{gS_{F_p}}{S_{ap}} \right) \left(\frac{E_{ap}}{E_{F_p}} \right) \\ = H_{I_{pp}}(\omega) \left(\frac{1}{1 + m_c A_{pp}(\omega)} \right) A_{pp}(\omega) \quad [31]$$

where the denominator shows the force contamination due to the $m_c A_{pp}(\omega)$ term and the instrument system FRF $H_{I_{pp}}(\omega)$ given by:

$$H_{I_{pp}}(\omega) = \frac{H_{a_p}(\omega)}{H_{E_b}(\omega)} \quad [32]$$

The actual driving point accelerance can be obtained from eqn [31] as:

$$A_{pp}(\omega) = \frac{A_{pp}^m(\omega)}{H_{L_m}(\omega) - m_c A_{pp}^m(\omega)} \quad [33]$$

When $H_{Ipp}(\omega) = 1.0$, eqn [33] reduces to a very simple form of:

$$A_{pp}^m(\omega) = \frac{A_{pp}^m(\omega)}{1 - m_c A_{pp}^m(\omega)} \quad [34]$$

Correcting the Transfer Accelerance

The measured transfer accelerance, $A_{qp}^m(\omega)$, is given by:

$$\begin{aligned} A_{qp}^m(\omega) &= \left(\frac{gS_{F_p}}{S_{q_q}} \right) \left(\frac{E_{a_q}(\omega)}{E_{F_p}(\omega)} \right) \\ &= H_{I_{qp}}(\omega) \left[\frac{1}{1 + m_c A_{pp}(\omega)} \right] A_{qp}(\omega) \end{aligned} \quad [35]$$

where $H_{I_{qp}}(\omega)$ is the instrumentation combined FRF given by:

$$H_{I_{qp}}(\omega) = \frac{H_{a_q}(\omega)}{H_{F_p}(\omega)} \quad [36]$$

The actual transfer acceleration can be obtained from eqn [35] as:

$$A_{qp}(\omega) = \left[\frac{1 + m_c A_{pp}(\omega)}{H_{I_{qp}}(\omega)} \right] A_{qp}^m(\omega) \quad [37]$$

which reduces to:

$$A_{qp}(\omega) = [1 + m_c A_{pp}(\omega)] A_{qp}^m(\omega) \quad [38]$$

when $H_{I_{qp}}(\omega) = 1.0$. It is clear that $A_{pp}(\omega)$ must be corrected first in order to correct the measured transfer acceleration.

Errors when $H_{I_{pp}}(\omega)$ is Nonunity

McConnell and Hu (1993) and Hu (1991) studied the effect of $H_{I_{pp}}(\omega)$ being nonunity and developed an error expression given by:

$$\varepsilon(\omega) = \left[\frac{\{H_{I_{pp}}(\omega) - 1\}\{1 + m_c A_{pp}(\omega)\}}{1 + m_c A_{pp}(\omega)\{1 - H_{I_{pp}}(\omega)\}} \right] \times 100 \quad [39]$$

where $H_{I_{pp}}(\omega) = 1.0$ gives zero error. It was found that reasonable magnitude errors in $H_{I_{pp}}(\omega)$ created only modest errors in eqn [39]. However, positive phase shifts between data channels as defined by:

$$H_{I_{pp}}(\omega) = e^{-j\theta} \quad [40]$$

caused large errors when combined with the resonance condition of a SDOF system to give:

where $r = \omega/\omega_n$, $\omega_n^2 = k_s/m_s$, $M = m_c/m_s$, $\zeta = c_s/2\sqrt{k_s m_s}$. The critical angle and frequency ratio that cause the denominator to be zero are given by:

$$\theta_c \cong \left[\frac{2\zeta}{M(1 - \zeta^2 M)} \right] \text{ (radians)} \quad [42]$$

and:

$$r_c \cong \left[\frac{1}{1 - \zeta^2 M} \right] \quad [43]$$

When $M = 0.1$ and $\zeta = 0.5\%$, the critical angle is 0.1 rad or 5.7° , a value that is within the antialiasing filter phase match between channels in some multichannel data acquisition systems. Thus, application of these correction schemes can cause very large magnitude errors near a structure's resonance, particularly for light-weight structures. Note that these errors are detectable when the correction is done in the frequency domain but are not detectable when time history signal subtraction is used in an attempt to remove the force signal contamination effects.

Transducer Calibration

Calibration is a process in which a known input is applied to an instrument and the resulting output is recorded in order to establish the transducer's input-output relationship or sensitivity over its usable frequency range. Manufacturers usually use secondary standards that are traceable to a national standard organization that uses absolute calibration methods. In this section, several practical calibration methods for accelerometers and force transducers are summarized. These methods use either secondary standards or an experimental arrangement based on Newton's second law.

Accelerometer Calibration (Back-to-back Method)

Accelerometers are often calibrated by using the back-to-back method where the accelerometer to be calibrated is mounted on a calibration standard so that both accelerometers are measuring the same mounting surface acceleration, as shown in Figure 12A. The calibration standard should be traceable to an absolute standard. The calibration standard is mounted on

$$\varepsilon(r) = \left[\frac{-\{1 - \cos(\theta) + j \sin(\theta)\}\{1 - (1 + M)r^2 + j2\zeta r\}}{1 - \{1 + M[1 - \cos(\theta)]\}r^2 + j2\zeta r\{1 - (Mr/2\xi) \sin(\theta)\}} \right] \times 100 \quad [41]$$

a vibration exciter that is driven by an appropriate signal such as a chirp, pure tone sinusoid, or an impulse. Both signals are measured and compared over a range of frequencies. This is a good method to be employed in the laboratory environment, but it is cumbersome to use in the field. The hand-held calibrator shown in Figure 12B is convenient for verifying the sensitivity of an accelerometer in the field. This particular calibrator generates a 1.0 g rms sinusoidal acceleration at 79.6 Hz with less than 3% error for accelerometer mass under 70 g by using a feedback scheme from a built-in reference accelerometer.

Acceleration Calibration (Gravimetric Calibration Method)

Lally (1990) developed the gravimetric method, as shown in Figure 13A, which is a portable field type of

calibration method based on Newton's second law. The accelerometer to be calibrated is mounted to a steel cylinder that falls in a guide tube and strikes an impact cushion between the force transducer and the steel cylinder. The force transducer is attached to a heavy base mass on the lower end. The output signal from each transducer is connected to either a digital oscilloscope or a frequency analyzer. This method employs two steps. First, the steel cylinder is quickly lifted off the force transducer so that an approximate step change in force signal E_{mg} is recorded as shown in Figure 13B. Second, the cylinder is dropped on to the force transducer and both the force and acceleration signals are recorded. If the transducers are linear and no transducer ringing occurs, then the signals plot as a straight line with slope S , as shown in Figure 13C, so that:

$$S = \frac{E_a}{E_F} \quad [44]$$

Then, the accelerometer's voltage sensitivity in units of $V g^{-1}$ is given by:

$$S_a = S E_{mg} \quad [45]$$

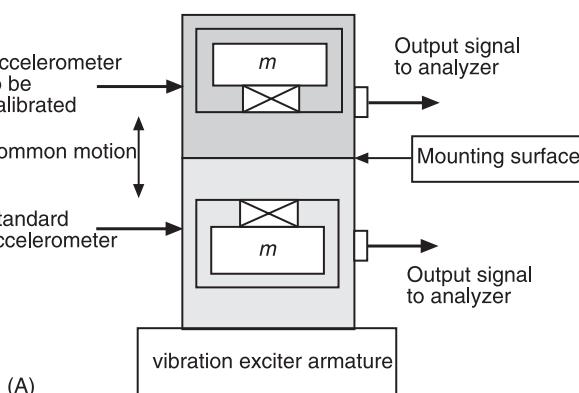

This method is dependent on the local acceleration due to gravity since E_{mg} is a measure of the local weight of the steel mass and accelerometer. Also, note that this method does not require knowledge of the force transducer voltage sensitivity, it only requires that both transducers are linear. The slope S can also be determined from a frequency analyzer where one uses the mean value of the frequency domain ratio:

$$S(\omega) = \frac{E_a(\omega)}{E_F(\omega)} \quad [46]$$

over a range of frequencies where this ratio is essentially constant. This method requires the pulse duration to be short enough to excite the range of frequencies of interest and long enough to prevent transducer ringing.

Force Transducer Calibration (Gravimetric Method)

The force transducer can be calibrated using the gravimetric method if the weight of the steel cylinder and accelerometer assembly is determined by a weighing method that is independent of local gravity, such as a balance against a known mass or weight. Then, eqn [45] can be modified to give the force transducer sensitivity with units of volts/unit force (pound or newton) from:

(A)

(B)

Figure 12 (A) Cross-section of accelerometers used in back-to-back calibration arrangement. (B) Photograph of a hand-held calibrator. Courtesy of PCB Piezotronics, Depew, NY.

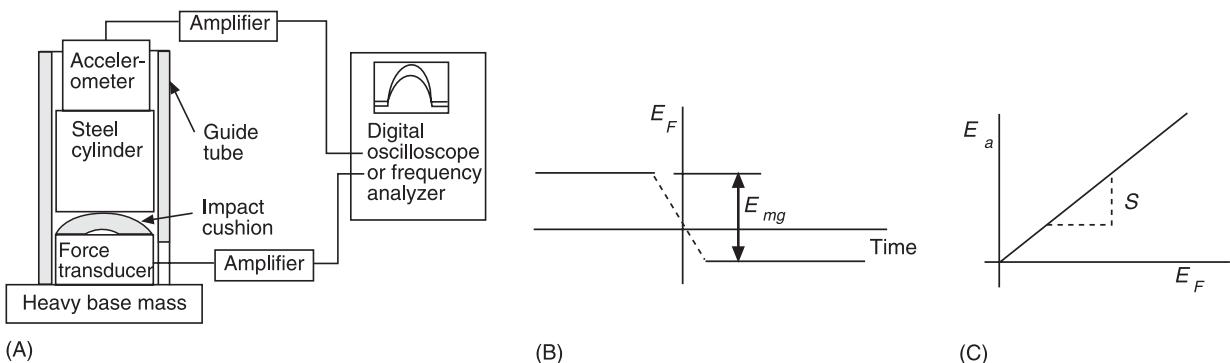

Figure 13 Gravimetric transducer calibration. (A) Test set-up; (B) first step showing static weight measurement of E_{mg} ; (C) second step impulse signals plotted against one another to determine slope S . Reproduced with permission from Dally JW, Riley WF and McConnell KG (1993) *Instrumentation for Engineering Measurements*. New York: John Wiley.

$$S_F + \left[\frac{S_a}{S} \right] \left[\frac{1}{mg} \right] \quad [47]$$

$$S_F^* = \begin{bmatrix} E_F \\ E_a \end{bmatrix} \begin{bmatrix} S_a \\ W_c \end{bmatrix} \quad [48]$$

where mg is the standard weight of the calibration and accelerometer mass with units of either pounds or newtons. Obviously, the accelerometer calibration must be done first so that S_a is known.

Impact Calibration of Impact Hammers and Accelerometers

This calibration method is primarily used to verify the calibration of hammer-mounted force transducers and accelerometers under field conditions using Newton's second law and the arrangement shown in **Figure 14**. The calibration mass m_c includes the accelerometer's mass and should be suspended as a pendulum using two equal length light-weight cables or strings. The effective force transducer sensitivity in volts/unit force is given by:

where the ratio of E_a/E_F can be obtained by either plotting the time histories as shown in Figure 13C or using the mean ratio of E_a/E_F from a frequency analyzer, as described above. It is clear that this method is essentially the same as the gravimetric method. The reader is warned that a similar method was presented at technical meetings during the 1980s where a lightweight calibration mass m_c was held by hand. These calibration results depended on the hand mass of the person doing the calibration as well as how hard that person held the calibration mass. This hand-held mass method is not recommended unless the mass exceeds 50 kg!

Environmental Factors

Transducers are purchased to make accurate measurements. The above topics have addressed some of

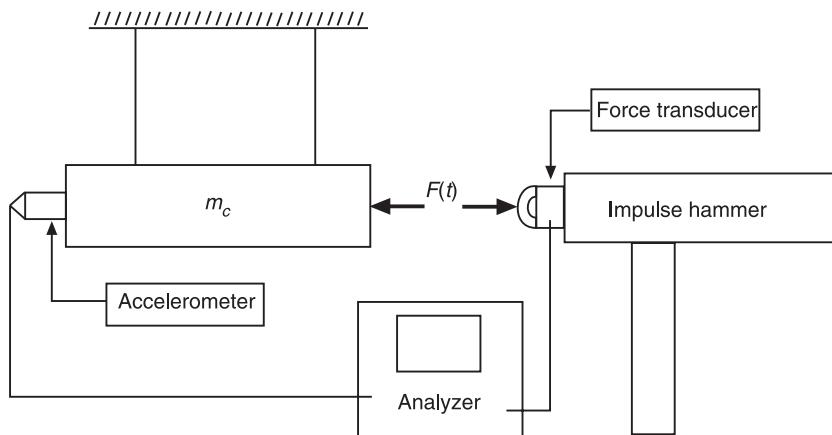

Figure 14 Schematic of calibration method either to calibrate the force transducer or to compare force and accelerometer sensitivities.

the more serious phenomena that can affect transducer performance. However, additional factors are known to affect piezoelectric transducers, such as cable noise, humidity and dirt, transducer mounting, nuclear radiation, and temperature.

Cable Noise

Three different types of cable noise effects have been identified when using charge amplifiers: electromagnetic fields, ground loops, and triboelectric effects.

Electromagnetic fields Electromagnetic fields are caused by electrical power cables carrying large currents that generate strong magnetic fields. Instrument cables should not share the same electrical conduit with these power cables. Instrument cables should be shielded in their own grounded steel conduit.

Ground loops Ground loops are due to the transducer being attached to a structure with a different electrical potential than the charge amplifier's ground so that a current flows through the cable's ground shield and causes a false signal to appear. This signal can usually be detected in frequency domain measurements such as autospectral density since ground loops usually contain line frequency and integer multiples of line frequency. However, this signal is often difficult to remove without great effort such as using an electrical isolation mounting in order to break the current flow, a task that is nearly impossible when using force transducers. However, it is often useful to ground all points of the test to a common point that is well grounded. Sometimes a building's electrical system has poor electrical grounds which causes significant ground loop-type problems.

Triboelectric effects Triboelectric effects are caused by damaged instrument cables that generate charge when the center conductor has broken free from and rubs on the insulation material to cause signals at the same frequencies as the test. The easiest way to detect this problem is to shake the instrument cable when the transducer is in a benign environment. If the cable produces significant signals, cutting the offending cable into two parts before discarding cures the problem. Then install a new undamaged cable. Note: damaged cables that are not cut into two parts and discarded have an uncanny way of showing up in other tests. The triboelectric cable-shaking check should be done at the beginning and end of each test in order to eliminate this error source. Proper mounting of cables is required to reduce cable damage.

Humidity and Dirt

Humidity and dirt can cause significant deterioration of signal quality by draining significant amounts of generated charge, particularly when using charge amplifiers. Dirty fingerprints and/or moisture on transducer connectors are a prime location for this signal contamination. The connector should be periodically cleaned using acetone or other approved cleaning agent. Using either silicone grease before assembly or covering the connection with RTV silicone rubber can reduce the connector humidity and/or moisture problem.

Mounting the Transducer

In order to work accurately, the transducer must move with the contact surface without significant relative motion. This can be achieved by using a bolted connection along with wax or waxy grease to ensure contact at high frequencies. Often it is good practice to polish the interface surface to reduce the local rough spots. A magnetic mounting is convenient to use. In this case, polishing the surface and using waxy grease will improve contact at high frequencies. Miniature accelerometers can be successfully mounted using only instrument-grade wax provided the mounting surface is clean, smooth, and the temperature is low enough. The hand-held probe is not recommended except for large structures when measuring low-frequency vibrations.

Nuclear Radiation

When using transducers in nuclear radiation fields, it is recommended that the user contact the manufacturer.

Temperature

Temperature can cause three undesirable effects. First, transducer charge sensitivity may change with temperature. Second, rapid temperature changes can cause false low-frequency signals. Third, high temperatures can cause permanent damage to piezoelectric sensing crystals when temperatures exceed about 250 °C. Once the Curie temperature is exceeded, piezoelectric crystals are permanently damaged. It is prudent to consult the manufacturers for recommendations for both low temperatures and high temperature applications.

Nomenclature

a	transducer acceleration
$A_s(\omega)$	driving point acceleration
b	apparent acceleration
$F(\omega)$	interface force

m_c	calibration mass
M	mass ratio
S	slope
S_o	effective sensing axis
\mathbf{S}_o	sensitivity vector
\ddot{x}	base excitation
$\ddot{y}(\omega)$	seismic mass acceleration
$\boldsymbol{\epsilon}^{-1}$	correction matrix
ϕ, θ	angle
ζ_s	structural damping

As discussed in the article on **Piezoelectric materials and continua**, piezoelectricity is an electromechanical phenomenon coupling the elastic field and the electric field, and it is governed by the direct piezoelectric effect and the converse piezoelectric effect. This article will discuss its advanced applications to distributed sensing and control of elastic continua (or distributed parameter systems), e.g., shells, plates, etc., based on distributed piezoelectric sensors and actuators. This synergistic integration of smart materials, sensors, actuators, and control electronics

leads to a new distributed strucronic (*structure + electronic*) system capable of self-sensing, diagnosis, and control. The fundamental background of the distributed parameter systems is introduced, followed by definitions of distributed sensors and actuators and their theories and governing equations. Application examples and design principles are presented afterwards.

Distributed Sensors and Actuators

Mass, stiffness, static and dynamic characteristics of elastic continua or structures (e.g., shells and plates) are generally distributed in nature, i.e., their properties or behaviors are functions of time and spatial coordinates. Accordingly, these systems are usually classified as distributed parameter systems (DPSs)

and they are usually modeled by partial differential equations (PDEs). In practical applications, however, due to their complexity, discretization techniques are often employed and, for convenience, the derived simplified lumped (or discrete) parameter systems (LPSs) are analyzed and evaluated. Accordingly, simplified LPS only reveals partial system characteristics of the original DPS. Similarly, sensing and control of DPS using conventional (discrete or point) sensors and actuators at spatially discrete locations also pose many technical problems, especially if they are placed at (or near) modal nodes or on nodal lines of DPSs. Eventually, these modes are neither observable nor controllable by these discrete transducers. To remedy the discrete sensor/actuator deficiencies and to observe and control the elastic DPS, spatially distributed sensors and actuators are highly desirable.

Thinly distributed piezoelectric layers are excellent candidates for distributed sensor and actuator applications, because of their distributed nature, excellent sensitivity, and easy application to elastic continua or structural DPSs. Note that distributed sensors are based on the direct piezoelectric effect and distributed actuators are based on the converse piezoelectric effect. Similar to conventional strain gauges, distributed piezoelectric sensors are strain-sensitive sensors; unlike strain gauges, their signals are rather strong and they usually do not need additional signal conditioning units. Figure 1 illustrates two spatially distributed piezoelectric layers respectively laminated on the top and bottom surfaces of a generic deep elastic shell continuum – a generic elastic DPS. One piezoelectric layer serves as a distributed sensor and the other serves as a distributed actuator. Generic sensing and actuation theories based on the double-curvature shells are defined first, followed by applications to other geometries using four system para-

meters, two Lamé parameters and two radii of curvature, R_1 and R_2 .

Distributed Sensing

As discussed previously, the distributed sensing layer responds to strain variations and generates signals due to the direct piezoelectric effect. Based on the Gaussian theory ($\nabla \mathbf{D}_i = 0$), the Maxwell equation ($\mathbf{E}_j = -\nabla \Phi$), and the direct piezoelectric effect, an open-circuit voltage ϕ^s , in the transverse direction, forms the distributed sensor layer made of hexagonal piezoelectric materials is:

$$\phi^s = (h^s / S^e) \times \int_{\alpha_1} \int_{\alpha_2} [h_{31}S_{11}^s + h_{32}S_{22}^s + h_{36}S_{12}^s] \times A_1 A_2 d\alpha_1 d\alpha_2 \quad [1]$$

where h^s is the sensor thickness; S^e is the effective sensor electrode area; h_{3i} is the piezoelectric constant indicating a signal generation in the transverse direction due to the strain in the i th direction; and S_{ij}^s is the strain on the i th surface in the j th direction. These strains are two in-plane normal strains and one shear strain. (Most current commercial materials, e.g., polyvinylidene fluoride and piezoceramics, are usually insensitive to the shear strain.) Since the sensor layer is laminated on the shell, the effective strains generating signals are the two in-plane normal strains and one in-plane shear strain. Note that the open-circuit voltage reflects the induced strains over the effective sensor area and it is averaged over the effective electrode area. Strains can be further divided into the membrane strain component s_i^o and the bending strain component k_i , i.e., $S_{ii}^s = s_i^o + \alpha_3 k_i$; these two components are expressed as follows.

Membrane Strains

$$s_1^o = \frac{1}{A_1} \frac{\partial u_1}{\partial \alpha_1} + \frac{u_2}{A_1 A_2} \frac{\partial A_1}{\partial \alpha_2} + \frac{u_3}{R_1} + \frac{1}{2} \left(\frac{\partial u_3 / \partial \alpha_1}{A_1} \right)^2 \quad [2]$$

$$s_2^o = \frac{1}{A_2} \frac{\partial u_2}{\partial \alpha_2} + \frac{u_1}{A_1 A_2} \frac{\partial A_2}{\partial \alpha_1} + \frac{u_3}{R_2} + \frac{1}{2} \left(\frac{\partial u_3 / \partial \alpha_2}{A_2} \right)^2 \quad [3]$$

$$s_6^o = \frac{1}{A_2} \frac{\partial u_1}{\partial \alpha_2} + \frac{1}{A_1} \frac{\partial u_2}{\partial \alpha_1} - \frac{u_1}{A_1 A_2} \frac{\partial A_1}{\partial \alpha_2} - \frac{u_2}{A_1 A_2} \frac{\partial A_2}{\partial \alpha_1} + \left(\frac{1}{A_1 A_2} \frac{\partial u_3 / \partial \alpha_1}{\partial \alpha_2} \right) \quad [4]$$

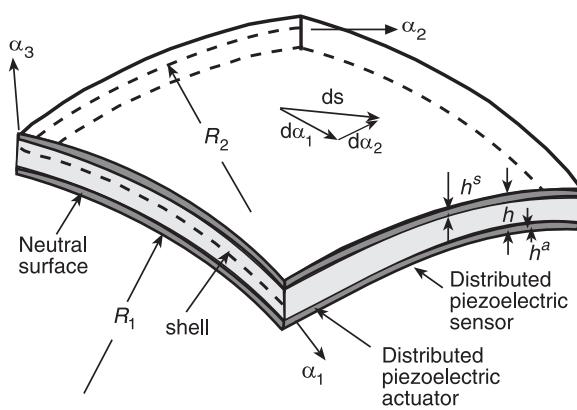

Figure 1 An elastic shell laminated with distributed piezoelectric sensor and actuator – a strucronic shell system.

Bending Strains

$$k_1 = \frac{1}{A_1} \frac{\partial}{\partial \alpha_1} \left(\frac{u_1}{R_1} - \frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \right) + \frac{1}{A_1 A_2} \left(\frac{u_2}{R_2} - \frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \right) \frac{\partial A_1}{\partial \alpha_2} \quad [5]$$

$$k_2 = \frac{1}{A_2} \frac{\partial}{\partial \alpha_2} \left(\frac{u_2}{R_2} - \frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \right) + \frac{1}{A_1 A_2} \left(\frac{u_1}{R_1} - \frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \right) \frac{\partial A_2}{\partial \alpha_1} \quad [6]$$

$$k_6 = \frac{1}{A_2} \frac{\partial}{\partial \alpha_2} \left(\frac{u_1}{R_1} - \frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \right) + \frac{1}{A_1} \frac{\partial}{\partial \alpha_1} \left(\frac{u_2}{R_2} - \frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \right) - \frac{1}{A_1 A_2} \left(\frac{u_1}{R_1} - \frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \right) \frac{\partial A_1}{\partial \alpha_2} - \frac{1}{A_1 A_2} \left(\frac{u_2}{R_2} - \frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \right) \frac{\partial A_2}{\partial \alpha_1} \quad [7]$$

where u_i is the displacement in the i th direction; A_i is the Lamé parameter defined by the fundamental form; and R_i is the radius of curvature of the i th axis. Note that this definition incorporates large (nonlinear) strain generation in the distributed sensor layer. The nonlinear strain terms are the quadratic terms defined by the von Karman geometric nonlinearity in the membrane strain equations. For small (linear) deformation, these quadratic terms vanish in the membrane strains and thus the signal reflects the strains resulting from only linear vibration of the thin shell DPS. Furthermore, depending on sensor placement and geometry, the sensor layer can be solely sensitive to either membrane vibrations, bending vibrations, or a combination of both components. Taking the example of a sensor layer surface laminated on beams or flat plates, its primary strain component contributing to the sensor signal generation is the bending strain. However, when referring to a sensor laminated on the neutral surface of rings or shells, the primary strain component to the signal generation is the membrane strain. Thus, knowing what to measure on what structure is the key to sensor placement and location on distributed plate or shell systems. Furthermore, significant observation deficiency can occur when the signal generated by the positive strain is canceled out with that resulting from the negative strain in certain natural modes, especially antisymmetrical modes of symmetrical structures with symmetrical boundary conditions, e.g., simply supported beams or plates. In this case, other techniques, such as sensor segmentation or spatial (thickness or surface)

shaping, can be used to alleviate the observation deficiency.

Distributed Actuation and Control

Distributed actuation and control of elastic DPSs using the distributed piezoelectric layer is based on the converse piezoelectric effect. The strain induced by a control potential ϕ^a (the converse piezoelectric effect) leads to stress (i.e., strain multiplied by Young's modulus Y_p), and then the membrane control force N_{ii}^a (Figure 2).

$$N_{ii}^a = d_{ii} Y_p \phi^a \quad [8]$$

Note that $d_{ii} = d_{3i}$ for the induced force resulting from a transversely applied control signal. Since the distributed actuator is surface-laminated, the control force also induces a counteracting control moment effect (M_{ii}^a) to the shell continuum.

$$M_{ii}^a = r^a d_{ii} Y_p \phi^a \quad [9]$$

where r^a is the moment arm measured from the shell neutral surface to the midplane of the distributed actuator. Accordingly, distributed actuation and control can be achieved. Previous studies have revealed that the membrane control force is important when controlling curved structures (e.g., shells and rings) and the control moment is effective in controlling zero-curvature structures (e.g., plates and beams). Furthermore, control deficiencies can also occur on antisymmetrical modes of symmetrical structures, due to cancellation of input control potential on the distributed actuator layer. Again, using segmentation and shaping (thickness or surface) techniques can alleviate the problem. Figure 2 illustrates the control actions of the distributed piezoelectric actuator.

Following Hamilton's principle and integrating all control forces into thin shell equations yield open- or closed-loop shell system equations in the three axial directions:

$$\begin{aligned} & - \frac{\partial(N_{11}^* A_2)}{\partial \alpha_1} + N_{22}^* \frac{\partial A_2}{\partial \alpha_1} - \frac{\partial(N_{21} A_1)}{\partial \alpha_2} - N_{12} \frac{\partial A_1}{\partial \alpha_2} \\ & + \frac{1}{R_1} \left[\frac{\partial(M_{11}^* A_2)}{\partial \alpha_1} - M_{22}^* \frac{\partial A_2}{\partial \alpha_1} + \frac{\partial(M_{21} A_1)}{\partial \alpha_2} + M_{12} \frac{\partial A_1}{\partial \alpha_2} \right] \\ & + A_1 A_2 \rho h \ddot{u}_1 = A_1 A_2 F_1 \end{aligned} \quad [10]$$

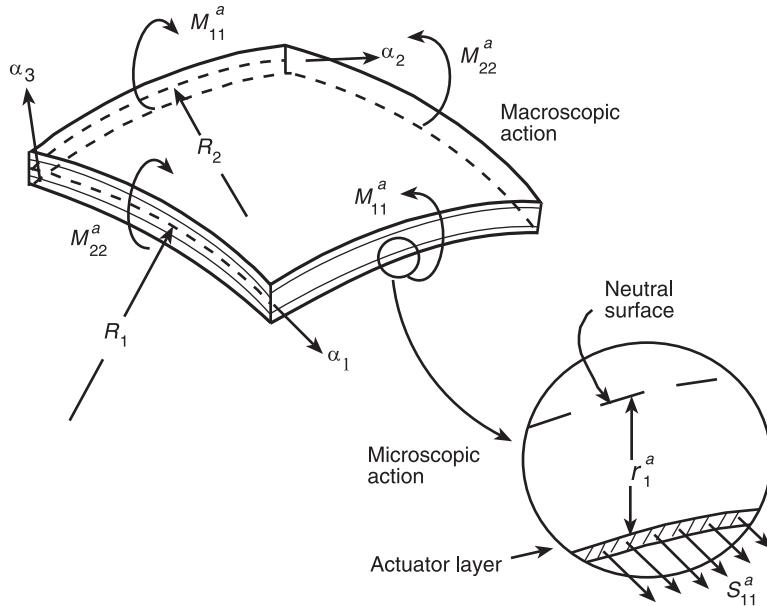

Figure 2 Distributed control induced by the distributed actuator layer.

$$\begin{aligned}
 & -\frac{\partial(N_{22}^* A_1)}{\partial \alpha_2} + N_{11}^* \frac{\partial A_1}{\partial \alpha_2} - \frac{\partial(N_{12} A_2)}{\partial \alpha_1} - N_{21} \frac{\partial A_2}{\partial \alpha_1} \\
 & -\frac{1}{R_2} \left[\frac{\partial(M_{22}^* A_1)}{\partial \alpha_2} - M_{11}^* \frac{\partial A_1}{\partial \alpha_2} + \frac{\partial(M_{12} A_2)}{\partial \alpha_1} + M_{21} \frac{\partial A_2}{\partial \alpha_1} \right] \\
 & + A_1 A_2 \rho h \ddot{u}_2 = A_1 A_2 F_2
 \end{aligned} \quad [11]$$

$$\begin{aligned}
 & -\frac{\partial}{\partial \alpha_1} \left[\frac{1}{A_1} \left(\frac{\partial(M_{11}^* A_2)}{\partial \alpha_1} - M_{22}^* \frac{\partial A_2}{\partial \alpha_1} \right. \right. \\
 & \left. \left. + \frac{\partial(M_{21} A_1)}{\partial \alpha_2} + M_{12} \frac{\partial A_1}{\partial \alpha_2} \right) \right] \\
 & -\frac{\partial}{\partial \alpha_2} \left[\frac{1}{A_2} \left(\frac{\partial(M_{22}^* A_1)}{\partial \alpha_2} - M_{11}^* \frac{\partial A_1}{\partial \alpha_2} \right. \right. \\
 & \left. \left. + \frac{\partial(M_{12} A_2)}{\partial \alpha_1} + M_{21} \frac{\partial A_2}{\partial \alpha_1} \right) \right] \\
 & + A_1 A_2 \left(\frac{N_{11}^*}{R_1} + \frac{N_{22}^*}{R_2} \right) + A_1 A_2 \rho h \ddot{u}_3 = A_1 A_2 F_3
 \end{aligned} \quad [12]$$

where u_i is the displacement in the α_i direction; ρ is the mass density; F_i is the external input; A_1 and A_2 are the Lamé parameters; and R_1 and R_2 are the radii of curvature. Note that the force and moment components consist of the original elastic component and the control component, i.e., $N_{ii}^* = N_{ii} + N_{ii}^a$ and $M_{ii}^* = M_{ii} + M_{ii}^a$, governed by control algorithms, which are either open-loop or closed-loop. This set of generic shell equations can be simplified to account for other geometries such that distributed sensing and control of other geometries can be investigated.

There are four geometric parameters – two Lamé parameters (A_1 and A_2) and two radii (R_1 and R_2) of curvature – required to carry out the simplification and reduction of generic shell sensing/control governing equations. Examples of various simplified geometries are shown in Figure 3; simplification procedures are briefly discussed below.

1. Select a coordinate system. The original generic shell continuum was defined in a tri-orthogonal curvilinear coordinate system (α_1 , α_2 , α_3). Depending on the given geometries (host elastic structure) and/or sensor/actuator shapes, these coordinates can be redefined to best represent the problem, e.g., $\alpha_1 = x$ and $\alpha_2 = y$ for a rectangular plate; $\alpha_1 = x$ and $\alpha_2 = \theta$ for a cylindrical shell and thin cylindrical tube shell; $\alpha_1 = \psi$ and $\alpha_2 = \theta$ for a spherical shell, etc.
2. Determine the radii of curvature. The radii of curvatures R_1 and R_2 of the two in-plane coordinate axes α_1 and α_2 can be easily observed from the coordinate system defined in step 1. For example, the radii of the x and y axes in a rectangular plate are $R_1 = \infty$ and $R_2 = \infty$. In a cylindrical shell, $R_1 = \infty$ and $R_2 = R$. In a spherical shell, the radii are $R_1 = R_2 = R$.
3. Derive a fundamental form. A fundamental form represents an infinitesimal distance ds on the neutral surface of the shell continuum; the distance is the hypotenuse of a (or an approximate) right-angle triangle defined by the projected infinitesimal distances ($d\alpha_1$ and $d\alpha_2$) of the two in-plane coordinates (Figure 1). From the fundamental form, the two Lamé parameters A_1 and A_2

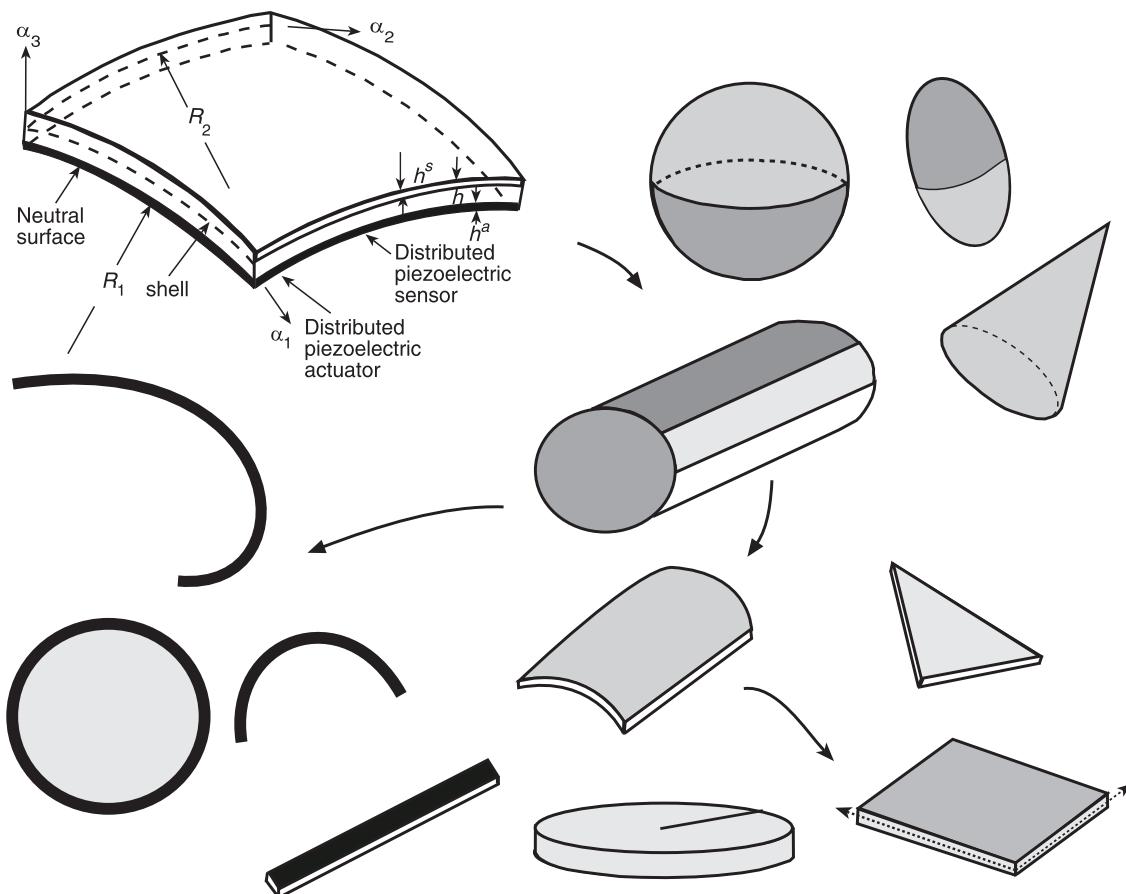

Figure 3 Applications of the distributed sensing and control of shells.

and the two selected coordinates α_1 and α_2 can be defined, i.e.,

$$(ds)^2 = (A_1)^2(d\alpha_1)^2 + (A_2)^2(d\alpha_2)^2 \quad [13]$$

For example, the fundamental form for a rectangular plate (defined in a Cartesian coordinate system x and y) is $(ds)^2 = (1)^2(dx)^2 + (1)^2(dy)^2$, thus, the Lamé parameters are $A_1 = 1$ and $A_2 = 1$. For a cylindrical shell defined by the x and β axes, the fundamental form is $(ds)^2 = (1)^2(dx)^2 + (R)^2(d\beta)^2$, thus, $A_1 = 1$ and $A_2 = R$ (radius of the cylinder). The fundamental form defining the spherical shell is $(ds)^2 = R^2(d\psi)^2 + R^2 \sin^2\psi(d\theta)^2$ where R is the radius of the spherical shell. Thus, the Lamé parameters are $A_1 = R$ and $A_2 = R \sin\psi$, where ψ is the meridional angle and θ is defined accordingly.

4. Simplify the shell sensor/actuator equations. By substituting the four parameters A_1 , A_2 , R_1 , and R_2 into the generic shell sensor/actuator and/or system equations, one can easily derive the governing equations for that geometry or sensor/actuator,

e.g., shells (cylindrical shells, conical shells, spherical shells, shells of revolution, etc.) or non-shell continua (rings, arches, beams, rods, etc.; Figure 3). (Detailed sensing/actuation and shell equations can be found in the further reading section.)

Furthermore, distributed sensors and actuators can be surface- or thickness-shaped using orthogonal functions, e.g., modal strain functions. In this case, the shaped sensor or actuator is only sensitive to the designated natural mode (i.e., the orthogonal modal sensor or actuator) and it is insensitive to other natural modes, based on the modal orthogonality of natural modes. In order to demonstrate the distributed sensor/actuator functionality and the bending/membrane effects, an example of strucronic cylindrical shells is presented next.

Case Study: Sensing and Control of Strucronic Cylindrical Shells

One of the important applications of distributed sensors and actuators is to evaluate detailed electro-mechanical sensing/control behaviors of distributed

adaptive structronic systems. Adaptive structures and structronic systems usually involve shape transformation, changing from one geometry to another, in order to achieve specific functional advantages in practical applications. A zero-curvature plate can transform to a shallow shell, a deep shell, and to a closed cylindrical shell (i.e., tube shell) when its curvature continuously changes from 0° to 360° (Figure 4). Usually, the bending effect dominates the plate or shallow shell dynamics; however, the membrane effect dominates the deep shell dynamics, especially for lower natural modes. (Recall that plates are defined as zero-curvature shells, i.e., radii R_1 and R_2 are infinity and the Lamé parameters A_1 and A_2 are ones.) This structronic cylindrical shell case demonstrates the utilities of distributed sensors and actuators and reveals the detailed electromechanics and functionalities, and design guideline of these devices as applied to various shell structures with different curvatures.

A cylindrical shell structronic system consists of elastic shell layers and distributed piezoelectric layers serve as distributed sensors and/or actuators (Figure 5). It is assumed that there is perfect bonding between the layers. Recall that the cylindrical shell is defined by the x and β axes, the fundamental form is $(ds)^2 = (1)^2(dx)^2 + (R)^2(d\beta)^2$. Thus, the Lamé parameters are $A_1 = 1$ and $A_2 = R$ (radius of the cylinder). (Note that the sensor/actuator segmented patches laminated on the cylindrical shell can be defined by their corresponding x and β coordinates generically. When $x = L$ and $\beta = \beta^*$, it becomes a fully distributed sensor/actuator, e.g., Figure 1.)

Following the procedures described previously and substituting the four parameters into the generic structronic shell system equations yields the governing equations of structronic cylindrical shells:

$$-\frac{\partial N_{xx}}{\partial x} - \frac{1}{R} \frac{\partial N_{x\beta}}{\partial \beta} + \rho h \ddot{u}_1 = F_1 + \frac{\partial N_{xx}^c}{\partial x} \quad [14]$$

$$\begin{aligned} & -\frac{\partial N_{x\beta}}{\partial x} - \frac{1}{R} \frac{\partial N_{\beta\beta}}{\partial \beta} - \frac{1}{R} \left[\frac{\partial M_{x\beta}}{\partial x} + \frac{1}{R} \frac{\partial M_{\beta\beta}}{\partial \beta} \right] + \rho h \ddot{u}_2 \\ &= F_2 + \frac{1}{R} \frac{\partial N_{\beta\beta}^c}{\partial \beta} + \frac{1}{R^2} \frac{\partial M_{\beta\beta}^c}{\partial \beta} \end{aligned} \quad [15]$$

$$\begin{aligned} & -\frac{\partial^2 M_{xx}}{\partial x^2} - \frac{2}{R} \frac{\partial^2 M_{x\beta}}{\partial x^2} - \frac{1}{R^2} \frac{\partial^2 M_{\beta\beta}}{\partial \beta^2} + \frac{N_{\beta\beta}}{R} + \rho h \ddot{u}_3 \\ &= F_3 + \frac{\partial^2 M_{xx}^c}{\partial x^2} + \frac{1}{R^2} \frac{\partial^2 M_{\beta\beta}^c}{\partial \beta^2} - \frac{N_{\beta\beta}^c}{R} \end{aligned} \quad [16]$$

and forces and moments are defined by $N_{ii}/M_{ii} = N_{ii}^m/M_{ii}^m + N_{ii}^a/M_{ii}^a$. As discussed previously, injecting high voltages into the distributed piezoelectric actuators induces two major control actions. One is the in-plane membrane control force(s) and the other is the out-of-plane control (bending) moment(s). In general, the control moments are essential in planar structures, e.g., plates and beams; the membrane control forces are effective to deep shells. In this study, numerical solutions are plotted to evaluate the sensing and control effectiveness.

Free Vibration Analysis

As discussed previously, adaptive structures with continuous geometry transformation have many potential applications, e.g., optical focusing, flow control, etc. Frequency variation of a continuously changing cylindrical shell (Figures 4 and 5) is investigated in this

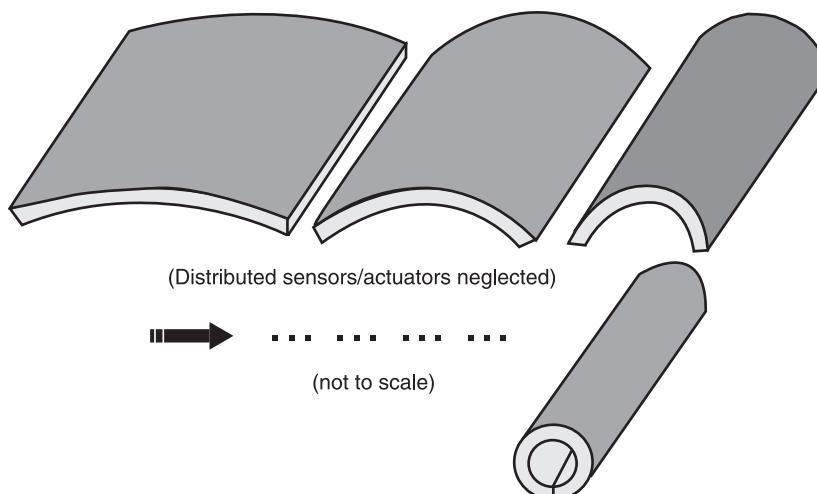

Figure 4 Shell transformation, from a shallow shell to a cylindrical.

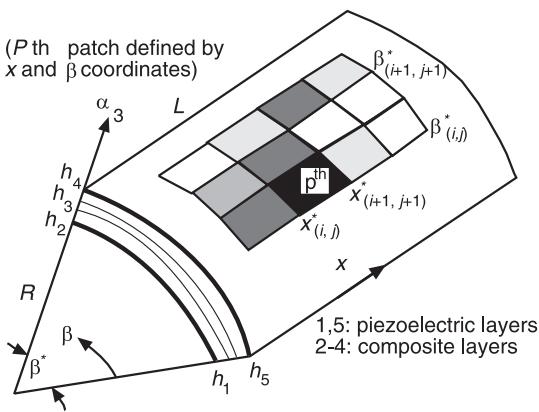

Figure 5 A cylindrical shell laminated with distributed piezoelectric layers.

section; their sensor (modal) sensitivities are presented in the next section. It is assumed that the total effective arc (circumferential) length is constant, i.e., $R\beta^* = 0.05 \times (\pi/2)m$ and the curvature angles are $\beta^* = 30^\circ 60^\circ 90^\circ 120^\circ 150^\circ$ respectively. Note that the total shell size and area remains the same; only its curvature changes, resembling geometry transformation in adaptive shells. (However, the forces inducing the changes are not considered.) Natural frequencies, i.e., (mn) , where m corresponds to x and n to β , of these shells are calculated and plotted in Figure 6. There is a total of 16 modes for each curvature presented in the figure.

As expected, the natural frequencies of shallow shells increase as the mode number increases, and those of deep shells decrease for the first few natural

modes and increase as the mode number increases when the curvature is magnified. This is due to the fact that the kinetic strain energies of lower modes are dominated by the membrane strain energies and those of higher modes are dominated by the bending strain energies. This coupling between the membrane effect and the bending effect increases as the shell curvature is magnified.

Sensor Sensitivity

Distributed sensor sensitivity can generally be divided into two components: first, the membrane sensitivity, and second, the bending sensitivity. Sensor (modal) sensitivities at various shell curvatures are presented in Figure 7. Recall that the bending sensitivity is important to shallow shells and plates; the membrane sensitivity is important to deep shells and shells of revolution. Accordingly, the membrane sensitivity increases when the shell curvature increases. However, the bending sensitivity remains unchanged since the moment arm never changes over the period of shell transformation. Overall, the total sensor sensitivity still increases due to the significantly increased membrane sensitivities in deep shells.

Actuator Sensitivity and Control Authority

Curvature effects to open-loop modal actuation factors and closed-loop modal damping ratios are investigated. It is assumed that the total shell size remains the same, i.e., $R\beta^* = 0.05 \times (\pi/2)m$, only the shell curvature changes, i.e., $\beta^* = 30^\circ 60^\circ 90^\circ 120^\circ 150^\circ$. Open-loop modal actuation factors, closed-loop

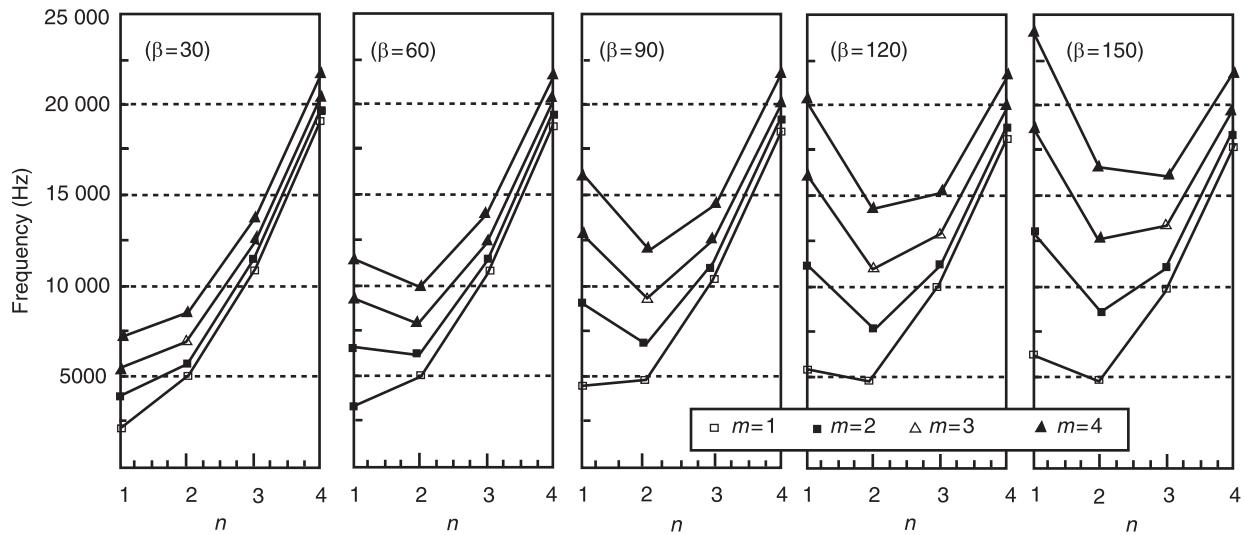

Figure 6 Frequency variations due to shell curvature changes.

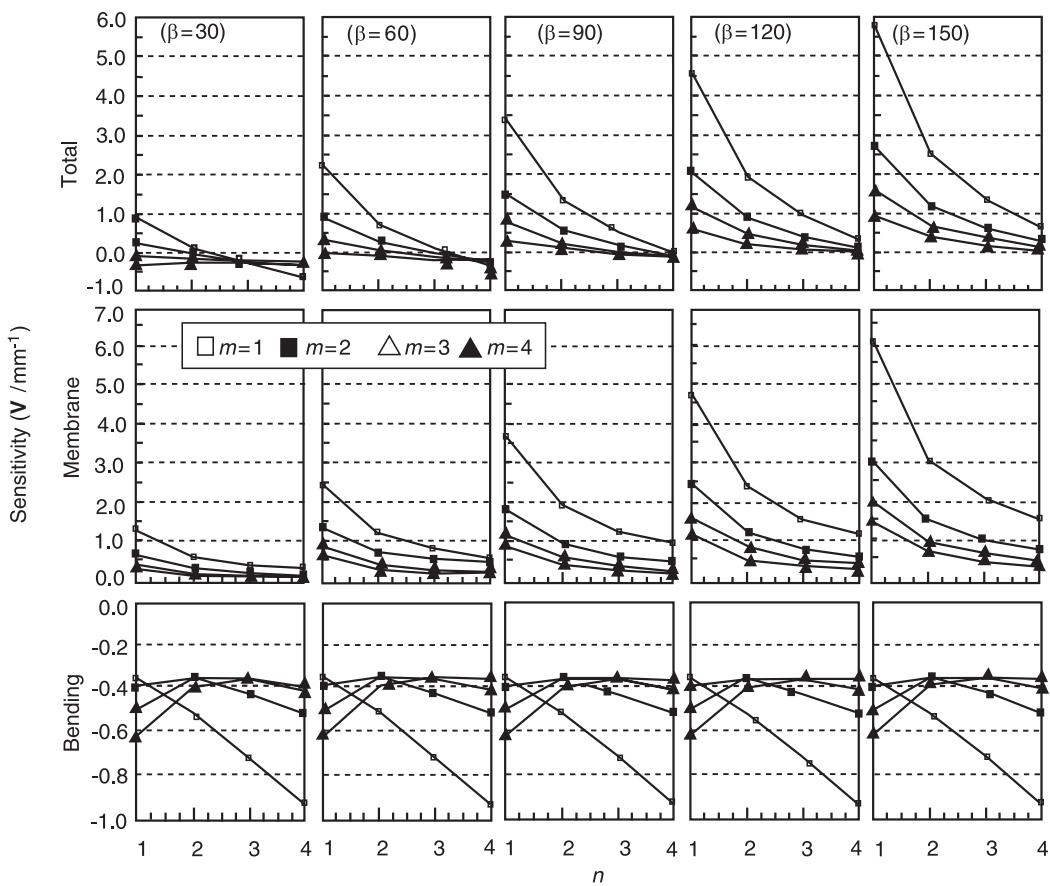

Figure 7 Sensor sensitivity and mode relationship of shells at various curvatures.

modal velocity feedback factors, and closed-loop modal damping ratios are calculated and presented in Figures 8–10, respectively. Note that the open-loop modal actuation factor (m nth) is the m nth modal control force magnitude per unit control voltage ($\text{N kg}^{-1} \text{V}^{-1}$), which is independent of time and spatial distribution. Analytical results suggest that the membrane actuation effect increases significantly as the shell curvature increases, due to an increased membrane effect in curved shells. The bending control effect remains about the same, since the moment arm remains unchanged in Figure 8.

Distributed sensor sensitivity is contributed by the membrane sensitivity and the bending sensitivity respectively, related to the induced membrane and bending strains in the distributed sensor layer. In contrast, the total control effect of the distributed actuator can be divided into two control actions: the membrane control force and the control moment. Thus, ideally, it is possible to utilize the individual sensor signals, i.e., the membrane signal and the bending signal, amplify the signals, and feed them to either the membrane control action or the bending control action. Accordingly, there are four possibilities: (1) membrane signal to membrane control action

(M, M); (2) membrane signal to bending control action (M, B); (3) bending signal to membrane control action (B, M); and (4) bending signal to bending control action (B, B).

Figure 9 illustrates the closed-loop velocity feedback factor and the shell curvature relationship (the modal feedback factors F_{mn} derived from the four control possibilities of the cylindrical shells at various curvatures. There are nine natural modes, $(m, n) = (1, 1)–(3, 3)$; the feedback factor of each mode (the modal feedback factor) has the above four feedback possibilities and a total effect which are plotted versus the shell curvatures from 30° to 150° . Note that the (M, B) and the (B, M) are of equal magnitude and opposite sign. Furthermore, these results clearly indicate that the membrane control action (M, M) dominates the overall control effect in deep shells; however, this effect decreases as the mode increases. The bending control action, on the other hand, dominates the control action for shallow shells and it gradually influences the total control action of higher modes for deep shells.

Examining the velocity feedback factors (F_{mn}) is only to study further the enhanced closed-loop damping characteristics, $\zeta_{mn}^T = \zeta_{mn} + F_{mn}/2\omega_{mn}$, among

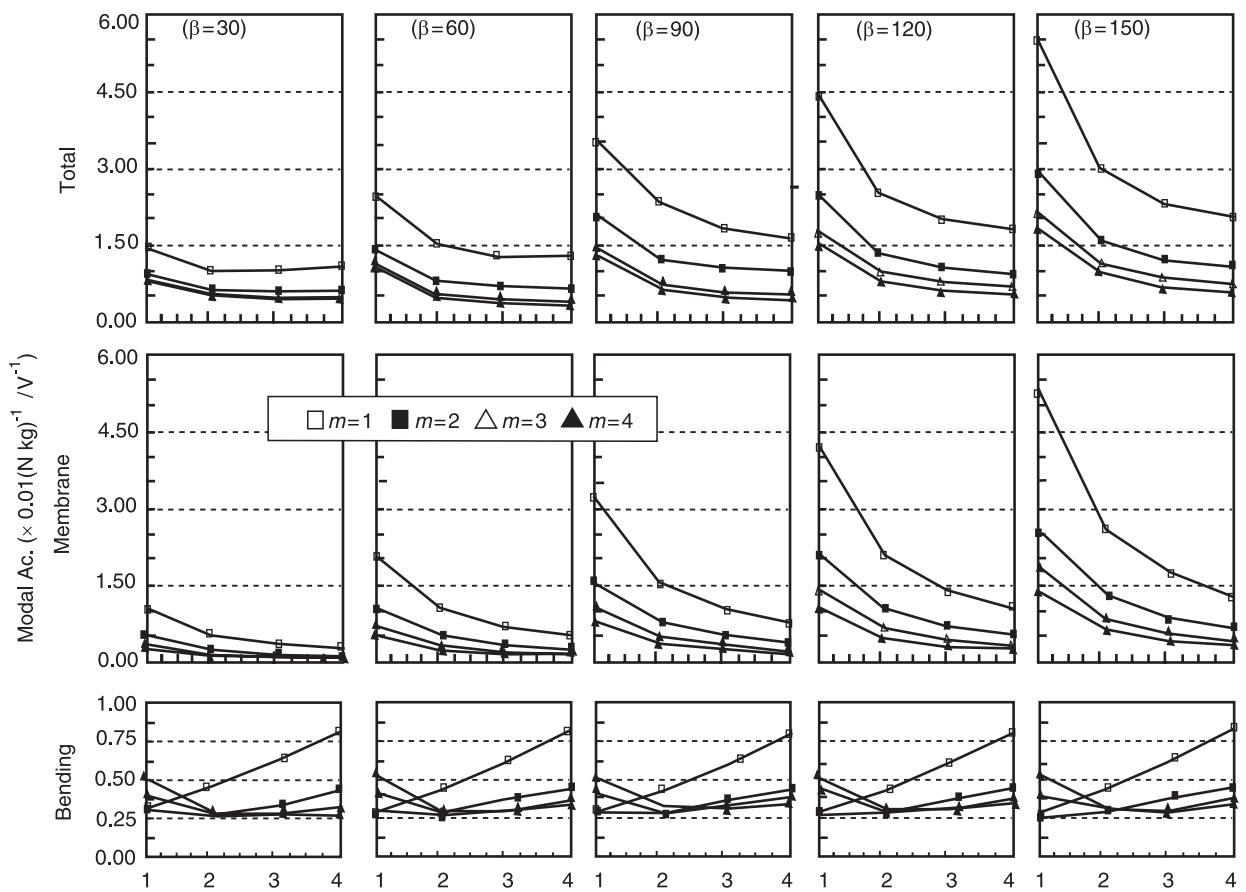

Figure 8 Modal actuation factors of shells at various curvature angles.

the four feedback possibilities, and thus to evaluate the overall closed-loop controllability of the shells with various curvatures. Inferred damping ratios of the four feedback possibilities are plotted versus various shell curvatures (**Figure 10**). Again, the membrane control effect dominates the lower natural modes as well as the total control effect in deep shells. Recall that the membrane strain energy dominates in lower natural modes of deep shells and the bending strain energy dominates in shallow or zero-curvature shells. For lower natural modes, the natural frequency of shallow shells keeps increasing, while the natural frequency of highly curved shells drops for the first few modes. This frequency variation due to the curvature changes also affects the relatively irregular variations of controlled modal damping ratios, i.e., $\zeta_{mn}^T = \zeta_{mn} + \mathbf{F}_{mn}/2\omega_{mn}$.

Remarks

In the recent development of smart structures and strucronic systems, piezoelectric materials are widely used as sensors and actuators in sensing, actuation,

and control applications. This article aims to introduce distributed sensors and actuators and their functionalities and utilities, and design guidelines applied to distributed sensing and control of elastic DPSs, precision systems, MEMS, smart structures, and strucronic systems. Sensitivities, actuation factors, feedback factors, and controlled damping ratios were reported. The membrane and bending contributions to the sensor sensitivities and control effectiveness were evaluated.

Distributed sensor signal is determined by electro-mechanical coupling coefficients, material properties, mode numbers, locations, spatial distributions, etc. The total sensor sensitivity is contributed by two components: a membrane sensitivity and a bending sensitivity, in which the former depends on the membrane strains and the latter depends on the bending strains. Analytical results have suggested that increasing the shell curvature enhances the membrane energies while the bending energies remain identical. This can be observed in the frequency shifts of various curvatures. Consequently, the sensor membrane sensitivities significantly increase and the bending

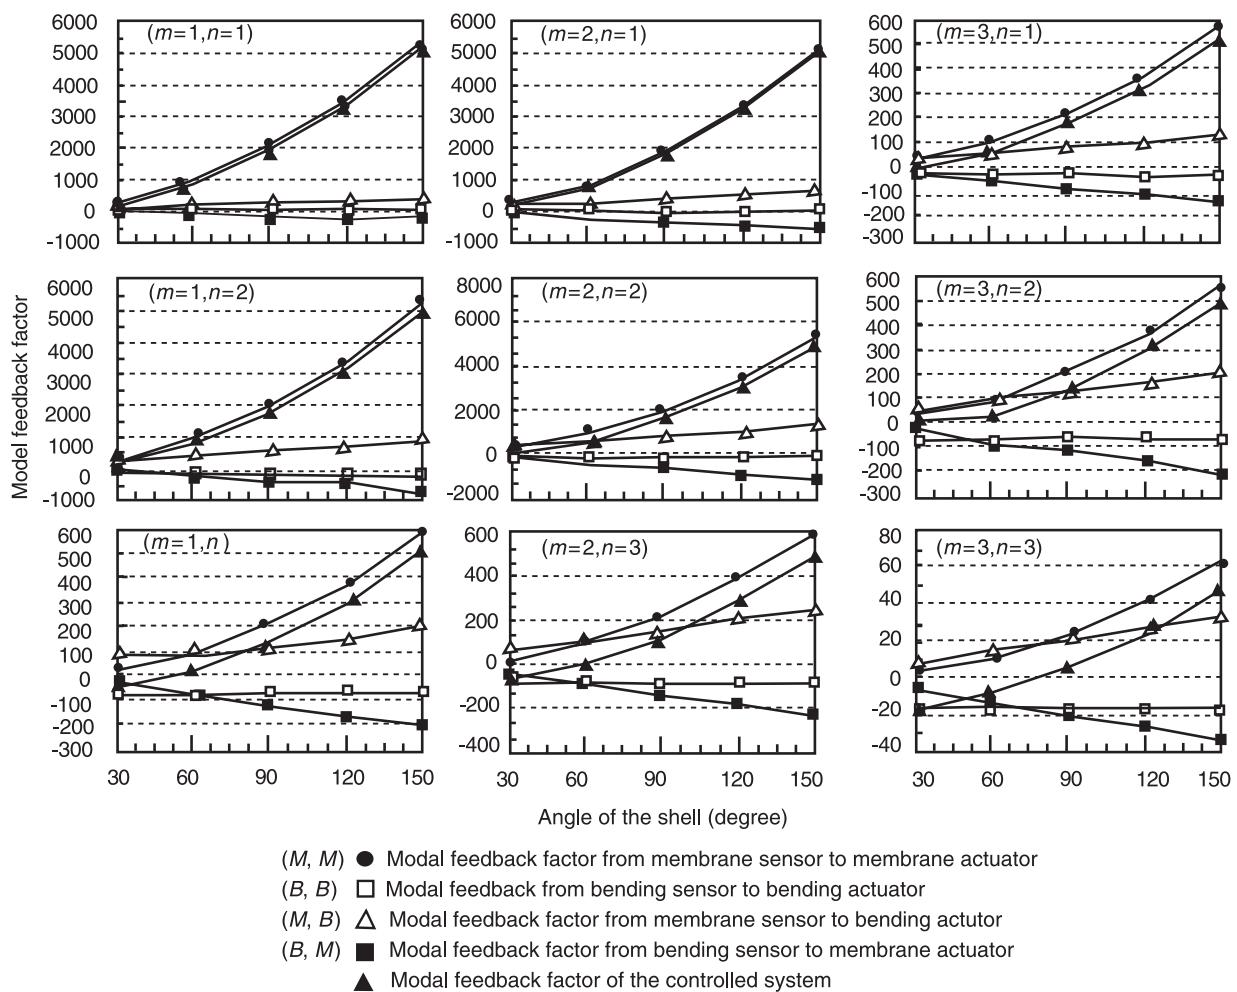

Figure 9 Modal velocity feedback factors of shells at various curvature angles.

sensitivities remain the same. The total sensitivities also increase due to a significant increase in the membrane sensitivities.

Furthermore, spatial actuation and control effectiveness of distributed actuator patches laminated on a simply supported piezoelectric laminated cylindrical shell were also studied. Modal control forces of open and closed-loop vibration control effects were respectively evaluated. Open-loop modal actuation factor and its membrane and bending components were defined. Closed-loop modal feedback factors and controlled damping ratios were presented and their membrane and bending contributions were evaluated with respect to various shell curvatures and natural modes. Analytical results suggested that the membrane control action is of importance for lower natural modes and the bending control action becomes dominating for higher natural modes in deep shells. Since the dominating control action

comes from the membrane control action, the curvature increase significantly enhances the modal actuation factor and, thus, the controlled damping ratio of deep-shell strucronic systems. Note that all results were evaluated based on constant piezoelectric coefficients without any hysteresis or temperature influences.

Nomenclature

A_1, A_2	Lamé parameters
F_{mn}	velocity feedback factors
R	radius of the spherical shell
R_1, R_2	radii of curvature
Y_p	Young's modulus
ρ	mass density

Considerable attention has recently been devoted to the utilization of shape memory alloys (SMA) as an effective means of attenuating the vibration of flexible structures. Such effectiveness stems from the unique thermomechanical characteristics of the SMA. A brief description of these characteristics is

necessary to understand the principles behind the different SMA vibration control mechanisms.

Basic Properties of SMA

SMAs undergo a unique and reversible phase transformation from martensite to austenite as the temperature and/or the stress acting on the alloy are changed. Figure 1 shows the effect of the temperature on the martensite fraction of a typical SMA. In the figure, M_s , M_f , A_s , and A_f denote the martensite start, martensite finish, austenite start, and austenite finish temperatures.

Shape Memory Effect

At temperatures below M_f , the SMA has the stress-strain characteristics shown in Figure 2A. Note that the SMA retains a large amount of residual strain when the stress is removed. As the temperature is increased to A_f , the strain can be completely recovered, resulting in the well-known shape memory effect.

Superelastic Effect

When the temperature is increased to above A_f , the SMA exhibits a different type of stress-strain characteristic, as shown in Figure 2B. In that case, the residual strains vanish and the alloy can undergo a large deformation without any significant increase in the applied stress. Such a phenomenon is known as the superelastic (pseudoelastic) effect.

Modulus of Elasticity

The effect of temperature on Young's modulus of a SMA made of nickel-titanium alloy (nitinol) is shown in Figure 3. Note that Young's modulus increases by almost four times as the SMA is transformed from martensite to austenite. Such changes are unique and are unlike most alloys, as the SMA becomes stiffer when heated and softer when cooled.

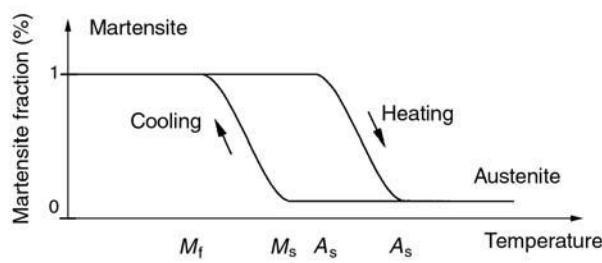

Figure 1 Effect of temperature on phase transformation of SMA.

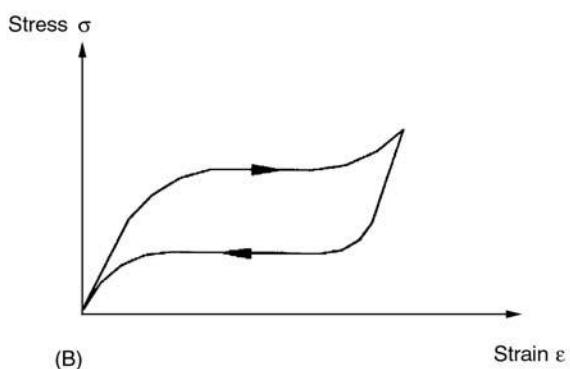

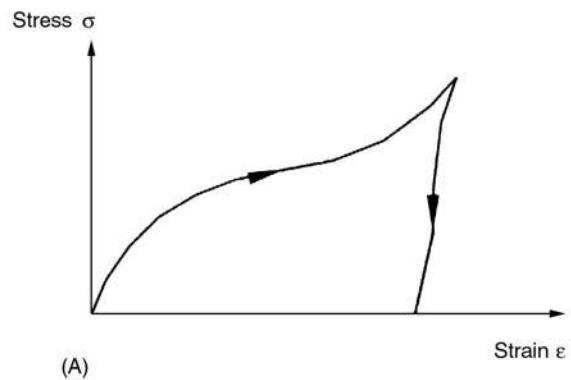

Figure 2 Stress-strain characteristics of SMA. (A) Shape memory effect; (B) superelastic effect.

Other Basic Properties

For SMA made of nitinol, typical strain recovery is about 8%. When restrained, the SMA can develop stresses in the order of 400 MPa.

Constitutive Equations

The martensitic phase transformation process of the nitinol strips is governed by the following constitutive equation:

$$(\sigma - \sigma_0) = E_s(\varepsilon - \varepsilon_0) + \Theta(T - T_0) + \Omega(\xi - \xi_0) \quad [1]$$

where σ , ε , and T denote the stress, strain, and temperature respectively. Also, E_s , Θ , and Ω define Young's modulus, the thermal expansion modulus and phase transformation modulus of nitinol. Subscript 0 correspond to the initial conditions. In eqn [1], the martensitic fraction ξ is defined as follows.

Transformation from Martensite to Austenite

$$\xi = \xi_M e^{[a_A(A_s - T) + b_A \sigma]} \quad [2]$$

where:

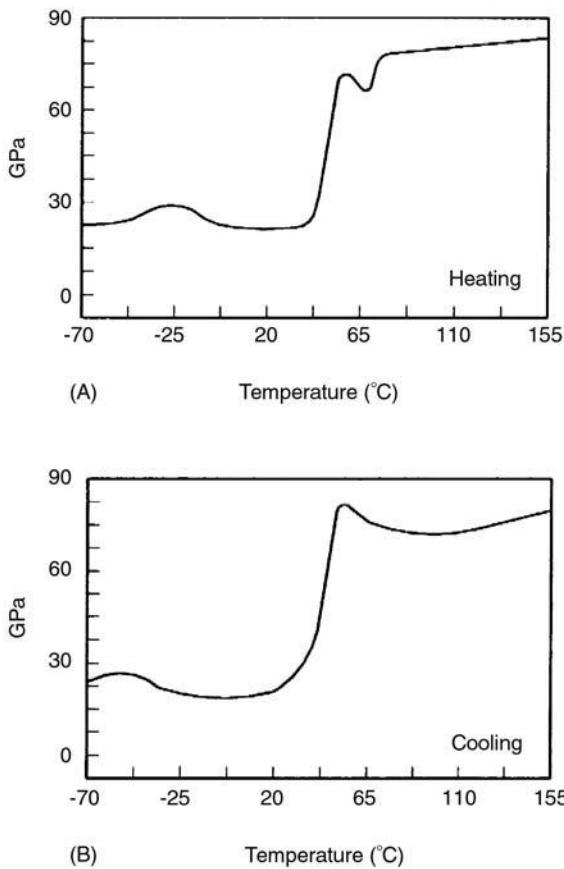

Figure 3 Typical Young's modulus of SMA (nitinol). (A) During heating; (B) during cooling.

$$a_A = \ln(0.01/\xi_M)/(A_s - A_f) \quad \text{and} \quad b_A = a_A/C \quad [3]$$

where ξ_M , A_s , A_f , and C denote the initial martensitic fraction, austenite start temperature, austenite finish temperature, and slope of stress-transition temperature characteristics.

The domain of the transformation is defined by:

$$\begin{aligned} \ln(0.01/\xi_M)/b_A + a_A/b_A(T - A_s) &\leq \sigma \\ \leq a_A/b_A(T - A_s) \end{aligned} \quad [4]$$

Transformation from Austenite to Martensites

$$\xi = (1 - \xi_A) \left[1 - e^{[a_M(M_s - T) + b_M \sigma]} \right]$$

where:

$$a_M = \ln [1 - 0.99/(1 - \xi_A)] / (M_s - M_f)$$

and:

$$b_M = a_M/C \quad [6]$$

where ξ_A , M_s , M_f , and C denote the initial austenitic fraction, martensite start temperature, martensite finish temperature and slope of stress-transition temperature characteristics.

The domain of the transformation is defined by:

$$a_M/b_M(T - M_s) \leq \sigma \leq \ln [1 - 0.99/(1 - \xi_A)]/b_M + a_M/b_M(T - M_s) \quad [7]$$

The constitutive eqns [1]–[7] can be used to determine the stress–strain–temperature characteristics of a one-dimensional SMA fiber. These relationships can be utilized to compute the recovered strain or stress of the SMA resulting from the shape memory effect as well as the energy dissipated due to the hysteresis associated with the superelastic effect.

Vibration Control Mechanisms

Based on the basic properties of the SMA, one can identify five distinct mechanisms that have been successfully utilized to control structural vibration, as outlined in Table 1.

There follows a brief description of these mechanisms.

Passive Damping Mechanism

In this mechanism, the inherent hysteresis characteristics of the shape memory alloy, in its superelastic form, are utilized to dissipate the vibration energy. The amount of energy dissipated is equal to the area enclosed inside the stress-strain characteristics (**Figure 4**). This passive mechanism has been successfully used to damp out the vibration of a wide variety of structures, including large structures subject to seismic excitation. In these applications, the structures are supported on springs, of one form or another, made of superelastic SMA.

Control Actuators

In this class of mechanisms, the SMA actuator takes the form of fibers or springs which are attached to

Table 1 Vibration control mechanisms of the SMA

No.	Mechanism	Mode
1	Passive damping mechanism	Passive
2	Control actuator	Active
3	Active stiffening mechanism	Active
4	Active damping augmentation	Active
5	Active impedance controller	Active

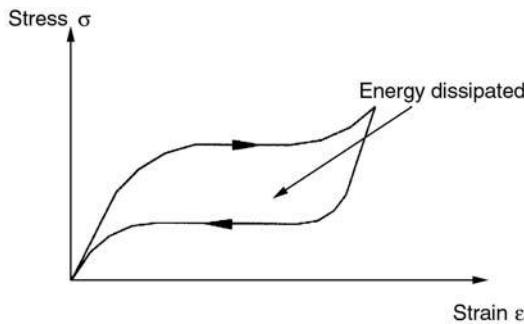

Figure 4 Hysteresis characteristics of superelastic SMA.

critical points of the vibrating structures, as shown in **Figure 5**. Usually, a pair of actuators is needed to control the vibration of the structure effectively. For example, when the vibrating beam of **Figure 5A** moves downward, the actuator A is activated thermally to counterbalance the external disturbance while actuator B remains inactive. If the motion is reversed, actuator B is activated while actuator A stays inactive. A similar arrangement is used to control the vibration of larger structures, as shown in **Figure 5B**.

Note that the need for two actuators is because most of the commonly used shape memory actuators have one-way memory, i.e., can only operate in one direction when activated and revert back to their undeflected position under the action of external load generated, for example, by a bias spring.

A block diagram of the dynamics of a structure, the SMA actuator, and the controller is shown in **Figure 6**. Simple first-order transfer functions have been considered to represent the dynamics of the SMA

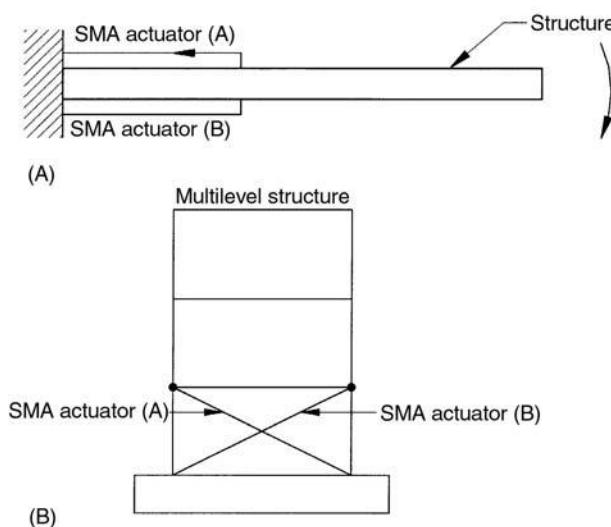

Figure 5 Use of SMA as a control actuator.

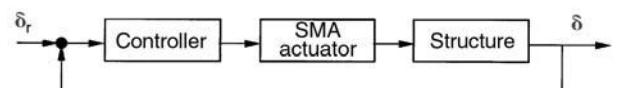

Figure 6 Block diagram of structure/SMA/control system.

actuators. With such transfer functions, classical and robust controllers, such as LQG/LTR and sliding mode controllers, have been successfully employed to control the vibration of simple beams and multilevel structures. Mathematically, the dynamics of the structure with the SMA actuator is given by:

$$\text{Structure } \mathbf{M}\ddot{\delta} + \mathbf{K}\delta = \mathbf{B}\mathbf{F}_{\text{sma}} \quad [8]$$

$$\text{Shape memory force } \tau\dot{\mathbf{F}}_{\text{sma}} + \mathbf{F}_{\text{sma}} = \gamma\mathbf{V} \quad [9]$$

$$\text{Control law } \mathbf{V} = -\mathbf{GC}\delta \quad [10]$$

where \mathbf{K} and \mathbf{M} are the stiffness and mass matrices. Also, $\boldsymbol{\delta}$, \mathbf{B} and \mathbf{F}_{sma} denote the nodal deflection vector, location matrix of the actuators, and the shape memory control forces respectively. The control voltage \mathbf{V} is generated using a negative feedback control law such that \mathbf{G} is the control gain matrix and \mathbf{C} is the measurement matrix. In eqn [9], τ denotes the time constant of the thermodynamic behavior of the SMA actuator.

Other more complex models of the SMA actuator are considered. Some of these models are extracted experimentally using classical linear and nonlinear identification methods.

Active Stiffening Mechanism

This mechanism is used extensively in shape memory composites, as shown in **Figure 7**. In the figure, a composite beam is reinforced with SMA (nitinol) fibers embedded inside sleeves placed along the neutral axes of the beam. In this arrangement, the fibers are free to move during the phase transformation process in order to avoid degradation and/or destruction of the shape memory effect which may result when the fibers are completely bonded to the composite matrix. The beam is considered to be supported

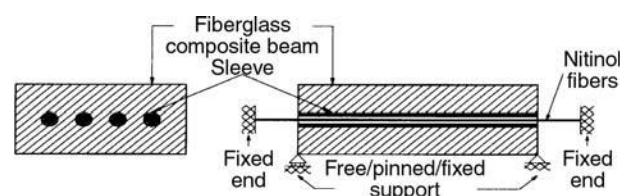

Figure 7 Typical SMA-reinforced composite beams.

on a tunable elastic foundation made of the embedded nitinol fibers. The load transfer between the matrix and the nitinol foundation, in the transverse direction, is controlled by adjusting the tension of the nitinol fibers through proper prestraining and activation of the shape memory effect.

The beam stiffness is made up of different components which include the flexural rigidity of the beam, the geometric stiffness that accounts for the axial and thermal loading, as well as the stiffness imparted by the elasticity of the nitinol fibers. Consider the nitinol-reinforced beam element shown in Figure 8 whose length is l and is bounded by the two nodes i and j . The beam element consists of a composite with randomly oriented fibers, which is reinforced with unidirectional nitinol fibers aligned along the x -axis. In the figure, P_m , P_t , and T_t denote the axial mechanical loads, the axial thermal load, and the total tension developed by the nitinol fibers respectively. Also acting on the element are the external shear forces $V_{i,j}$ and moments $M_{i,j}$.

The stiffness matrix \mathbf{K}_e of the element is obtained by using the principle of conservation of energy and equating the work done by external loads to the strain energies stored in the element. This yields the following relationships:

$$\frac{1}{2} \delta_e^T \mathbf{F} = \frac{1}{2} E_m I_m \int_0^1 [w'']^T [w''] dx - \frac{1}{2} P_n \int_0^1 [w']^T [w'] dx \quad [11]$$

where δ_e and \mathbf{F} denote the nodal deflection and force vectors defined by:

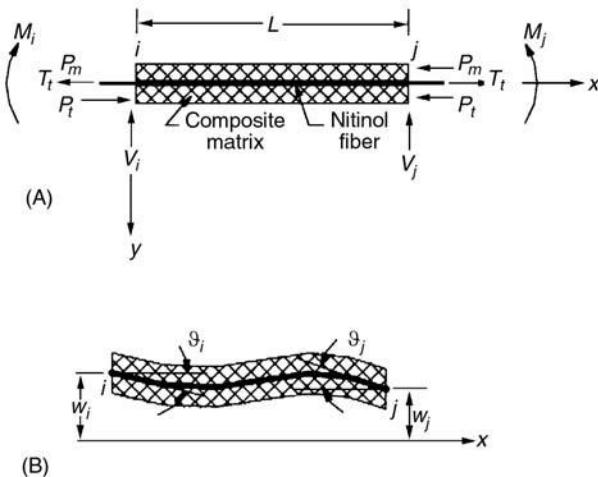

Figure 8 SMA/beam element with forces (A) and displacements (B).

$$\delta_e = [w_i \ w'_i \ w_j \ w'_j]^T$$

and:

$$\mathbf{F} = [V_i \ M_i \ V_j \ M_j]^T \quad [12]$$

with w denoting the transverse deflection and the primes representing derivatives with respect to x . Also, $E_m I_m$ define the flexural rigidity of the beam element and P_n is the net axial force given by:

$$P_n = (P_m + P_t - T_t) \quad [13]$$

The thermal load P_t is given by:

$$P_t = \alpha \Delta \Theta E_m A_m \quad [14]$$

This thermal load is generated by changes in the temperature $\Delta \Theta$ of the element caused by the activation and deactivation of the nitinol fibers. In eqn [14], α , E_m , and A_m denote the thermal expansion coefficient of the composite, its modulus of elasticity, and cross-sectional area respectively.

Using the classical finite element formulation, the transverse deflection w and the force vector \mathbf{F} are defined in terms of the nodal deflection vector δ_e as follows:

$$w = \mathbf{A} \delta_e \quad \text{and} \quad \mathbf{F} = \mathbf{K}_e \delta_e \quad [15]$$

where \mathbf{A} and \mathbf{K}_e are an interpolating vector and the element stiffness matrix respectively.

From eqns [11] and [15], the stiffness matrix \mathbf{K}_e is:

$$\mathbf{K}_e = E_m A_m \int_0^1 \mathbf{A}''^T \mathbf{A}'' dx - P_n \int_0^1 \mathbf{A}'^T \mathbf{A}' dx \quad [16]$$

Eqn [16] represents the basic equation for understanding the role that the Nitinol fibers play in controlling the stiffness of the composite beam. For example, if the initial fiber tension, T_0 , is high enough to counterbalance the mechanical and thermal effects (i.e., $P_n = 0$), then the beam stiffness can be maintained unchanged. For higher prestrain levels, the beam stiffness can be enhanced. Further enhancement can be achieved when the shape memory effect of the nitinol fibers is activated by heating the fibers above their phase transformation temperature. The additional phase recovery force make the net axial load P_n negative and accordingly increase the overall stiffness of the beam. The magnitude of the tension can be predicted using the constitutive equation of the SMA (eqn [1]). However, it is essential that the total tension in the nitinol fibers, i.e., the sum of the tension

due to the prestrain and the phase recovery force, must exceed the mechanical and thermal loads to compensate for the softening effect in the matrix resulting from heating the nitinol fibers inside the composite matrix.

The mass matrix M_e of the beam element is:

$$M_e = \rho_m A_m \int_0^1 A^T A dx \quad [17]$$

where ρ_m denotes the density of the composite beam.

The dynamic characteristics of nitinol-reinforced beams are obtained by combining the stiffness matrix K_e with the mass matrix M_e as follows:

$$M_e \ddot{\delta}_e + K_e \delta_e = F \quad [18]$$

where F is the external load vector.

Solution for the eigenvalues of the above equations gives the natural frequencies of the composite beam as influenced by the properties of the composite matrix and the nitinol fibers. It is important to note that these properties are influenced by the temperature distribution inside the beam which is developed by virtue of activating and deactivating the nitinol fibers.

Figure 9A shows typical changes in the first natural frequency of a beam when it is reinforced with untrained nitinol fibers which are prestrained at different levels. The changes are normalized with respect to the natural frequency of the unreinforced beam measured at 25°C, i.e., 50.1 Hz. It can be seen that the frequency of the unreinforced beam drops as the ambient temperature increases and the beam loses its elastic stability and starts to buckle when the temperature exceeds 40°C. The drop in the natural frequency of the unreinforced beam is attributed to the softening of the matrix, which is clearly demonstrated by the loss in the modulus of elasticity of the beam, as shown in Figure 10.

Reinforcing the beam with prestrained untrained nitinol fibers considerably increases the natural frequency of the beam. The extent of the upward shift in natural frequency increases with increased prestrain level. However, as the ambient temperature increases, the frequency shift drops in a manner similar to the characteristics of the plain unreinforced beam. Such a drop is again attributed to the softening effect of the matrix and the fact that the untrained nitinol fibers act as a static pretensioning device that produces constant tension independently of temperature. Therefore, the frequency enhancement is only gener-

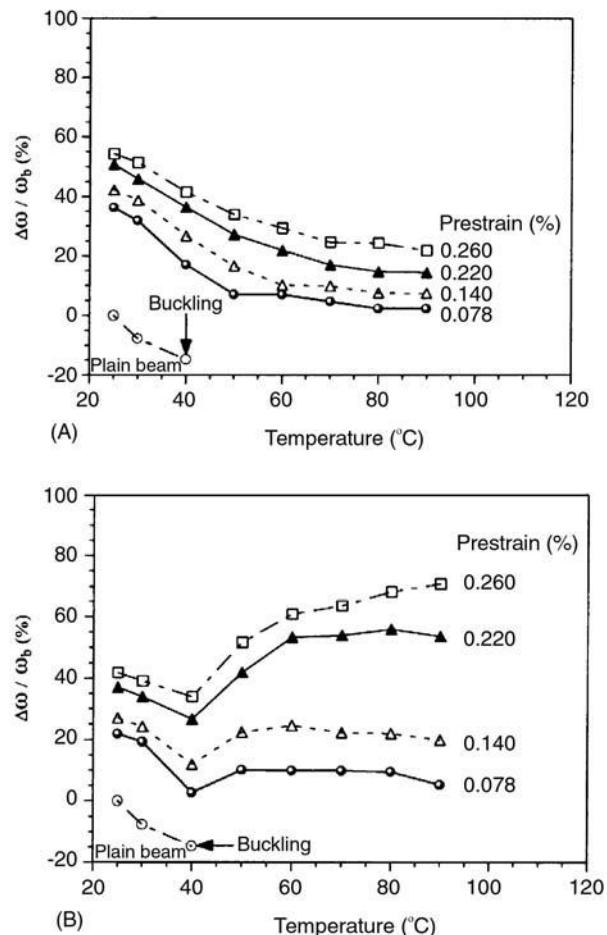

Figure 9 Effect of temperature and initial strain on enhancing first natural frequency (A) without shape memory; (B) with shape memory.

ated by the reinforcement and the prestrain effects, and not by the shape memory effect.

However, a greater frequency shift can be achieved by imparting the shape memory effect to the nitinol fibers. The trained fibers are inserted into the composite beam to replace the untrained set and the frequency shifts become significant, particularly at high ambient temperatures. This is clearly demonstrated in Figure 9B. For temperatures between room temperature and 40°C, the frequency shifts obtained are similar to those with the untrained fibers within experimental accuracy. Once the ambient temperature exceeds 50°C, i.e., the austenite phase transformation temperature of the nitinol fibers, the frequency shift characteristics change from a gradually decaying trend to one that is gradually increasing. Such a sudden change is the result of the contribution of the phase recovery forces developed by the shape memory effect, which is illustrated in Figure 10.

The shape memory effect generates strain energy in the nitinol fibers to counterbalance the softening

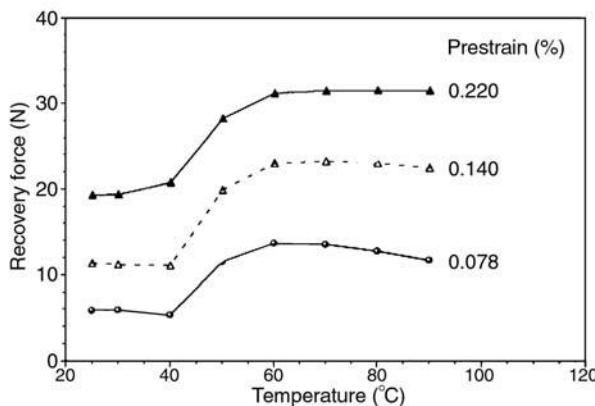

Figure 10 Young's modulus and loss factor of a typical matrix.

effect of the composite matrix with increasing temperature. As the amount of strain energy developed depends on the initial prestrain level, it can merely compensate for the softening effect to maintain the beam frequency at a near constant value which is independent of ambient temperature, as shown for a prestrain level of 0.078%. It can also increase the beam frequency as the ambient temperature increases, as indicated for prestrain levels of 0.22 and 0.26%. For a prestrain level of 0.26% and ambient temperature of 90 °C, the frequency increase reaches about 70% as compared to an 18% increase when untrained fibers are used.

Active Damping Augmentation Mechanism

Using the active stiffening mechanism of the SMA composites is particularly important when the static characteristics, as the critical buckling loads, are to be controlled. But, when the dynamic response is of

concern, the stiffening mechanism alone becomes ineffective in attenuating vibrations resulting from broad band excitations unless it is augmented with a controlled energy dissipation mechanism. Fortunately, SMA composites have a unique source of damping, which is built in the composite matrix itself. It is therefore possible to simultaneously utilize both the stiffening and the energy dissipation mechanisms to achieve optimal vibration attenuation over broad-frequency spectrum. The nature of interaction between the two mechanisms can easily be seen from the typical characteristics of composites shown in Figure 11. The displayed characteristics indicate that activation of the SMA fibers can influence both the stiffness and damping characteristics of the composite. This is attributed to the fact that the modulus of elasticity E_m of the composite beam is a complex modulus ($E_m = E'(1 + i\eta)$) whose storage modulus E' and loss factor η are controlled by the temperature and frequency.

Figure 12 shows the effect of the operating temperature and initial tension of the nitinol fibers on the first mode of vibration and the corresponding modal loss factor of a typical SMA-reinforced beam.

In Figure 12A, it is evident that increasing the operating temperature of the composite beam with untensioned fibers results in quick degradation of the fundamental natural frequency of the beam. This degradation quickly leads to the buckling of the beam when the temperature reaches 45 °C. But, when the nitinol fibers are tensioned to 13.34 N per fiber (3 lb per fiber), buckling is avoided even when the beam temperature is increased to 100 °C. This is due to the combined stiffening of the beam by the initial tension of the fibers and by the shape memory

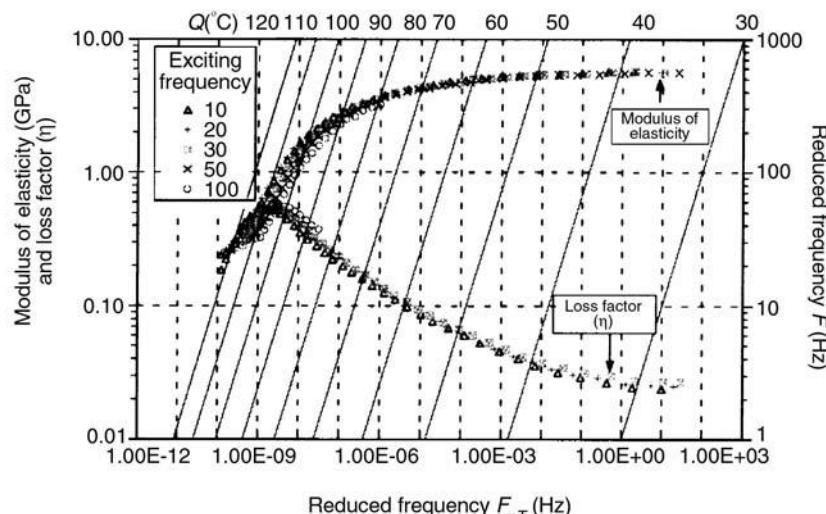

Figure 11 Phase recovery forces for different prestrains.

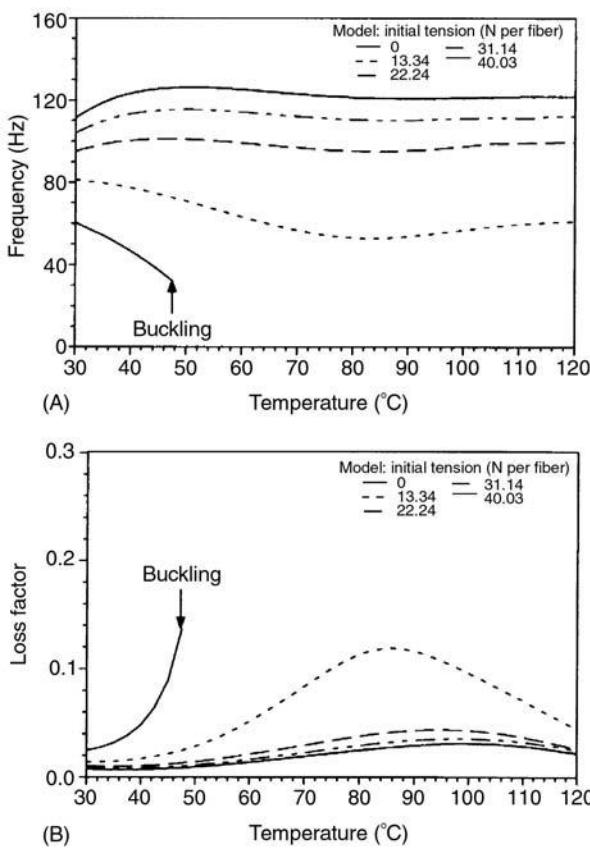

Figure 12 Effect of temperature and prestrains on frequency (A) and loss factor (B).

forces generated as the temperature is increased above the phase transformation temperature. However, the fundamental frequency still exhibits a gradual drop with increased temperature. When the initial tension of the fibers is increased to 22.24 N per fiber (i.e., 5 lb per fiber), the natural frequency is maintained almost constant over the considered temperature range. Further increase of the initial tension to 31.14 N per fiber (or 7 lb per fiber) results in a significant increase of the natural frequency with temperature followed by a plateau which is independent of temperature rise.

Figure 12B shows the modal loss factor at the first mode of vibration as a function of the operating temperature and initial tension of the nitinol fibers. It is evident that the loss factor decreases as the initial tension of the fibers is increased. This is attributed to the increased stiffness of the composite. However, for any particular tension the loss factor increases as the temperature is increased towards the glass transition temperature.

Therefore, the results displayed in Figures 12A and 12B indicate that low levels of initial tensions are inadequate for compensating for the softening of the matrix. But, they are essential for increasing the loss

factor. Also, operating at low temperatures will not allow for the utilization of the built-in damping capabilities of the composites. On the other hand, operating at a very high temperature will reduce not only the loss factor but also the structural stiffness. Accordingly, an optimal balance can be attained by selecting the best combination of initial tension and operating temperature in order to achieve optimal attenuation.

Optimal tuning of the initial tension and operating temperature of the nitinol fibers is determined in order to minimize the maximum amplitude of vibration of the composite beam when subjected to external excitations. Such amplitude of vibration is measured by the maximum frequency response function (FRF) β_{\max} which is determined from:

$$\beta_{\max} = \max_{j,k,\omega} \sum_{n=1}^N [\phi_n(j)\phi_n(k)] / [\omega_n^2 - \omega^2 + i\eta_n\omega_n] \quad [19]$$

where $\phi_n(j)$, ω_n and η_n denote the mode shape at location j for the n th mode, the natural frequency of the n th mode, and the loss factor at the n th mode respectively. The three parameters $\phi_n(j)$, ω_n , and η_n are obtained from the solution of the eigenvalue problem of the homogeneous equation of motion of the composite beam which is given by eqn [18]. In eqn [19], ω denotes the excitation frequency of a force located at k .

Figure 13 shows the effect of the temperature and initial tension on the maximum FRF. Figure 13A displays a three-dimensional plot of these characteristics and Figure 13B shows a projection of the maximum FRF on the temperature-tension plane. It is evident that there is an optimal operating temperature for each value of the initial tension. At that temperature, the maximum FRF attains its minimum value. For example, when the initial tension is 31.14 N per fiber, the optimal operating temperature is about 92 °C. Increasing the tension beyond 31.14 N per fiber is found to produce an insignificant reduction in the maximum FRF, as can clearly be seen from Figure 13A.

Figure 14 shows the FRF, at beam midspan due to excitation at the same location, as a function of the excitation frequency. The figure shows the FRF for optimally tuned and activated fibers at initial tensions of 13.34 and 31.14 N per fiber respectively. For comparison purposes, the FRF of a beam with untensioned and unactivated nitinol fibers is shown in the same figure. It is evident that vibration attenuation is achieved by the activation of the nitinol fibers whether their initial tension is low (13.34 N per

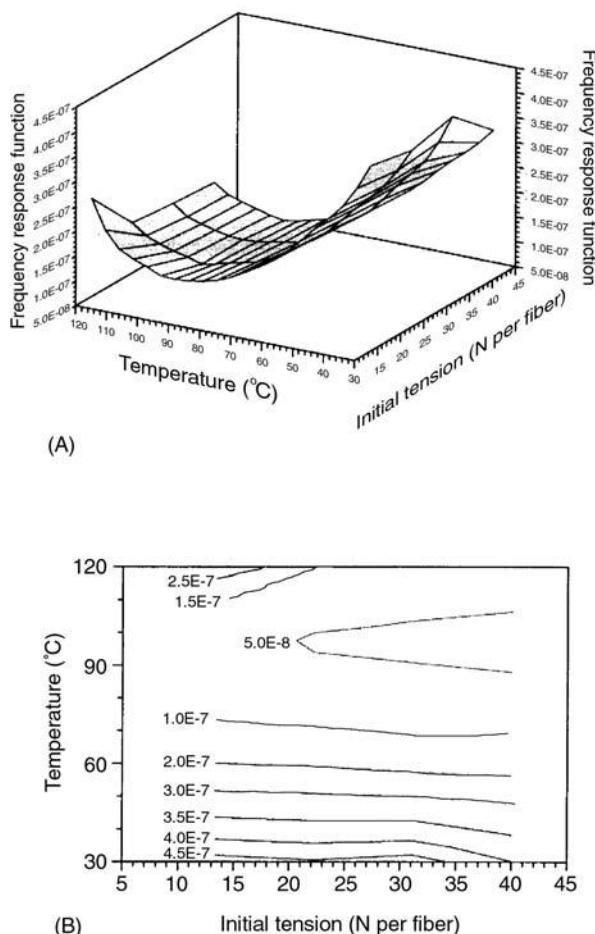

Figure 13 Effect of temperature and initial tension on frequency-response functions.

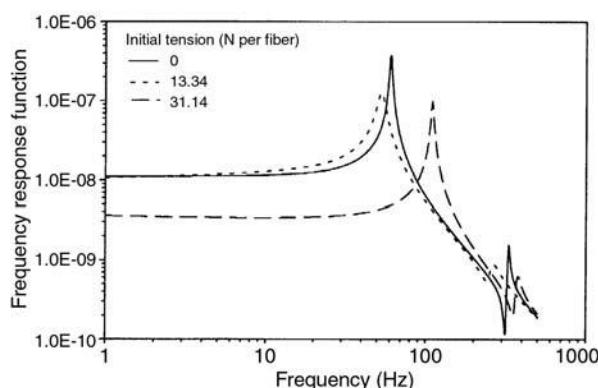

Figure 14 Effect of initial tension and excitation frequency on frequency-response function.

fiber) or high (31.14 N per fiber). In the former case, attenuation is primarily attributed to the enhanced damping which results from heating the composite matrix towards its glass transition region and not to the stiffening mechanism. This is evident as the

stiffening mechanism, due to the activation of the fibers, is inadequate to compensate for the softening effect of the beam and the beam modes shift towards lower frequencies. In the latter case, when the tension is increased to 31.14 N per fiber, the attenuation is developed by the combined stiffening and damping mechanism. It is therefore more effective and higher attenuation is observed.

Active Impedance Controller

Vibration and wave propagation can also be controlled using shape memory inserts placed periodically along a structure. The inserts act as sources of impedance mismatch with tunable characteristics. Such characteristics are attributed to the unique behavior of the shape memory alloy whereby the elastic modulus of the inserts can be varied up to three to five times as the alloy undergoes a phase transformation from martensite to austenite. With such controllable capability, the inserts can introduce the proper impedance mismatch necessary to impede the wave propagation along the vibrating structures.

The propagation of waves in structures has traditionally been controlled by various passive or reactive means. For example, control can be achieved by introducing geometric and/or material discontinuities (i.e., impedance mismatch zones) along the structure in order to impede and attenuate the propagation of waves from one end of the structure to the other. Such attenuation results from the proper interaction between the incident, reflected, and transmitted waves at the discontinuity zones. The interaction is similar to that of reactive mufflers of passenger cars.

When the impedance mismatch zones are introduced periodically in a structure, very interesting wave dynamic characteristics can develop. For example, waves can be allowed to pass or stop only over selected frequency bands, called the pass and stop bands. The width of these bands can be passively controlled by proper selection of the period and nature of the impedance mismatch zones. Examples of structures with periodic impedance mismatch zones include beams, plates, and shells which are reinforced with periodic ribs and stiffeners.

Here, the structures are provided with periodic sources of impedance mismatch, which are made of shape memory inserts, as shown in Figure 15. When activated thermally, a phase transformation takes place, increasing Young's modulus of the inserts up to three times. With such smart inserts, the impedance can be tuned and the width of the pass and stop bands can be adjusted according to the nature of the external loading in order to reject the propagation of undesirable excitations.

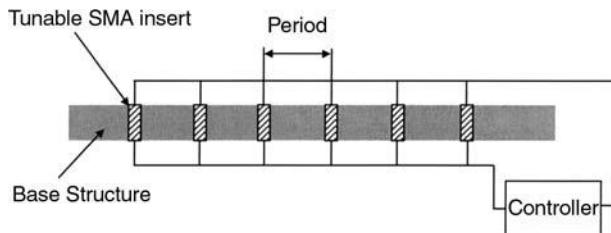

Figure 15 Periodic structures with SMA impedance mismatch zones.

Longitudinal wave propagation in composite rods with SMA inserts, as shown in **Figure 16**, is governed by the following one-dimensional equation:

$$\frac{\partial}{\partial x} \left[E(x) \cdot \frac{\partial u(x, t)}{\partial x} \right] - \rho(x) \cdot \frac{\partial^2 u(x, t)}{\partial t^2} = 0 \quad [20]$$

where $u(x, t)$ is the displacement of the rod at the longitudinal coordinate x and at time t . In eqn [1], $\rho(x)$ and $E(x)$ are respectively the density and the Young's modulus of the rod at position x . For harmonic motion of frequency ω , a solution is $u(x, t) = U(x) \cdot e^{j\omega t}$.

Under such conditions, eqn [20] reduces to the following ordinary differential equation:

$$\frac{d}{dx} \left[E(x) \cdot \frac{dU(x)}{dx} \right] + \omega^2 \cdot \rho(x) \cdot \frac{d^2 U(x)}{dt^2} = 0 \quad [21]$$

The considered composite is a rod which has periodically varying material properties and is composed of parallel, homogeneous layers, as shown in **Figure 16**. The layers are perfectly bonded along plane interfaces across which there is continuity of displacements and equilibrium of stresses. The composite rod is considered to be infinite so that the dynamics of wave propagation in its periodic layering can be studied by analyzing the behavior of its smallest physical unit, denoted as cell, whose repeated translation generates the periodic structure.

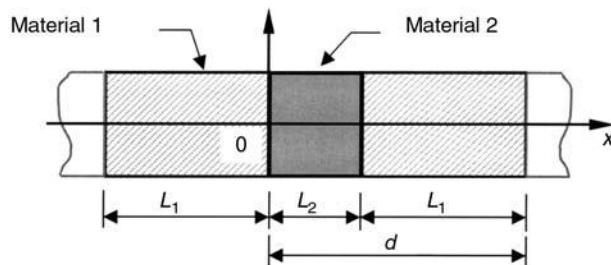

Figure 16 Geometry of a periodic composite rod with SMA inserts.

The material properties can be described by the following periodic functions of period $d = L_1 + L_2$:

$$E(x) = \begin{cases} E_1 & -L_1 < x < 0 \\ E_2 & 0 < x < L_2 \end{cases}; \quad \rho(x) = \begin{cases} \rho_1 & -L_1 < x < 0 \\ \rho_2 & 0 < x < L_2 \end{cases} \quad [22]$$

Within each material, the rod can be taken as homogeneous and the wave propagation is described by the solution of the one-dimensional wave equation:

$$\frac{d^2 U(x)}{dx^2} + k_i^2 \cdot U(x) = 0; \quad i = 1, 2 \quad [23]$$

where $k_i = \omega \cdot \sqrt{\rho_i/E_i} = \omega/c_i$ = wave number of the i th layer with $c_i = \sqrt{E_i/\rho_i}$ = wave speed.

By applying Floquet theorem, the solution of eqn [21] can be expressed as a wave characterized by the propagation constant μ :

$$u_i(x, t) = U_i(x) \cdot e^{j(\mu x + \omega t)}; \quad i = 1, 2 \quad [24]$$

where:

$$U_i(x) = A_i e^{j(k_i - \mu)x} + B_i e^{-j(k_i + \mu)x}; \quad i = 1, 2 \quad [25]$$

with $i = 1$ and 2 denoting the layers defined over $-L_1 < x < 0$ and $0 < x < L_2$ respectively.

The physical meaning of the propagation coefficient μ can easily be extracted from eqn [24]. At $x = 0$, $u_i(x, t) = e^{j\mu x} u_i(0, t)$. Therefore, μ acts as an effective wave number that relates the displacements of any two points located at a distance x apart inside material i .

Hence, the nature of wave propagation inside the material depends on the value of the propagation coefficient μ . If μ is real, then the wave at $u_i(0, t)$ will propagate whereas if μ is complex, the wave will be attenuated.

The coefficients A_1, A_2, B_1, B_2 can be found by imposing the continuity at the interface $x = 0$, where both the displacement and the normal stress have to join smoothly. The other conditions required for determining the constants can be obtained by imposing the periodicity of the problem. This also yields the following characteristic equation of the composite rod:

$$\cos(\mu \cdot d) = \cos(\Omega \cdot \tau) \cdot \cos(\Omega \cdot \tau) + \frac{1}{2} \cdot \left(\frac{\zeta^2 + 1}{\zeta} \right) \cdot \sin(\Omega \cdot \tau) \cdot \sin(\Omega \cdot \tau) \quad [26]$$

where ζ = the relative impedance of the composite:

$$\zeta = \frac{z_1}{z_2} = \frac{\sqrt{E_1 \cdot \rho_1}}{\sqrt{E_2 \cdot \rho_2}}$$

Ω =normalized frequency, $\Omega = k_1 \cdot L_1 = \omega \cdot L_1 / c_1$ and τ =ratio of the times taken by a wave to cross the layers of the composite:

$$\tau = \frac{L_2}{L_1} \cdot \sqrt{\frac{\rho_2 \cdot E_1}{\rho_1 \cdot E_2}} = \frac{L_2}{L_1} \cdot \frac{c_1}{c_2}$$

The influence of the geometrical and physical properties of the composite on its wave propagation characteristics is demonstrated by plotting the contours of the stop and pass bands as a function of the normalized frequency Ω and $\lambda = L_1/L_2$.

The shaded areas in Figure 17 correspond to stop bands ($|\cos(\mu \cdot d)| > 1$, i.e., μ is complex), while the white areas represent the pass-band regions ($|\cos(\mu \cdot d)| \leq 1$, i.e., μ is real). The maps are obtained for two values of the relative impedance, i.e., $\zeta = 2$ (Figure 17A) and $\zeta = 4$ (Figure 17B). Note that the increase of ζ from 2 to 4 results from the full activation of the SMA inserts. The figures indicate that the width of the stop bands varies significantly with the relative thickness λ . However, note that the width of the stop bands attains a maximum for $\lambda \approx 0.5$, as shown in Figure 17A. Comparison between Figure 17A and 17B suggests that, a higher impedance mismatch results in a higher density of the stop bands.

Experimental demonstration of the effectiveness of the SMA in controlling the wave propagation in rods is shown in Figure 18A. In the figure, composite rods

with three SMA inserts are excited from one end by a piezoelectric shaker and the force transmitted to the other end is monitored by a force cell. Figure 18B displays the transmitted force at various temperatures normalized with respect to that of the rod with unactivated inserts. Full activation of the SMA insert, when the temperature is maintained at 70°C, results in a 54% reduction in the amplitude of the transmitted force. Note that heating the entire rod/insert assembly reduces its natural frequency. This phenomenon results from the softening effect of the base structure with increased temperature. However, because of the unique characteristics of the SMA inserts, the impedance mismatch increases considerably with increased temperature. This is due to the increase of Young's modulus of the SMA with temperature whereas the inverse is true for the base structure. Generally, the amplitude of the force tends to decrease with increasing temperatures. However, when the temperature is gradually increased from 30°C to 50°C, the SMA inserts undergo a softening effect similar to that of the base structure. This contributes to the amplification of the force transmitted, as shown in Figure 18B. Therefore, for effective operation of the SMA inserts, it is essential to complete the phase transformation process in order to achieve maximum impedance mismatch at the interface between the inserts and the base structure.

Concluding Remarks

The use of SMA presents a viable and effective means of controlling structural vibrations. A brief summary of the basic properties of the SMA has been presented

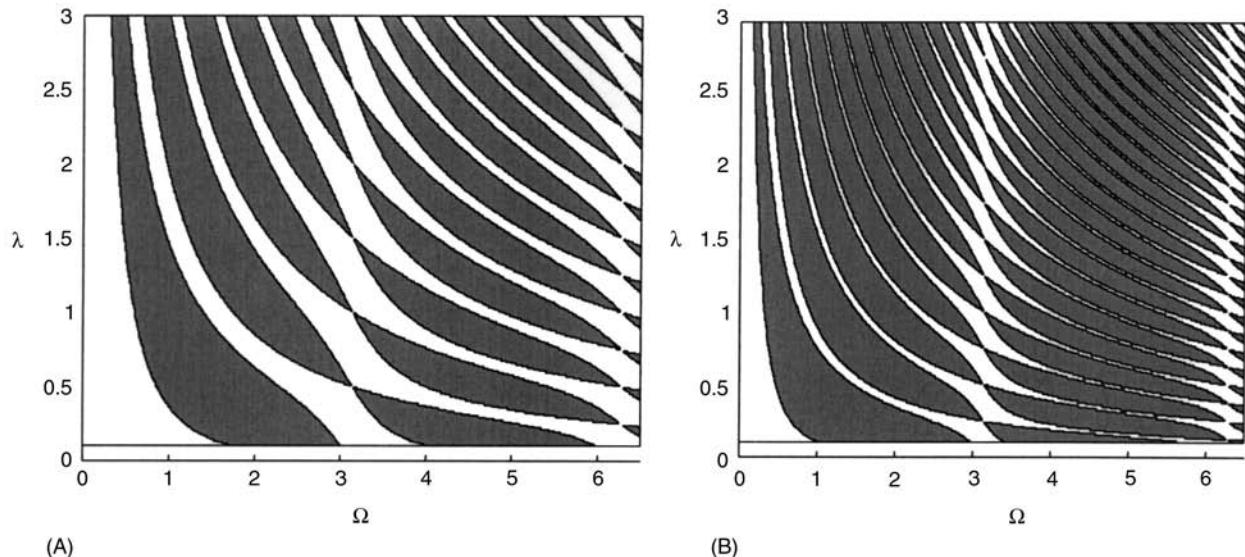

Figure 17 Effect of frequency and relative layer thickness λ on stop and pass bands ($\zeta = 2$ (A) and $\zeta = 4$ (B)).

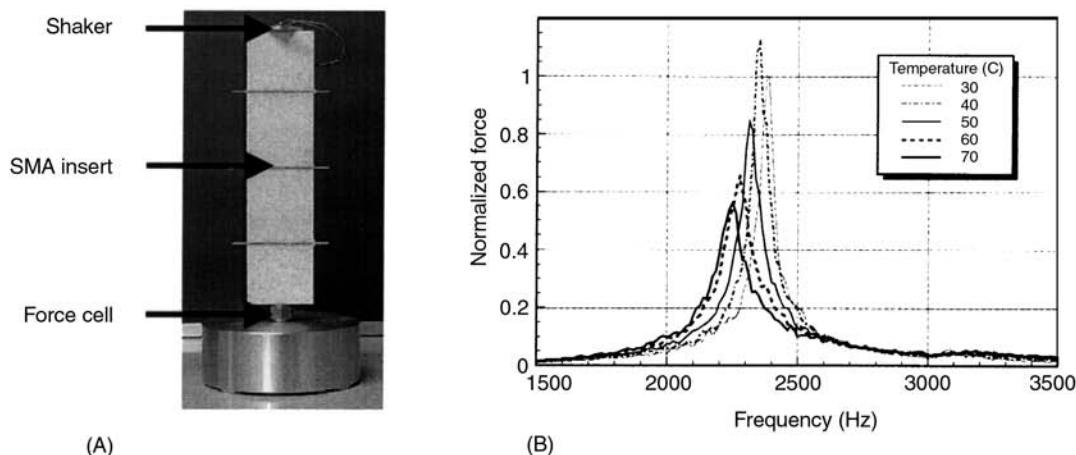

Figure 18 Experimental control of wave propagation in composite rods with three SMA inserts.

along with some of the most common mechanisms for controlling the vibration and wave propagation in simple flexible structures. Application of the SMA to other more complex structures is limited only by our imagination.

Curvilinear Surface Coordinates

For simplicity of formulation, it is required that coordinates are orthogonal. The coordinates are surface coordinates, with two coordinates following the refer-

ence surface which, for homogeneous and isotropic material, is halfway between the inner and outer surface, and the third coordinate is normal to the reference surface. This means that the selection of coordinates for classical geometries is dictated by the surface shape: cylindrical shells are described by cylindrical coordinates, spherical shells by spherical coordinates, and so on. For shells that are not classical shapes, orthogonal surface coordinates can be assigned by utilizing the property of surfaces that

lines of maximum and minimum curvature are orthogonal. Thus, all coordinates used in proper shell descriptions are lines of maximum and minimum curvature, with the third coordinate being normal to the surface.

To avoid having to reformulate the equations of motion of a shell each time a different orthogonal surface coordinate system is used, the equations are, in the following, expressed in a general, curvilinear form, defined by the coordinates α_1 , α_2 and α_3 , the Lamé parameters A_1 and A_2 , and the radii of curvature in α_1 and α_2 direction, R_1 and R_2 . Equations written in this form can then be easily reduced to the coordinate system being used. For example, for a circular cylindrical shell of radius a , where the lines of minimum and maximum curvature are described by cylindrical coordinates x and θ , one obtains $\alpha_1 = x$, $\alpha_2 = \theta$, $A_1 = 1$, $A_2 = a$, $R_1 = \infty$ ($1/R_1$, the curvature, = 0), and $R_2 = a$. **Table 1** gives the curvilinear coordinate terms for some of the common classical geometries (see **Figure 1**).

Love-type Equations of Motion

A set of equations that is consistent with assumptions used in the Bernoulli–Euler beam equations and the Lagrange–Kirchhoff plate equations was developed by Love and later modified in minor ways by others such as Flügge.

The assumptions are that the thickness is small relative to characteristic surface dimensions, that deflections are small, that plane sections normal to the reference surface before deflection remain plane and normal during deflection, and that deflections are small relative to the characteristic dimensions of the shell, and of course that the material follows Hooke's law.

The general equations of motion are:

$$L_1\{u_1, u_2, u_3\} + \rho h \ddot{u}_1 = q_1 \quad [1]$$

$$L_2\{u_1, u_2, u_3\} + \rho h \ddot{u}_2 = q_2 \quad [2]$$

$$L_3\{u_1, u_2, u_3\} + \rho h \ddot{u}_3 = q_3 \quad [3]$$

where:

$$\begin{aligned} L_1\{u_1, u_2, u_3\} = & \frac{1}{A_1 A_2} \left[-\frac{\partial(N_{11} A_2)}{\partial \alpha_1} - \frac{\partial(N_{21} A_1)}{\partial \alpha_2} \right. \\ & \left. - N_{12} \frac{\partial A_1}{\partial \alpha_2} + N_{22} \frac{\partial A_2}{\partial \alpha_1} - A_1 A_2 \frac{Q_{13}}{R_1} \right] \end{aligned} \quad [4]$$

$$\begin{aligned} L_2\{u_1, u_2, u_3\} = & \frac{1}{A_1 A_2} \left[-\frac{\partial(N_{12} A_2)}{\partial \alpha_1} - \frac{\partial(N_{22} A_1)}{\partial \alpha_2} \right. \\ & \left. - N_{21} \frac{\partial A_2}{\partial \alpha_1} + N_{11} \frac{\partial A_1}{\partial \alpha_2} - A_1 A_2 \frac{Q_{23}}{R_2} \right] \end{aligned} \quad [5]$$

$$\begin{aligned} L_3\{u_1, u_2, u_3\} = & \frac{1}{A_1 A_2} \left[-\frac{\partial(Q_{13} A_2)}{\partial \alpha_1} - \frac{\partial(Q_{23} A_1)}{\partial \alpha_2} \right. \\ & \left. + A_1 A_2 \left(\frac{N_{11}}{R_1} + \frac{N_{22}}{R_2} \right) \right] \end{aligned} \quad [6]$$

and where:

$$N_{11} = K(\varepsilon_{11}^0 + \mu \varepsilon_{22}^0) \quad [7]$$

$$N_{22} = K(\varepsilon_{22}^0 + \mu \varepsilon_{11}^0) \quad [8]$$

$$N_{12} = N_{21} = \frac{K(1-\mu)}{2} \varepsilon_{12}^0 \quad [9]$$

$$M_{11} = D(k_{11} + \mu k_{22}) \quad [10]$$

$$M_{22} = D(k_{22} + \mu k_{11}) \quad [11]$$

$$M_{12} = M_{21} = \frac{D(1-\mu)}{2} k_{12} \quad [12]$$

K and D , the membrane and bending stiffnesses, characterize the resistance of the shell to deformation.

Table 1 Curvilinear coordinates

Type of shell	α_1	α_2	A_1	A_2	R_1	R_2
Shell of revolution (Figure 1A)	ϕ	θ	R_ϕ	$R_\theta \sin \phi$	R_ϕ	R_θ
Circular cylindrical shell (Figure 1B)	x	θ	1	a	∞	a
Conical shell (Figure 1C)	x	θ	1	$x \sin \alpha$	∞	$x \tan \alpha$
Spherical shell (Figure 1D)	ϕ	θ	a	$a \sin \phi$	a	a
Toroidal shell (Figure 1E)	ϕ	θ	a	$R+a \sin \phi$	a	$(R/\sin \phi) + a$

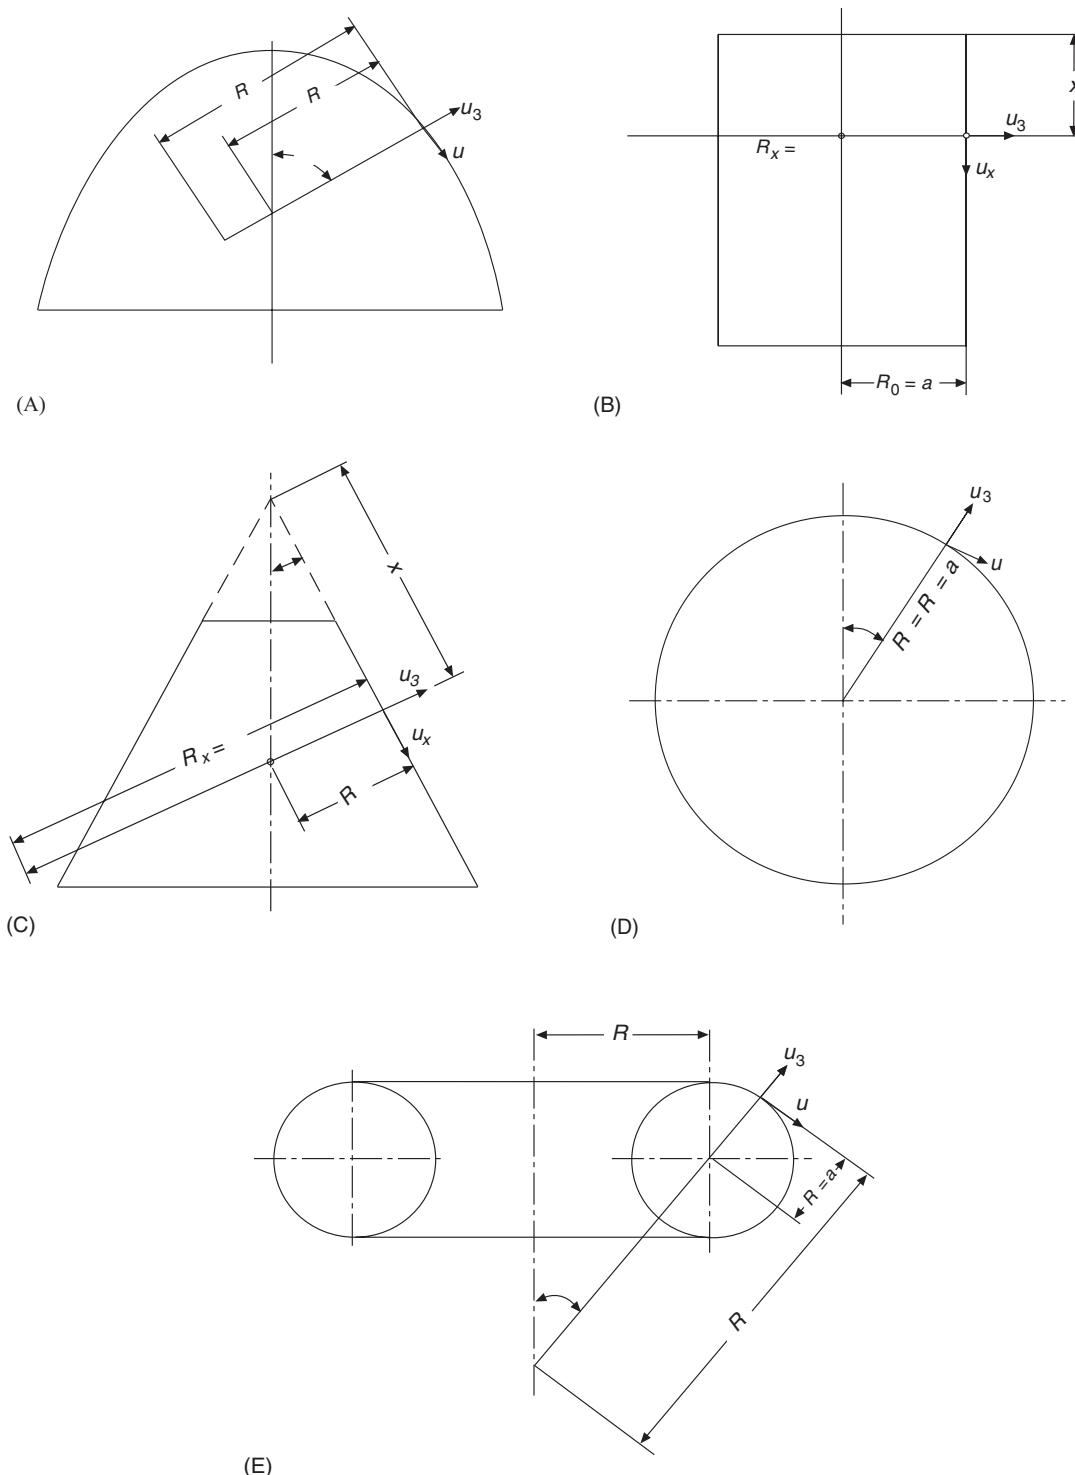

Figure 1 Examples of typical shell shapes and coordinates describing them: (A) general shell of revolution; (B) circular cylindrical shell; (C) conical shell; (D) spherical shell; (E) toroidal shell. See **Table 1** for the associated Lamé parameters and the radii of curvature expressions. The coordinate θ , in every case, is measured clockwise as viewed from below, and the displacement u_θ (not shown) is in the direction of increasing θ .

The membrane stiffness is:

$$K = \frac{Eh}{1 - \mu^2} \quad [13]$$

where E is Young's modulus, h is the shell thickness and μ is Poisson's ratio. It corresponds to the term EA in the equation governing the longitudinal vibrations of a rod of cross-section A . The bending stiffness is:

$$D = \frac{Eb^3}{12(1 - \mu^2)} \quad [14]$$

It corresponds to the term EI in the Bernoulli–Euler equation for a transversely vibrating beam of area moment I . The transverse shear forces per unit length are given by:

$$\begin{aligned} Q_{13} &= \frac{1}{A_1 A_2} \left[\frac{\partial(M_{11} A_2)}{\partial \alpha_1} + \frac{\partial(M_{21} A_1)}{\partial \alpha_2} \right. \\ &\quad \left. + M_{12} \frac{\partial A_1}{\partial \alpha_2} - M_{22} \frac{\partial A_2}{\partial \alpha_1} \right] \end{aligned} \quad [15]$$

$$\begin{aligned} Q_{23} &= \frac{1}{A_1 A_2} \left[\frac{\partial(M_{12} A_2)}{\partial \alpha_1} + \frac{\partial(M_{22} A_1)}{\partial \alpha_2} \right. \\ &\quad \left. + M_{21} \frac{\partial A_2}{\partial \alpha_1} - M_{11} \frac{\partial A_1}{\partial \alpha_2} \right] \end{aligned} \quad [16]$$

The membrane strains ε_{11}^0 , ε_{22}^0 , $\varepsilon_{12}^0 = \varepsilon_{21}^0$ and the changes of curvature k_{11} , k_{22} , $k_{12} = k_{21}$ are related to the three deflections u_1 , u_2 , u_3 by:

$$\varepsilon_{11}^0 = \frac{1}{A_1} \frac{\partial u_1}{\partial \alpha_1} + \frac{u_2}{A_1 A_2} \frac{\partial A_1}{\partial \alpha_2} + \frac{u_3}{R_1} \quad [17]$$

$$\varepsilon_{22}^0 = \frac{1}{A_2} \frac{\partial u_2}{\partial \alpha_2} + \frac{u_1}{A_1 A_2} \frac{\partial A_2}{\partial \alpha_1} + \frac{u_3}{R_2} \quad [18]$$

$$\varepsilon_{12}^0 = \varepsilon_{21}^0 = \frac{A_2}{A_1} \frac{\partial}{\partial \alpha_1} \left(\frac{u_2}{A_2} \right) + \frac{A_1}{A_2} \frac{\partial}{\partial \alpha_2} \left(\frac{u_1}{A_1} \right) \quad [19]$$

and:

$$k_{11} = \frac{1}{A_1} \frac{\partial \beta_1}{\partial \alpha_1} + \frac{\beta_2}{A_1 A_2} \frac{\partial A_1}{\partial \alpha_2} \quad [20]$$

$$k_{22} = \frac{1}{A_2} \frac{\partial \beta_2}{\partial \alpha_2} + \frac{\beta_1}{A_1 A_2} \frac{\partial A_2}{\partial \alpha_1} \quad [21]$$

$$k_{12} = k_{21} = \frac{A_2}{A_1} \frac{\partial}{\partial \alpha_1} \left(\frac{\beta_2}{A_2} \right) + \frac{A_1}{A_2} \frac{\partial}{\partial \alpha_2} \left(\frac{\beta_1}{A_1} \right) \quad [22]$$

where the slope changes β_1 , β_2 in the α_1 , α_2 directions are:

$$\beta_1 = \frac{u_1}{R_1} - \frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} \quad [23]$$

$$\beta_2 = \frac{u_2}{R_2} - \frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} \quad [24]$$

Boundary Conditions

Four bounding conditions have to be specified at each edge (the star superscript means ‘specified’):

$$N_{nn} = N_{nn}^* \text{ or } u_n = u_n^* \quad [25]$$

$$M_{nn} = M_{nn}^* \text{ or } \beta_n = \beta_n^* \quad [26]$$

$$V_{n3} = V_{n3}^* \text{ or } u_3 = u_3^* \quad [27]$$

$$T_{nt} = T_{nt}^* \text{ or } u_t = u_t^* \quad [28]$$

where n means in normal direction to the edge, and t means in tangential direction to the edge. To resolve a problem similar to the one for free edges of plates, Kirchhoff effective shear resultants of the first and second kind are introduced:

$$V_{13} = Q_{13} + \frac{1}{A_2} \frac{\partial M_{12}}{\partial \alpha_2} \quad [29]$$

$$V_{23} = Q_{23} + \frac{1}{A_1} \frac{\partial M_{21}}{\partial \alpha_1} \quad [30]$$

and:

$$T_{12} = N_{12} + \frac{M_{12}}{R_2} \quad [31]$$

$$T_{21} = N_{21} + \frac{M_{21}}{R_1} \quad [32]$$

Note that, while $N_{12} = N_{21}$ and $M_{12} = M_{21}$, $T_{12} \neq T_{21}$ because of the different radii of curvature. Some examples of boundary conditions are given in Table 2, where $(-)$ means ‘not defined’.

Composite Shells

For laminated and other composite shells, where the relationships between N_{11} , N_{22} , $N_{12} = N_{21}$, M_{11} ,

Table 2 Typical boundary conditions for Love-type equations

Edge condition	N_{nn}	M_{nn}	V_{n3}	T_{nt}	u_n	β_n	u_3	u_t
Completely clamped (welded)	(-)	(-)	(-)	(-)	0	0	0	0
Completely free	0	0	0	0	(-)	(-)	(-)	(-)
Transversely simply supported and free to slide in the tangential plane	0	0	(-)	0	(-)	(-)	0	(-)
Transversely simply supported, but not able to slide in the tangential plane	(-)	0	(-)	(-)	0	(-)	0	0

$M_{22}, M_{12} = M_{21}$ and the membrane strains $\varepsilon_{11}^0, \varepsilon_{22}^0, \varepsilon_{12}^0 = \varepsilon_{21}^0$ and the bending initiated change of curvature terms $k_{11}, k_{22}, k_{12} = k_{21}$ can be expressed as:

$$\begin{aligned} & \left\{ \begin{array}{l} N_{11} \\ N_{22} \\ N_{12} \\ M_{11} \\ M_{22} \\ M_{12} \end{array} \right\} \\ &= \begin{bmatrix} A_{11} & A_{12} & A_{13} & B_{11} & B_{12} & B_{13} \\ A_{21} & A_{22} & A_{23} & B_{21} & B_{22} & B_{23} \\ A_{31} & A_{32} & A_{33} & B_{31} & B_{32} & B_{33} \\ B_{11} & B_{12} & B_{13} & D_{11} & D_{12} & D_{13} \\ B_{21} & B_{22} & B_{23} & D_{21} & D_{22} & D_{23} \\ B_{31} & B_{32} & B_{33} & D_{31} & D_{32} & D_{33} \end{bmatrix} \left\{ \begin{array}{l} \varepsilon_{11}^0 \\ \varepsilon_{22}^0 \\ \varepsilon_{12}^0 \\ k_{11} \\ k_{22} \\ k_{12} \end{array} \right\} \quad [33] \end{aligned}$$

derived under the assumptions that plane sections normal to the reference surface before deflection remain so during deflection, the Love equations in the form of eqs [1]–[6] are still valid. The mass density per unit area, ρh , has to be viewed as a value averaged over the shell thickness.

Other Love-type Theories

The variations in use are only slightly different. The differences are, basically, that in the derivations of the Love equations, the simplification is made that $\alpha_3/R_i(i=1, 2) \ll 1$, leading to the approximation $1/(1 + \alpha_3/R_i) \cong 1$. Theories by Novozhilov, Flügge, Byrne, Lur'ye and others either do not follow at all, or not consistently, this approximation and typically expand these types of expressions as geometric series, keeping certain higher-order terms.

Shear Deformation and Rotatory Inertia Included

In the Love-type equations of motion, deformations due to shear are not considered. Also, only the inertia

effects due to the translation of mass points are included. While this is quite sufficient for thin shells and lower-mode calculations, at some point the deformations due to shear forces and the inertial resistance due to the rotation of the mass elements become important.

A theory consistent with the Timoshenko beam equation is summarized in the following. The equations of motion are:

$$L_1\{u_1, u_2, u_3, \beta_1, \beta_2\} + \rho h \ddot{u}_1 = q_1 \quad [34]$$

$$L_1\{u_1, u_2, u_3, \beta_1, \beta_2\} + \rho h \ddot{u}_2 = q_2 \quad [35]$$

$$L_3\{u_1, u_2, u_3, \beta_1, \beta_2\} + \rho h \ddot{u}_3 = q_3 \quad [36]$$

$$L_4\{u_1, u_2, u_3, \beta_1, \beta_2\} + \frac{\rho h^3}{12} \ddot{\beta}_1 = 0 \quad [37]$$

$$L_5\{u_1, u_2, u_3, \beta_1, \beta_2\} + \frac{\rho h^3}{12} \ddot{\beta}_2 = 0 \quad [38]$$

where:

$$\begin{aligned} & L_1\{u_1, u_2, u_3, \beta_1, \beta_2\} \\ &= \frac{1}{A_1 A_2} \left[-\frac{\partial(N_{11} A_2)}{\partial \alpha_1} - \frac{\partial(N_{21} A_1)}{\partial \alpha_2} - N_{12} \frac{\partial A_1}{\partial \alpha_2} \right. \\ & \quad \left. + N_{22} \frac{\partial A_2}{\partial \alpha_1} - A_1 A_2 \frac{k' \varepsilon_{13} G h}{R_1} \right] \quad [39] \end{aligned}$$

$$\begin{aligned} & L_2\{u_1, u_2, u_3, \beta_1, \beta_2\} = \frac{1}{A_1 A_2} \left[-\frac{\partial(N_{12} A_2)}{\partial \alpha_1} \right. \\ & \quad \left. - \frac{\partial(N_{22} A_1)}{\partial \alpha_2} - N_{21} \frac{\partial A_2}{\partial \alpha_1} + N_{11} \frac{\partial A_1}{\partial \alpha_2} - A_1 A_2 \frac{k' \varepsilon_{23} G h}{R_2} \right] \quad [40] \end{aligned}$$

$$L_3\{u_1, u_2, u_3, \beta_1, \beta_2\} = \frac{1}{A_1 A_2} \left[-k' G b \frac{\partial(\varepsilon_{13} A_2)}{\partial \alpha_1} - k' G b \frac{\partial(\varepsilon_{23} A_1)}{\partial \alpha_2} + A_1 A_2 \left(\frac{N_{11}}{R_1} + \frac{N_{22}}{R_2} \right) \right] \quad [41]$$

$$L_4\{u_1, u_2, u_3, \beta_1, \beta_2\} = \frac{1}{A_1 A_2} \left[-\frac{\partial(M_{11} A_2)}{\partial \alpha_1} - \frac{\partial(M_{21} A_1)}{\partial \alpha_2} - M_{12} \frac{\partial A_1}{\partial \alpha_2} + M_{22} \frac{\partial A_2}{\partial \alpha_1} + G b k' \varepsilon_{13} A_1 A_2 \right] \quad [42]$$

$$L_5\{u_1, u_2, u_3, \beta_1, \beta_2\} = \frac{1}{A_1 A_2} \left[-\frac{\partial(M_{12} A_2)}{\partial \alpha_1} - \frac{\partial(M_{22} A_1)}{\partial \alpha_2} - M_{21} \frac{\partial A_2}{\partial \alpha_1} + M_{11} \frac{\partial A_1}{\partial \alpha_2} + G b k' \varepsilon_{23} A_1 A_2 \right] \quad [43]$$

and where:

$$\varepsilon_{13} = \frac{1}{A_1} \frac{\partial u_3}{\partial \alpha_1} - \frac{u_1}{R_1} + \beta_1 \quad [44]$$

$$\varepsilon_{23} = \frac{1}{A_2} \frac{\partial u_3}{\partial \alpha_2} - \frac{u_2}{R_2} + \beta_2 \quad [45]$$

The definitions of N_{11} , N_{22} , $N_{12} = N_{21}$, M_{11} , M_{22} , $M_{12} = M_{21}$ are the same as previously used for the Love-type equations. Note that the slope changes β_1 and β_2 are now included as two additional degrees-of-freedom of motion. It can be shown that the influence of rotatory inertia is of the same order as the influence of shear deformation. Thus, taking account of one without the other is not advisable. The value of k' is usually taken as 2/3, assuming a parabolic distribution of shear strain through the thickness of the shell.

Boundary Conditions

While these equations are more complicated than the Love-type equations, they have the advantage that they admit five boundary conditions at each edge; the use of the Kirchhoff shear equations of the first and second kind is now not necessary. The five physical conditions correspond now to five admissible boundary conditions:

$$N_{nn} = N_{nn}^* \text{ or } u_n = u_n^* \quad [46]$$

$$N_{nt} = N_{nt}^* \text{ or } u_t = u_t^* \quad [47]$$

$$Q_{n3} = Q_{n3}^* \text{ or } u_3 = u_3^* \quad [48]$$

$$M_{nn} = M_{nn}^* \text{ or } \beta_n = \beta_n^* \quad [49]$$

$$M_{nt} = M_{nt}^* \text{ or } \beta_t = \beta_t^* \quad [50]$$

This is applied in **Table 3** to the same examples used in **Table 2**. Again, n means normal to an edge and t means tangential.

The Membrane Approximation

This simplified theory is not to be confused with equations of motion of shells that are inflated membranes. It simply assumes that the resistance of certain shells to deformation is dominated by the membrane strain terms and change in curvature strain components (bending components) can be neglected. The simplification is applied to Love-type equations by setting the bending stiffness to zero:

$$D = 0 \quad [51]$$

The consequence is that the Love equation operators L_1 , L_2 , and L_3 reduce to:

$$L_1\{u_1, u_2, u_3\} = \frac{1}{A_1 A_2} \times \left[-\frac{\partial(N_{11} A_2)}{\partial \alpha_1} - \frac{\partial(N_{21} A_1)}{\partial \alpha_2} - N_{12} \frac{\partial A_1}{\partial \alpha_2} + N_{22} \frac{\partial A_2}{\partial \alpha_1} \right] \quad [52]$$

$$L_2\{u_1, u_2, u_3\} = \frac{1}{A_1 A_2} \times \left[-\frac{\partial(N_{12} A_2)}{\partial \alpha_1} - \frac{\partial(N_{22} A_1)}{\partial \alpha_2} - N_{21} \frac{\partial A_2}{\partial \alpha_1} + N_{11} \frac{\partial A_1}{\partial \alpha_2} \right] \quad [53]$$

$$L_3\{u_1, u_2, u_3\} = \frac{N_{11}}{R_1} + \frac{N_{22}}{R_2} \quad [54]$$

This theory has some merit for shells that are nondevelopable, such as spherical shells and toroidal shells. It is, in general, not useful for shells that are developable, such as cylindrical and conical shells. Developable means that with a single cut, disregarding boundaries, a shell can be unfolded to a flat sheet. Cylindrical or conical shells can be cut along one coordinate and unfold. On the other hand, unfolding a spherical shell into a flat sheet is not possible. It can

Table 3 Typical boundary conditions for theory that includes shear deformation and rotatory inertia (same cases as in Table 2)

Edge condition	N_{nn}	M_{nn}	V_{n3}	T_{nt}	M_{nt}	u_n	β_n	u_3	u_t	β_t
Completely clamped (welded)	(-)	(-)	(-)	(-)	(-)	0	0	0	0	0
Completely free	0	0	0	0	0	(-)	(-)	(-)	(-)	(-)
Transversely simply supported and free to slide in the tangential plane	0	0	(-)	0	(-)	(-)	(-)	0	(-)	0
Transversely simply supported, but not able to slide in the tangential plane	(-)	0	(-)	(-)	(-)	0	(-)	0	0	0

only be approximated by multiple cuts along the meridional coordinate lines and then the unfolded shell looks like an orange peel, each segment only approximating flatness.

The Donnell–Mushtari–Vlasov Equations

This useful simplification assumes that tangential deflections can be neglected in the bending-strain (change of curvature) expressions, but not in the membrane-strain expressions. The theory is limited to transverse excitation q_3 ; q_1 and q_2 have to be zero. Also neglected are the transverse shear terms Q_{31}/R_1 and Q_{32}/R_2 . These ratios tend to be particularly small for shallow shells. This is the reason why this theory is sometimes referred to as shallow shell theory. But it also works well for deep shells of zero or small Gaussian curvature $1/R_1R_2$, such as cylindrical and conical shells.

The resulting equations are:

$$D\nabla^4 u_3 + \nabla_K^2 \phi + \rho b \frac{\partial^2 u_3}{\partial t^2} = q_3 \quad [55]$$

$$Eh\nabla_K^2 u_3 - \nabla^4 \phi = 0 \quad [56]$$

where ϕ is a stress function defined such that:

$$N_{11} = \frac{1}{A_2} \frac{\partial}{\partial \alpha_2} \left(\frac{1}{A_2} \frac{\partial \phi}{\partial \alpha_2} \right) + \frac{1}{A_1^2 A_2} \frac{\partial A_2}{\partial \alpha_1} \frac{\partial \phi}{\partial \alpha_1} \quad [57]$$

$$N_{22} = \frac{1}{A_1} \frac{\partial}{\partial \alpha_1} \left(\frac{1}{A_1} \frac{\partial \phi}{\partial \alpha_1} \right) + \frac{1}{A_1 A_2^2} \frac{\partial A_1}{\partial \alpha_2} \frac{\partial \phi}{\partial \alpha_2} \quad [58]$$

$$N_{12} = N_{21} = -\frac{1}{A_1 A_2} \times \left(\frac{\partial^2 \phi}{\partial \alpha_1 \partial \alpha_2} - \frac{1}{A_1} \frac{\partial A_1}{\partial \alpha_2} \frac{\partial \phi}{\partial \alpha_1} - \frac{1}{A_2} \frac{\partial A_2}{\partial \alpha_1} \frac{\partial \phi}{\partial \alpha_2} \right) \quad [59]$$

and where $\nabla^4(\cdot) = \nabla^2 \nabla^2(\cdot)$ such that:

$$\nabla^2(\cdot) = \frac{1}{A_1 A_2} \left[\frac{\partial}{\partial \alpha_1} \left(\frac{A_2}{A_1} \frac{\partial(\cdot)}{\partial \alpha_1} \right) + \frac{\partial}{\partial \alpha_2} \left(\frac{A_1}{A_2} \frac{\partial(\cdot)}{\partial \alpha_2} \right) \right] \quad [60]$$

and where:

$$\nabla_K^2(\cdot) = \frac{1}{A_1 A_2} \left\{ \frac{\partial}{\partial \alpha_1} \left[\frac{1}{R_2} \frac{A_2}{A_1} \frac{\partial(\cdot)}{\partial \alpha_1} \right] + \frac{\partial}{\partial \alpha_2} \left[\frac{1}{R_1} \frac{A_1}{A_2} \frac{\partial(\cdot)}{\partial \alpha_2} \right] \right\} \quad [61]$$

Natural Frequencies and Modes

Setting $q_1 = q_2 = q_3 = 0$ in eqns [1]–[3], for example, and separating the time variable either mathematically or by arguing physically that at each natural frequency the shell will vibrate harmonically leads to solutions of the form:

$$u_i(\alpha_1, \alpha_2, t) = U_i(\alpha_1, \alpha_2) e^{j\omega t} \quad [62]$$

where $i = 1, 2, 3$, and where the natural mode components $U_i(\alpha_1, \alpha_2)$ are defined by:

$$L_i\{U_1, U_2, U_3\} + \rho h \omega^2 U_i = 0 \quad [63]$$

with boundary conditions from which time has been eliminated:

$$B_K\{U_1, U_2, U_3\} = 0 \quad [64]$$

The next analytical step is to try to separate variables again:

$$U_i(\alpha_1, \alpha_2) = R_i(\alpha_1) S_i(\alpha_2) \quad [65]$$

This is often not possible. In general, it can be done for certain shells of revolution. Therefore, exact analytical solutions are relatively rare. At this point, numerical methods such as the finite element method or finite difference method have to be used, or approximate methods such as the Rayleigh–Ritz

method or the Galerkin method. In the following, some examples of solutions are given.

Example: Simply Supported, Closed Circular Cylindrical Shell

Love's equations The Love equations reduce to ($\alpha_1 = x$, $\alpha_2 = \theta$, $A_1 = 1$, $A_2 = a$, $R_1 = \infty$, $R_2 = a$):

$$\frac{\partial N_{xx}}{\partial x} + \frac{1}{a} \frac{\partial N_{x\theta}}{\partial \theta} - \rho b \frac{\partial^2 u_x}{\partial t^2} = 0 \quad [66]$$

$$\frac{\partial N_{x\theta}}{\partial x} + \frac{1}{a} \frac{\partial N_{\theta\theta}}{\partial \theta} + \frac{Q_{\theta 3}}{a} - \rho b \frac{\partial^2 u_\theta}{\partial t^2} = 0 \quad [67]$$

$$\frac{\partial Q_{x3}}{\partial x} + \frac{1}{a} \frac{\partial Q_{\theta 3}}{\partial \theta} - \frac{N_{\theta\theta}}{a} - \rho b \frac{\partial^2 u_3}{\partial t^2} = 0 \quad [68]$$

For boundary conditions:

$$u_3(0, \theta, t) = 0, \quad u_3(L, \theta, t) = 0 \quad [69]$$

$$u_\theta(0, \theta, t) = 0, \quad u_\theta(L, \theta, t) = 0 \quad [70]$$

$$M_{xx}(0, \theta, t) = 0, \quad M_{xx}(L, \theta, t) = 0 \quad [71]$$

$$N_{xx}(0, \theta, t) = 0, \quad N_{xx}(L, \theta, t) = 0 \quad [72]$$

the natural frequencies are the roots of the equation:

$$\omega^6 + a_1 \omega^4 + a_2 \omega^2 + a_3 = 0 \quad [73]$$

where:

$$a_1 = -\frac{1}{\rho b} (k_{11} + k_{22} + k_{33}) \quad [74]$$

$$a_2 = \frac{1}{(\rho b)^2} \times (k_{11}k_{33} + k_{22}k_{33} + k_{11}k_{22} - k_{23}^2 - k_{12}^2 - k_{13}^2) \quad [75]$$

$$a_3 = \frac{1}{(\rho b)^2} \times (k_{11}k_{23}^2 + k_{22}k_{13}^2 + k_{33}k_{12}^2 + 2k_{12}k_{23}k_{13} - k_{11}k_{22}k_{33}) \quad [76]$$

and where:

$$k_{11} = K \left[\left(\frac{m\pi}{L} \right)^2 + \frac{(1-\mu)}{2} \left(\frac{n}{a} \right)^2 \right] \quad [77]$$

$$k_{12} = k_{21} = K \frac{(1+\mu)}{2} \left(\frac{m\pi}{L} \right) \left(\frac{n}{a} \right) \quad [78]$$

$$k_{13} = k_{31} = \frac{\mu K}{a} \left(\frac{m\pi}{L} \right) \quad [79]$$

$$k_{22} = \left(K + \frac{D}{a^2} \right) \left[\frac{(1-\mu)}{2} \left(\frac{m\pi}{L} \right)^2 + \left(\frac{n}{a} \right)^2 \right] \quad [80]$$

$$k_{23} = k_{32} = - \left(\frac{K}{a} \right) \left(\frac{n}{a} \right) - \left(\frac{D}{a} \right) \left(\frac{n}{a} \right) \left[\left(\frac{m\pi}{L} \right)^2 + \left(\frac{n}{a} \right)^2 \right] \quad [81]$$

$$k_{33} = D \left[\left(\frac{m\pi}{L} \right)^2 + \left(\frac{n}{a} \right)^2 \right]^2 + \frac{K}{a^2} \quad [82]$$

The $m = 1, 2, 3 \dots$ and $n = 0, 1, 2, 3 \dots$ numbers define the natural modes given by:

$$U_x(x, \theta) = A_i \cos \left(\frac{m\pi x}{L} \right) \cos n(\theta - \phi) \quad [83]$$

$$U_\theta(x, \theta) = B_i \sin \left(\frac{m\pi x}{L} \right) \sin n(\theta - \phi) \quad [84]$$

$$U_3(x, \theta) = C_i \sin \left(\frac{m\pi x}{L} \right) \cos n(\theta - \phi) \quad [85]$$

where the A_i and B_i are related to the arbitrary C_i by:

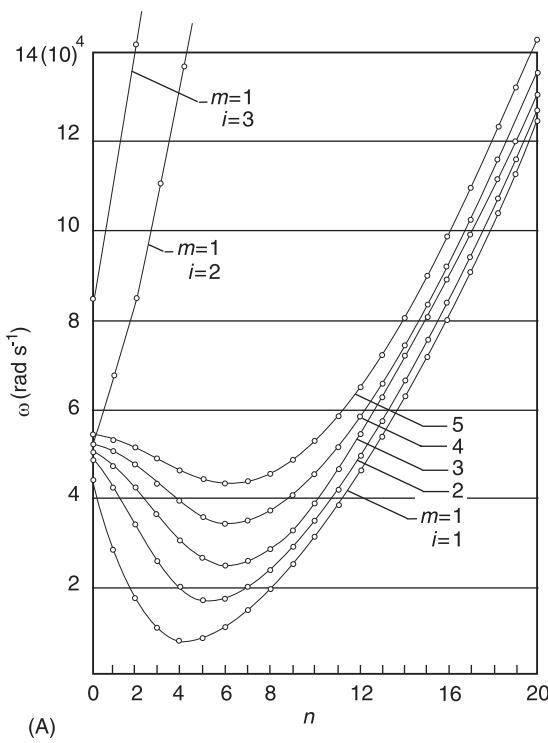

$$\frac{A_i}{C_i} = \frac{k_{12}k_{23} - k_{13}(\rho b \omega_{imn}^2 - k_{22})}{(\rho b \omega_{imn}^2 - k_{11})(\rho b \omega_{imn}^2 - k_{22}) - k_{12}^2} \quad [86]$$

$$\frac{B_i}{C_i} = \frac{k_{21}k_{13} - k_{23}(\rho b \omega_{imn}^2 - k_{11})}{(\rho b \omega_{imn}^2 - k_{11})(\rho b \omega_{imn}^2 - k_{22}) - k_{12}^2} \quad [87]$$

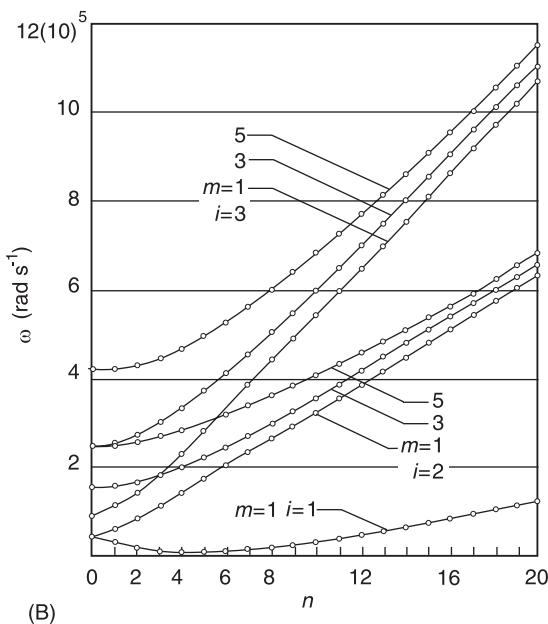

For each m, n combination, there are three roots of the frequency equation, designated by $i = 1, 2, 3$. Therefore, ω_{imn} is the i th natural frequency corresponding to a particular m, n combination.

For a steel shell of $E = 20.6(10^4)$ N mm $^{-2}$, $\rho = 7.85(10^{-9})$ N s 2 mm $^{-4}$, $\mu = 0.3$, $b = 2$ mm, $a = 100$ mm, $L = 200$ mm, the natural frequencies are plotted in Figure 2. The ratios A_i/C_i are plotted in Figure 3.

These plots illustrate a phenomenon which is peculiar to many deep shells, namely that the lowest natural frequency does not correspond to the simplest natural mode, as is typically the case for rods, beams, and plates. It is therefore difficult to use the Rayleigh method because we do not know if our assumed

(A)

(B)

Figure 2 Natural frequencies for a typical, simply supported cylindrical shell. For each m, n combination, three natural frequencies will occur. The three sets are: (A) the lowest, transverse deflection-dominated set ($i = 1$); (B) the two higher sets ($i = 2, 3$) dominated by motion in the tangent plane – it is the same graph as (A) but at a different scale. (Reproduced with permission of the publisher from Soedel W (1993) *Vibrations of Shells and Plates*, 2nd edn. New York: Marcel Dekker.

natural mode corresponds to the lowest natural frequency. The Rayleigh-Ritz procedure has to be used

with trial functions that include the natural mode corresponding to the lowest natural frequency.

Donnell–Mushtari–Vlasov equations For the same simply supported, circular cylindrical shell, we solve:

$$D\nabla^4 u_3 + \nabla_K^2 \phi + \rho b \frac{\partial^2 u_3}{\partial t^2} = 0 \quad [88]$$

$$Eb\nabla_K^2 u_3 - \nabla^4 \phi = 0 \quad [89]$$

where:

$$\nabla^4(\cdot) = \nabla^2 \nabla^2(\cdot) = \frac{1}{a^4} \frac{\partial^4(\cdot)}{\partial \theta^4} + \frac{\partial^4(\cdot)}{\partial x^4} + \frac{2}{a^2} \frac{\partial^4(\cdot)}{\partial x^2 \partial \theta^2} \quad [90]$$

$$\nabla_K^4(\cdot) = \frac{1}{a^2} \frac{\partial^4(\cdot)}{\partial x^4} \quad [91]$$

The natural frequencies corresponding to the $i = 1$ natural frequencies of the Love equation solution are:

$$\omega_{mn} = \frac{1}{a} \sqrt{\xi_1 + \xi_2} \sqrt{\frac{E}{\rho}} \quad [92]$$

where:

$$\xi_1 = \frac{(m\pi a/L)^4}{[(m\pi a/L)^2 + n^2]^2} \quad [93]$$

$$\xi_2 = \frac{(b/a)^2}{12(1 - \mu^2)} \left[\left(\frac{m\pi a}{L} \right)^2 + n^2 \right]^2 \quad [94]$$

Note that we have lost the ability to predict the higher (tangential motion-dominated) natural frequency sets $i = 2$ and 3 , because of the simplifications introduced by the Donnell–Mushtari–Vlasov approach. The agreement with the $i = 1$ set is excellent, however.

Example: Closed, Spherical Shell by the Membrane Simplification

Spherical shells have nondevelopable surfaces; therefore, reasonable results can be obtained with the membrane simplification. Introducing in the general Love's equations and the other definitions $\alpha_1 = \phi, \alpha_2 = \theta, A_1 = a, A_2 = a \sin \phi, R_1 = R_2 = a$, we obtain the natural frequencies that correspond to axisymmetric natural modes ($\partial(\cdot)/\partial \theta = 0$) from:

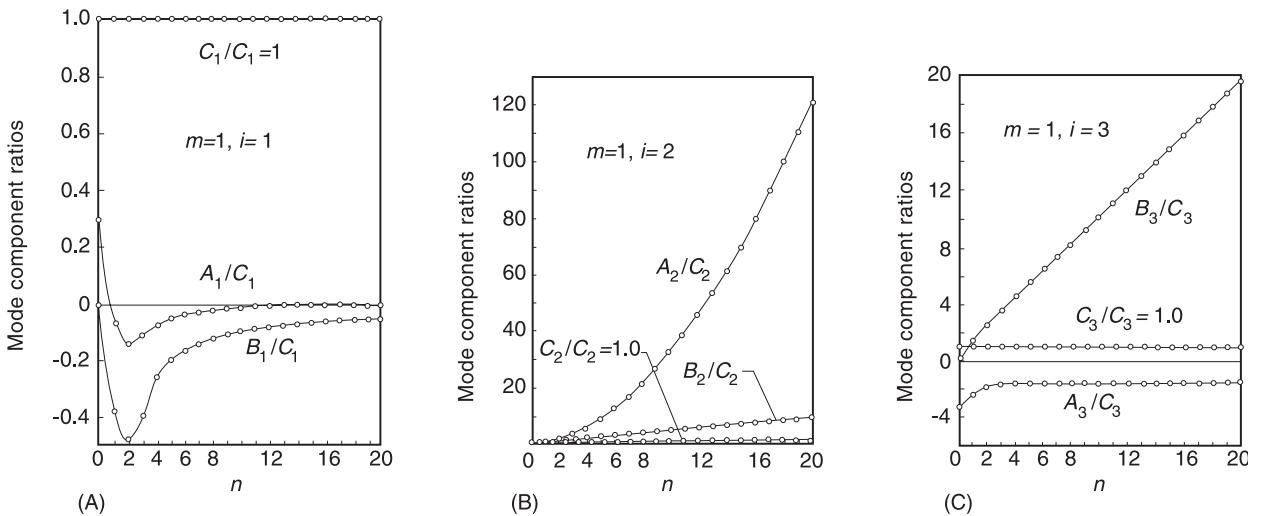

Figure 3 Mode component ratios for the natural frequencies given in **Figure 2**, to illustrate the dominance of certain components for various m, n combinations. A_i is the mode component amplitude in x direction, B_i in θ direction and C_i in transverse direction: (A) $m = 1, i = 1$; (B) $m = 1, i = 2$; (C) $m = 1, i = 3$. For example, (A) clearly indicates that for the $i = 1$ set, the transverse mode component dominates. (Reproduced with permission of the publisher from Soedel W (1993) *Vibrations of Shells and Plates*, 2nd edn. New York: Marcel Dekker.

$$-\frac{\partial}{\partial \phi} (N_{\phi\phi} \sin \phi) + N_{\theta\theta} \cos \phi + \alpha b h \frac{\partial^2 u_\phi}{\partial t^2} \sin \phi = 0 \quad [95]$$

$$(N_{\phi\phi} + N_{\theta\theta}) + \alpha b h \frac{\partial^2 u_3}{\partial t^2} = 0 \quad [96]$$

The natural frequencies are given by:

$$\omega_{n1,2} = \frac{\Omega_{n1,2}}{a} \sqrt{\frac{E}{\rho}} \quad [97]$$

where:

$$\Omega_{n1,2}^2 = \frac{1}{2(1-\mu^2)} \left[n(n+1) + 1 + 3\mu \pm \sqrt{[n(n+1) + 1 + 3\mu]^2 - 4(1-\mu^2)[n(n+1) - 2]} \right] \quad [98]$$

The natural mode components are ($i = 1, 2$):

$$U_{3i}(\phi) = \left(\frac{1 + (1 + \mu)\Omega_{ni}^2}{1 - \Omega_{ni}^2} \right) P_n(\cos \phi) \quad [99]$$

$$U_{\phi i}^{(\phi)} = \frac{d}{d\phi} P_n(\cos \phi) \quad [100]$$

and where $P_n(\cos \phi)$ are Legendre polynomials.

Example: Approximate Solutions of Donnell-Mushtari-Vlasov Equations for Closed Circular Cylindrical Shells of General Boundary Conditions

Using the Galerkin method, assumed natural modes of the form:

$$U_3(x, \theta) = U_{3m}(x) \cos n\theta \quad [101]$$

are used, where $U_{3m}(x)$ is the natural-mode function of a transversely vibrating beam having similar transverse boundary conditions as the circular cylindrical shell at ends $x = 0$ and $x = L$. The natural frequencies are given by:

$$\omega_{mn} = \frac{1}{a} \sqrt{\xi_1 + \xi_2} \sqrt{\frac{E}{\rho}} \quad [102]$$

where:

$$\xi_1 = \frac{(\lambda_m a/L)^4}{[(\lambda_m a/L)^2 + n^2]^2} \quad [103]$$

$$\xi_2 = \frac{(b/a)^2}{12(1-\mu^2)} \left[\left(\frac{\lambda_m a}{L} \right)^2 + n^2 \right]^2 \quad [104]$$

and where λ_m are the roots of the corresponding beam eigenvalue problem. Examples of natural modes of beams and the corresponding values of λ_m are given in Table 4.

Table 4 Examples of beam functions and λ_m values to be used in eqn [102]

Boundary conditions	$U_{3m}(x)$	λ_m
Simply supported at $x = 0$ and $x = L$	$\sin(m\pi x/L)$	$m\pi/L$
Clamped at $x = 0$ and free at $x = L$	$J\left(\frac{\lambda_m x}{L}\right) - \frac{G(\lambda_m)}{F(\lambda_m)} H\left(\frac{\lambda_m x}{L}\right)$	Roots of $\cos \lambda \cosh \lambda = -1$
Clamped at $x = 0$ and $x = L$	$J\left(\frac{\lambda_m x}{L}\right) - \frac{J(\lambda_m)}{H(\lambda_m)} H\left(\frac{\lambda_m x}{L}\right)$	Roots of $\cos \lambda \cosh \lambda = 1$
Free at $x = 0$ and $x = L$	$G\left(\frac{\lambda_m x}{L}\right) - \frac{J(\lambda_m)}{H(\lambda_m)} F\left(\frac{\lambda_m x}{L}\right)$	Roots of $\cos \lambda \cosh \lambda = 1$

Note: $J(\cdot) = \cosh(\cdot) - \cos(\cdot)$, $G(\cdot) = \cosh(\cdot) + \cos(\cdot)$

$F(\cdot) = \sinh(\cdot) + \sin(\cdot)$, $H(\cdot) = \sinh(\cdot) - \sin(\cdot)$

While this equation is quite useful, it must be remembered that it is an approximate solution to an approximate theory and results have to be interpreted accordingly.

Some Extensions to the Simply Supported Circular Cylindrical Shell Formula [92]

Effect of a small curvature in x direction (barrel shell) A small curvature $1/R$ is introduced in the circular, originally cylindrical shell, in x direction. A positive $1/R$ increases all natural frequency by:

$$\omega_{Bmn}^2 = \omega_{Cmn}^2 + \left(\frac{n}{a}\right)^2 \frac{\left[n^2(a/R)^2 + 2(a/R)(m\pi a/L)^2\right]}{\left[(m\pi a/L)^2 + n^2\right]} \left(\frac{E}{\rho}\right) \quad [105]$$

where ω_{Bmn} are the new natural frequencies in radians per second, and ω_{Cmn} are the original natural frequencies as given by eqn [92]. A negative $1/R$ (negative Gaussian curvature) will decrease natural frequencies.

Effect of axial tension A uniform tension T (force per unit circumference) in axial direction increases all natural frequencies:

$$\omega_{Tmn}^2 = \omega_{Cmn}^2 + \frac{T}{\rho h} \left(\frac{m\pi}{L}\right)^2 \quad [106]$$

For negative T (compression), the natural frequencies reduce until a critical buckling state is reached.

$$L_i\{u_1, u_2, u_3\} - \lambda \dot{u}_i - \rho h \ddot{u}_i = -q_i \quad [107]$$

The solution is:

$$u_i(\alpha_1, \alpha_2, t) = \sum_{k=1}^{\infty} \eta_k(t) U_{ik}(\alpha_1, \alpha_2) \quad [108]$$

where, for subcritical damping ($\zeta_k < 1$):

$$\begin{aligned} \eta_k(t) = & e^{-\zeta_k \omega_k t} \\ & \times \left\{ \eta_k(0) \cos \gamma_k t + [\eta_k(0)\zeta_k \omega_k + \dot{\eta}_k(0)] \frac{\sin \gamma_k t}{\gamma_k} \right\} \\ & + \frac{1}{\gamma_k} \int_0^t F_k(\tau) e^{-\zeta_k \omega_k (t-\tau)} \sin \gamma_k (t-\tau) d\tau \end{aligned} \quad [109]$$

where:

$$\gamma_k = \omega_k \sqrt{1 - \zeta_k^2}, \quad \zeta_k = \lambda / (2\rho h \omega_k) \quad [110]$$

For natural modes that are damped supercritically ($\zeta_k > 1$), the solution is:

$$\begin{aligned} \eta_k(t) = & e^{-\zeta_k \omega_k t} \\ & \left\{ \eta_k(0) \cosh \varepsilon_k t + [\eta_k(0)\zeta_k \omega_k + \dot{\eta}_k(0)] \frac{\sinh \varepsilon_k t}{\varepsilon_k} \right\} \\ & + \frac{1}{\varepsilon_k} \int_0^t F_k(\tau) e^{-\zeta_k \omega_k (t-\tau)} \sinh \varepsilon_k (t-\tau) d\tau \end{aligned} \quad [111]$$

7. Forced Vibrations

Utilizing an equivalent, distributed viscous damping model, the equations of motion to be solved are ($i = 1, 2, 3$):

The critical damping solution ($\zeta_k = 1$) can be obtained from either equation by letting ζ_k approach unity in the limit.

For both solutions:

$$F_k = \frac{1}{\rho b N_k} \times \int_{\alpha_2} \int_{\alpha_1} (q_1 U_{1k} + q_2 U_{2k} + q_3 U_{3k}) A_1 A_2 d\alpha_1 d\alpha_2$$

[112]

$$F_k^* = \frac{1}{\rho b N_k} \times \int_{\alpha_2} \int_{\alpha_1} (q_1^* U_{1k} + q_2^* U_{2k} + q_3^* U_{3k}) A_1 A_2 d\alpha_1 d\alpha_2$$

[121]

where:

$$N_k = \int_{\alpha_2} \int_{\alpha_1} (U_{1k}^2 + U_{2k}^2 + U_{3k}^2) A_1 A_2 d\alpha_1 d\alpha_2$$

[113]

The values $\eta_k(0)$ and $\dot{\eta}_k(0)$ are obtained from the initial conditions $u_i(\alpha_1, \alpha_2, 0)$ and $\dot{u}_i(\alpha_1, \alpha_2, 0)$ for $i = 1, 2, 3$:

$$\begin{aligned} \eta_k(0) &= \frac{1}{N_k} \int_{\alpha_2} \int_{\alpha_1} [u_1(\alpha_1, \alpha_2, 0) U_{1k} \\ &\quad + u_2(\alpha_1, \alpha_2, 0) U_{2k} + u_3(\alpha_1, \alpha_2, 0) U_{3k}] \\ &\quad \times A_1 A_2 d\alpha_1 d\alpha_2 \end{aligned}$$

[114]

$$\begin{aligned} \dot{\eta}_k(0) &= \frac{1}{N_k} \int_{\alpha_2} \int_{\alpha_1} [\dot{u}_1(\alpha_1, \alpha_2, 0) U_{1k} + \dot{u}_2(\alpha_1, \alpha_2, 0) U_{2k} \\ &\quad + \dot{u}_3(\alpha_1, \alpha_2, 0) U_{3k}] A_1 A_2 d\alpha_1 d\alpha_2 \end{aligned}$$

[115]

Special Case: Steady-State Harmonic Response

The solution to a forcing of:

$$q_i(\alpha_1, \alpha_2, t) = q_i^*(\alpha_1, \alpha_2) e^{j\omega t}$$

[116]

is in steady state:

$$u_i(\alpha_1, \alpha_2, t) = \sum_{k=1}^N \eta_k(t) U_i(\alpha_1, \alpha_2)$$

[117]

where:

$$\eta_k(t) = \Lambda_k e^{j(\omega t - \phi_k)}$$

[118]

$$\Lambda_k = \frac{F_k^*}{\omega_k^2 \sqrt{\left[1 - (\omega/\omega_k)^2\right]^2 + 4\zeta_k^2(\omega/\omega_k)}}$$

[119]

$$\phi_k = \tan^{-1} \frac{2\zeta_k(\omega/\omega_k)}{1 - (\omega/\omega_k)}$$

[120]

Special Case: Response to a Point Impulse

The solution to a forcing of:

$$q_i(\alpha_1, \alpha_2, t) = \frac{M_i}{A_1 A_2} \delta(\alpha_1 - \alpha_1^*) \delta(\alpha_2 - \alpha_2^*) \delta(t - t_1)$$

[122]

where $\delta(\cdot)$ is the Dirac-delta function and M_i is the momentum that is transferred to the shell by the impact, is:

$$u_i(\alpha_1, \alpha_2, t) = \sum_{k=1}^N \eta_k(t) U_i(\alpha_1, \alpha_2)$$

[123]

where for $t \geq t_1$:

$$\eta_k(t) = \frac{F_k^*}{\gamma_k} e^{-\varsigma_k \omega_k (t-t_1)} \sin \gamma_k (t-t_1)$$

[124]

and where:

$$\begin{aligned} F_k^* &= \frac{1}{\rho b N_k} \left[M_1 U_{1k}(\alpha_1^*, \alpha_2^*) + M_2 U_{2k}(\alpha_1^*, \alpha_2^*) \right. \\ &\quad \left. + M_3 U_{3k}(\alpha_1^*, \alpha_2^*) \right] \end{aligned}$$

[125]

Note that the impulse response at α_1, α_2, t in i -direction ($i = 1, 2, 3$) due to a unit impulse in j -direction ($j = 1, 2, 3$) at $\alpha_1^*, \alpha_2^*, t^*$ is the dynamic Green's function $G_{ij}(\alpha_1, \alpha_2, t; \alpha_1^*, \alpha_2^*, t^*)$.

Complex Modulus Model for Material Damping

For harmonic and periodic response calculations, material damping can be modeled by replacing Young's modulus E by $(1 + j\eta)E$, where η is the hysteresis loss factor. The equations of motion of the shell become ($i = 1, 2, 3$), for harmonic excitation:

$$(1 + j\eta) L_i \{u_1, u_2, u_3\} + \rho b \ddot{u}_i = +q_i^* e^{j\omega t}$$

[126]

The solution is:

$$u_i(\alpha_1, \alpha_2, t) = \sum_{k=1}^{\infty} \eta_k(t) U_{ik}(\alpha_1, \alpha_2)$$

[127]

where:

$$\eta_k(t) = \Lambda_k e^{j(\omega t - \phi_k)} \quad [128]$$

and where:

$$\Lambda_k = \frac{F_k^x}{\omega_k^2 \sqrt{\left[1 - (\omega/\omega_k)^2\right] + \eta^2}} \quad [129]$$

$$\phi_k = \tan^{-1} \frac{\eta}{1 - (\omega/\omega_k)^2} \quad [130]$$

$$F_k^* = \frac{1}{\rho h N_k} \times \int_{\alpha_2} \int_{\alpha_1} (q_1^* U_{1k} + q_2^* U_{2k} + q_3^* U_{3k}) A_1 A_2 d\alpha_1 d\alpha_2 \quad [131]$$

Nomenclature

$\alpha_1, \alpha_2, \alpha_3$	curvilinear coordinates
A_1, A_2	Lamé parameters
R_1, R_2, R	radii of curvature (m)
x, θ	cylindrical coordinates (m, rad)
a, R	radii (m)
ϕ, θ	shell of revolution, spherical, toroidal coordinates
u_1, u_2, u_3	deflections at reference surface (m)
q_1, q_2, q_3	distributed forces (N m^{-2})
ρ	mass density (kg m^{-3})
h	thickness (m)
N_{11}, N_{22}, N_{12}	membrane forces per length (N m^{-1})
M_{11}, M_{22}, M_{12}	bending moments per length (Nm m^{-1})
Q_{13}, Q_{23}	transverse shear forces per length (Nm^{-1})
K	membrane stiffness (Nm^{-1})
E	Young's modulus (Nm^{-3})
μ	Poisson's ratio
D	bending stiffness (Nm)
$\varepsilon_{11}^0, \varepsilon_{22}^0, \varepsilon_{12}^0$	membrane strains
k_{11}, k_{22}, k_{12}	curvature changes due to deflection (1 m^{-1})
β_1, β_2	slopes
V_{13}, V_{23}	Kirchhoff shear of first kind (Nm^{-1})
T_{12}, T_{21}	Kirchhoff shear of second kind (Nm^{-1})
t	time (s)
ϕ	stress function
$U_i(\alpha_1, \alpha_2)$	natural mode components (m)
L	length (m)
A_i, B_i, C_i	natural mode component amplitudes (m)
$\omega_k, \omega_{imn}, \omega_{mn}, \omega_{ni}$	natural frequencies (rad s^{-1})
ω	forcing frequency (rad s^{-1})
$\eta_k(t)$	modal participation factor
λ	equivalent viscous damping coefficient (Ns m^{-3})
η	hysteresis loss factor
T	axial tension (Nm^{-1})

General Background

The overall dynamic response of a ship can be conveniently separated into two parts: one is the motion as a rigid body in response to a seaway; the other is the

elastic or flexural response of the hull or other structure to external or internal forces. Rigid-body motion is considered under the general subject of sea keeping and is not traditionally referred to as vibration, although the theoretical basis is of course the same.

Flexural vibration can be excited in the form of vertical and horizontal bending, torsion, and axial modes of the elastic structure of the hull girder, as well as in the form of local vibration of substructures and components. Vibration excited by the propellers has been a particularly troublesome problem, and is the principal subject to be addressed in this presentation.
